The study of the proteolytic system in blood in its relation to various pathological and clinical conditions has not received the attention it deserves. Abderhalden (1937) and Hedin (1919) have demonstrated the presence of a proteinase in serum, active near neutrality. Schmitz (1937) and Iyengar and Scott (1940) have clearly shown that the proteinase circulating in blood is of a tryptic nature. Cooke (1932) has reported that blood protease is increased in chronic myeloid leukaemia. Loeper *et al.* (1932) have conducted experiments which indicate that the decrease in serum albumin during renal impermeability, whether due to nephritis or to ligation of the renal pedicle, is partly due to retention of proteolytic enzymes in blood. Vercellana (1935) has reported that trypsin is practically absent in blood from six cases of carcinoma. Ferranti and Slavich (1937) have found a high protease content in diabetes. However, there is no record of a systematic study of the plasma trypsin, both free and combined, in a number of pathological conditions commonly met with in hospital practice. This study was taken up to ascertain whether altered protein in the body as a whole brings about any changes in the enzymic content of blood.

EXPERIMENTAL

I. Materials and methods

(a) Determination of free plasma trypsin activity:—Two c.cm. of citrated plasma are precipitated with 8 c.cm. acetone and centrifuged. The precipitate is washed with acetone and allowed to dry for a few minutes. The whole precipitate is then mixed with 10 c.cm. of phosphate buffer of pH 8.4 in a glass mortar to get a uniform suspension. Three c.cm. of this suspension are taken in a test-tube and 3 c.cm. of 10 per cent trichloroacetic acid are added to it. The contents are well shaken and filtered. The nitrogen content of 3 c.cm. filtrate is estimated by the micro-kjeldahl method. A few drops of toluene are added to the remainder of the suspension which is incubated at 37°C. for 48 hours. At the end of this period, 3 c.cm. of this suspension are mixed with 3 c.cm. of 10 per cent trichloroacetic acid, filtered, and the nitrogen in 3 c.cm. of the filtrate is estimated. The increase in non-protein-nitrogen (NPN) is taken as a measure of tryptic activity of plasma. The

tryptic activity is finally calculated for 100 c.cm. of plasma in terms of the increase in NPN.

(b) Determination of total plasma trypsin (both free and combined):—Two c.cm. of citrated plasma are precipitated with 20 c.cm. of 2.5 per cent trichloroacetic acid and centrifuged. The precipitate is once washed with 2.5 per cent trichloroacetic acid and then twice with acetone. The final precipitate is treated in the same manner as above and the increase in NPN determined. By treatment of plasma first with trichloroacetic acid, the trypsin-inhibitor compound is dissociated into its components. The inhibitor being a low molecular weight polypeptide is not precipitated by trichloroacetic acid, whereas both the original free trypsin and the newly liberated trypsin being associated with plasma proteins are precipitated. This precipitate, after being washed with acetone, will be free from trichloroacetic acid and the total tryptic activity of the protein precipitate is indicated by increase in NPN after auto-digestion in the suitable phosphate buffer for 48 hours.

(c) The amount of trypsin inhibitor present in plasma was determined by the difference between the free tryptic activity and the total (free and combined) tryptic activity of plasma.

II. Results

The results of the determination of free and total plasma trypsin content in a number of normal cases and in various pathological conditions such as cancer, diabetes, kala-azar, filaria, nephritis, acute infectious diseases, anaemia, thrombocytopenic purpura, etc., are given in the following table:—

TABLE

Pathological conditions	Serial numbers	Free plasma trypsin content	Total plasma trypsin content	Difference
		expressed as increase in NPN for 100 c.cm. plasma		
Normal ..	1	15.4	75.2	59.8
	2	18.8	84.6	65.8
	3	24.6	78.1	53.5
	4	16.2	75.2	59.0

Comment and discussion

The free trypsin content of normal plasma is found to vary within fairly wide limits, whereas the total tryptic activity appears to be constant within reasonable limits considering the fact that we are dealing with a biological entity which is bound to vary from individual to individual. It should therefore be concluded that the inhibitor is present in varying quantities. The blocking of trypsin depends upon the amount of the inhibitor present. This variation in the

quantity of the inhibitor is reflected in the last column of the table wherein is expressed the difference between free trypsin and total trypsin in each subject. The average value (free trypsin content) for the increase in NPN for 100 c.cm. plasma as a result of auto-tryptic activity can reasonably be taken as 24 mg. as most of the values are round about this figure for normal cases.

If this average value is taken as the basis for comparison, a significant fall in the free tryptic activity of plasma is noticed in cancer patients. This reduction in tryptic activity of plasma cannot be due to any increase in the amount of trypsin inhibitor circulating in the blood, since the total (free and combined) tryptic activity has also undergone a radical fall from a normal average value of 77.9 mg. to 10.9 mg. At the present state of our knowledge of cancer, it is impossible to speculate on the cause of this reduction. If, as is generally recognized, the origin of plasma trypsin is from the formed elements in blood, it must be assumed that the formed elements have somehow lost the capacity of synthesizing this enzyme. Weil and Russell (*loc. cit.*) have found that the proteinase activity is restored to normal after the removal of tumour in rats by operation. It is likely therefore that the reduction in the trypsin content of plasma is more a manifestation of the disease rather than a causal factor. The malignant growth can only be digested by the proteolytic enzyme of the blood circulating through the tumour tissues. When the trypsin is practically absent the chances of the removal of the growth by enzymic digestion are very much reduced. This is probably the reason why the auto-regression of the tumour is rarely observed in clinical practice.

In diabetes, there appears to be a tendency for the free trypsin in plasma to rise. The average value is 41 as compared to the average normal value of 24. Though this cannot be regarded as very significant, it definitely points to an increase in trypsin content of plasma. The total trypsin content does not undergo any appreciable change. It is probable therefore that the observed rise in the free trypsin content is due to a lowered amount of inhibitor present in blood in diabetes. It is possible that the deranged carbohydrate metabolism in diabetes may be responsible for the deficiency in the formation of inhibitor in the blood.

No significant change either in free or combined plasma trypsin in kala-azar, filaria or acute infectious diseases, e.g., typhoid and smallpox, is observed. Although a rise in free plasma trypsin content is noticed in obstructive jaundice, biliary fistula and cirrhosis of liver, the number of cases experimented upon is too meagre to warrant any definite statement.

A significant increase in free trypsin content of plasma is observed in nephritis. The average value is 47.7 as compared with the normal of 24. In nephritis the degree of nitrogen accumulation in blood depends not only on the functional

efficiency of the kidney, but also on the rate of protein katabolism. The increased trypsin content is probably an index of enhanced protein katabolism.

In anæmia and thromboeytopenic purpura, the free trypsin is almost negligible. The total trypsin (free and combined) is also considerably reduced. These results lend very interesting experimental evidence to the popularly accepted belief that the trypsin in plasma is derived from the break-down of formed elements in blood during circulation. As the red blood corpuseles and the platelets are very much reduced in anæmia and thromboeytopenic purpura, respectively, the two important sources of trypsin supply to blood are not available and this is probably reflected in the very low free and total trypsin content of plasma.

Ferguson (1939) has explained the delay in the coagulation of hæmophilic plasma as due to a deficiency in the amount of thromboplastic enzyme. This enzyme is reported by the same author to be very much similar to trypsin. Iyengar (1942) has adduced experimental evidence in favour of the hypothesis that the physiological thromboplastic substance circulating in blood may be trypsin itself. It was therefore considered of great interest to study the trypsin content of hæmophilic plasma. It is very difficult to get a genuine case of hæmophilia. Advantage was taken of a bleeding case admitted to the Carmichael Hospital for Tropical Diseases, which was suspected to be hæmophilia with a very prolonged clotting time. The free plasma trypsin was found to be almost negligible.

Summary

1. In view of the generally recognized rôle of trypsin in various physiological processes, e.g., nitrogen metabolism, blood coagulation, destruction of hormones in the circulating blood, etc., a systematic study of the plasma trypsin contents in normal and various pathological conditions was undertaken.

2. The free trypsin content of the plasma in normal individuals was found to vary from 15 mg. to 41 mg. per 100 c.cm. of blood with an average reading in majority of cases of 24 mg. The total trypsin content was found to maintain a constant level in all the cases studied.

3. In cancer, the free trypsin content of the plasma showed a definite diminution whereas in diabetes and nephritis, there is either a tendency to increase or a marked increase in the content of free trypsin. In anæmia and thromboeytopenic purpura, both the free and total trypsin are practically absent. In filarial conditions, kala-azar and acute infectious diseases, such as enteric, variola, etc., no significant change in the trypsin contents was observed.

4. The possible explanation of such differential changes in normal and in the pathological conditions studied has been attempted.

DETERMINATION OF THE AGE IN BENGALI GIRLS IN MEDICO-LEGAL CASES—SOME PRACTICAL DIFFICULTIES. THE ROLE OF X-RAY EXAMINATIONS OF BONES *

By DABIRUDDIN AHMAD, O.B.E., L.M.S., F.S.M.F.
MAJOR, A.I.R.O.

*Superintendent, Campbell Medical School and Hospital
(Formerly Police Surgeon, Calcutta, and Professor of
Medical Jurisprudence, Medical College, Calcutta)*

DURING my tenure of office, for nearly 10 years, as police surgeon of Calcutta and professor of medical jurisprudence of both the medical colleges in Calcutta, no other subject presented so many difficulties and peculiarities as the determination of age in girls in medico-legal cases. So I thought that I would get some of my difficulties solved by bringing in this subject before you and starting a discussion.

I will put the subject before you in a simple way especially in connection with the cutting and growth of the teeth, and the union of the ends of the long bones to the shafts and the age at which this happens in our girls. Incidentally, examination of the teeth and the examination of the bones by x-rays are the two most important items in this connection.

Lately, I have noticed that there is a great tendency amongst lawyers to pin their faith on

* A résumé of a paper read at the Campbell Medical College Reunion.

Acknowledgment

The authors' thanks are due to Sir Ramnath Chopra, Dr. L. E. Napier, Dr. C. R. Das Gupta, Dr. S. Sundar Rao, Dr. J. P. Bose and several others who have kindly afforded facilities to take specimens of blood from their patients. They are particularly grateful to Sir Ramnath Chopra for his sustained interest in this investigation.

x-ray findings of bones. The question invariably asked was 'Doctor, is not x-ray the surest way of finding the real age of a girl?'. I may tell you at once, it is not. It has not improved matters very much. They want to know, for instance, whether a girl on the day the offence is committed was 14 years, or over or under. There is nothing by which you can say whether the girl is exactly 14 years or one day older or one day younger. Section 372 I. P. C. says—

'Whoever sells, lets to hire, or otherwise disposes of any person *under the age of 18 years* with intent that such person shall at any age be employed or used for the purpose of prostitution or illicit intercourse with any person or for any unlawful and immoral purpose, or knowing it to be likely that such person will at any age be employed or used for any such purpose, shall be punished with imprisonment of either description for a term which may extend to 10 years, and shall also be liable to fine.'

Section 375 I. P. C. says :—

'A man is said to commit "rape" who, except in the case hereinafter excepted, has sexual intercourse with a woman under circumstances falling under any of the five following descriptions—1, 2, 3, 4, and 5 with or without her consent, *when she is under 14 years of age.*'

'Whoever commits rape shall be punished with transportation for life, or with imprisonment of either description for a term which may extend to 10 years and shall also be liable to fine, etc., etc.'

With our present-day knowledge we may make a mistake of 1 to 3 years. Even with my long experience I may make a mistake of 6 months this side or the other side of the real age of the girl. I can never give the correct age. I always say, for instance, that a girl is about 15 years of age, that is to say, she may be 14 years 6 months to 15 years 6 months.

I may here give an instance of two sisters I had examined in connection with the Immoral Traffic Act in Calcutta. I examined a girl named Binapani brought to me by the police after they had rescued her from a brothel in the northern part of the city. After carefully examining her, I gave my opinion that she was about 16 years of age on the date of examination. A few days later, another girl named Saraswati was rescued from a neighbouring brothel in the same locality and sent up to me for examination. In this case also I gave my opinion that the girl was about 16 years of age. Whilst deposing in court I found that the two girls were sisters. Binapani was 16 years and 5 months old and Saraswati was 15 years and 6 months old, these two sisters having been born within one year of each other.

Now a healthy child when born is a perfect human being for all practical purposes. Of course, during the first 10 days or so, it is adjusting itself to its new surroundings. As is well known to you that before its birth the foetus floats in a bag of fluid almost like water and so its respiratory apparatus does not work, it gets all its nourishment and water from the mother through the placenta and the umbilical

cord and it purifies its blood through the mother's blood and so on. Immediately after birth, it has to breathe and purify its own blood through its own lungs, its circulatory system has to adapt itself to its new way of living, it has to imbibe its own nourishment and excrete its own waste products through its own systems concerned. After this initial period it continues to grow. Now what do we mean by the word 'grow'. Broadly speaking, mother nature does three things. Firstly, the mind of the baby begins to form and gradually goes on developing. Secondly, she makes the baby fit so that it will survive the struggle for existence and continue to live. Thirdly, she makes the baby fit gradually to be able to reproduce its own kind. All these in the case of human being takes about 16 to 18 years, and, after the end of this period, it is a complete natural being, able to think and act for himself, get its own food and is able to mate and reproduce its own kind. For our purpose its growth has ceased. Now all these facts connected with the growth of the being are taken advantage of by medical men for the determination of its age, say up to the 18th year of its life. That is to say, we can very approximately form an idea of its age after examining the various parts of its body including the growth and completion of the formation of the bones by x-ray examination. After this age there is nothing which is of slightest use to us in determining its age. For instance, a person may look to be 25, but may be 30 or 35.

Now let us see what facts or factors we consider while trying to determine the age of a girl. First, general appearance and development; second, the height; third, the weight; fourth, the cutting and growth of the teeth; fifth, signs of approaching puberty, namely, (i) the development of the breast, (ii) growth of hair in the arm-pits and over the pubic region, (iii) establishment of menstruation, (iv) general enlargement of the external genitals, (v) alteration of the disposition of the girl, and (vi) fuller contour of the body, namely, enlargement of the hips, general gracefulness, etc.; sixth, the x-ray examination of the bones to see how far their growth has taken place, and lastly seventh, the degenerative changes. As you know, most of these except the teeth and the bones do not help us very much. As a matter of fact these taken individually are of little use to us, but all of them considered together, an experienced doctor can give a fairly approximate idea of the age and his mistake may be within a year of the real age, i.e., 6 months more or 6 months less than her exact age. However I will take these up one by one and see how far we can rely on them.

I. *General appearance and development.*—This as you know is very unreliable. I will tell you how in an unguarded moment I let myself down once. I was asked by a friend of mine to go and examine his sister who was not well. She was a girl from western India. She was seated

on a bed when I saw her and she appeared to me at first sight to be about 17. I examined her and before writing the prescription I asked her mother about her age. She told me that her daughter was about 26 years of age. I was taken by surprise and I asked her if she was sure because to me the girl looked like 17. In spite of this, by experience gained after examining a large number of girls, we can have a rough idea of the age from the general appearance and development of the girl. The important thing is to look carefully at her face before forming the idea.

II. *Height*.—As you know there is no standard of height of our girls worked out which is of any use to us. The girl goes on growing taller and taller, so long the long bones are not completely ossified. As soon as the bones are completely ossified her growth in length ceases and she remains more or less constant. A girl generally shoots up about the age of 11 or 12, and may cease to grow after 14. Some of them may go on till 16 or 17. I shall tell you later how this growth takes place in connection with the bones. A healthy Bengali girl should be about 5 feet and 1½ inches tall at 16 and should weigh about 8 stone and 1 pound.

III. *Weight*.—This also varies very much and there is no standard on which we can depend for our guidance.

IV. *The teeth*.—As is well known, we have two sets of teeth, namely, the milk or temporary teeth and the permanent teeth. The milk teeth are 20 in number and are small, delicate, not meant for crushing or chewing hard substances. They begin to cut when the baby is about 6 months old and they all finish cutting about the age of 24 months. After this, up to the age of 6 years, they continue to grow in size, become bigger and rise higher and higher on the jaws till the whole crown (that is, the visible part of the teeth above the gum) is well up. There are two incisors, one canine and two molars or grinders in each half of each jaw. In the beginning they completely fill up all the available space in the alveoli of the jaws, but as the child grows older its jaw grows bigger and space becomes available for the cutting of the first permanent teeth behind them.

The permanent teeth begin to cut about the age of 6 years and it is the first molar which is first to cut, usually before any of the milk teeth are shed. The jaws become bigger and bigger and space becomes available behind for the cutting of the second and the third permanent molars. If, for defective growth or any other reason, space is not available we get lots of trouble with the cutting of the third molar which is also called the wisdom tooth or *akkal danth*. All the other permanent teeth appear in the space in front of the first molar, which is occupied by the milk teeth and which are gradually replaced by them. There are two incisors, one canine, two bicuspid or premolars, and three molars or grinders of the permanent set in each

half of each jaw. I have examined the cutting and growth of the teeth in a fair number of children of known ages and to my mind the following table gives an approximate idea of the age of their cutting. These are entirely approximate. There may be difference of 1 or 2 months in each case. For all practical purposes the figures are useful.

Milk teeth

Order of cutting	Name of tooth	Age
1	Lower central incisor ..	6-8 months
2	Upper central incisor ..	9 "
3	Upper lateral incisor ..	10 "
4	Lower lateral incisor ..	10 "
5	First temporary molar ..	12 "
6	Canine ..	18 "
7	Second temporary molar	24 "
<i>Permanent set</i>		
1	First molar ..	6 years
2	Central incisors ..	7 "
3	Lateral incisors ..	8 "
4	Anterior bicuspid ..	9 (9-10)
5	Posterior bicuspid ..	10 (10-12)
6	Canine ..	11 (11-12, rarely 13).
7	Second molar ..	12 (12-13)
8	Third molar ..	17-25 (generally about 18).

In these also the ages are approximate, the ages of their cutting may vary by 1 or 2 years, especially in the case of bicuspid and canines. Now it is apparent that a girl aged 12 or little over should have cut all her teeth, except the third molars. After the cutting of the second molar, a space is becoming available for the cutting of the third, they are gradually coming up, pushing up the muco-periosteum above them and about the 18th year the crowns of these teeth cut through the muco-periosteum and become visible. In my experience I have found that the third molars cut in a very large majority of girls about the age of 18. Of course, there are some variations, but these are almost always on the side of precocity, rarely on the other. This is a very important point to note. You will remember that the second molars, that is to say, the immediate predecessors of the third molars, are generally cut about the age of 12 or a little later. The jaw is getting bigger and a space is becoming available for the coming of the third molar. This begins to come up at the age of 16, pushes up the muco-periosteum and can now be seen or felt behind the second molar. Before actually cutting, it rises higher and about the age of 18 it comes through and is visible. Therefore when examining the teeth of girls who look 16, or about 16, we must carefully note the condition of the coming of the third molar. There is another very important point about this. The third

molars, especially the upper ones, are sometimes deflected so that they are not visible or felt just behind the second, but are on the lateral aspect of the gum. So we are likely to miss this tooth, if we are not careful, more especially if we remember that the third upper molars are comparatively smaller than their brothers.

V. *Signs of approaching puberty.*—Nature begins to prepare the girl for mating and conceiving. She is made attractive and her organs of reproduction both external and internal get mature and become fit for reproducing her kind. These begin about the age of 12 in healthy girls, and by about the 14th year she is generally sexually mature.

(i) *The breast.*—These two modified sweat glands are accessory glands of the generative system. They are present in males as well as in females, but in the former they remain mostly in the rudimentary state. In the female, they are two large hemi-spherical eminences lying within the superficial fascia on the front and sides of the chest. Each extends vertically from the second to the sixth rib and transversely at the level of the fourth costal cartilage from the sides of the sternum to near the mid-axillary line.

In weight and size they differ at different periods and in different individuals. Before puberty, they are small but they enlarge as the generative organs become more completely developed. On the superficial surface of the breast is a conical prominence called the nipple or papilla situated about the level of the fourth intercostal space. The breast begins to enlarge about the age of 12 and by about 14 years they are generally fully formed. I have seen fully formed breast in girls aged about 11; on the other hand I have seen girls of 15 who had small breasts.

(ii) *Growth of hair* (in the arm-pits and over the pubic region).—Over these places the hair begins to grow about the age of 11. At first, it is very thin downy soft and pale coloured. It gradually becomes thicker, coarser, and black, and by about the 14 or 15th year, it is fully developed and may be one or two inches long. But I have seen fairly formed hair in girls aged about 10, especially among the Jews. On the other hand, I have seen women of 17 or 18 with practically no hair in the arm-pits and very scanty hair over the pubic region.

(iii) *Establishment of menstruation.*—The period at which this takes place varies very much amongst our girls and for our purpose it is equally useless. A daughter of a friend of mine menstruated at the age of about 11 and became a mother at the age of about 12.

Regarding other items under this heading all are equally unreliable and are of very little use to us.

VI. *The x-ray examination of the bones.*—I will tell you what exactly happens in the bones which we x-ray and utilize for forming an idea

of the age of a girl. All workers on the subject agree that the completion of the growth of the bones in this country takes place much earlier than in Europe and America. It may be anything up to 1 to 3 years. Again, we have found that the same bone which has united and completed its growth, say at 14, has not done so in another girl at 18. For instance, it was found that the upper end of the humerus had united at 14 in one girl, whereas in another girl (my own daughter) it had not united when she was 17 years and 8 months old.

I will tell you now in a very simple and unscientific language what actually happens and how bones are formed and how we take advantage of this. When the embryo is only about 2 or 3 weeks old and is only about 1/8th of an inch long, it is still a mass of cells variously differentiated. Before this period there are no limbs. A little later two limb-buds appear, one for the future upper extremity and the other for the lower. They are also masses of cells but have their own blood and nerve supply, etc. In the places in the limbs where the future bones are going to be, the cells become concentrated and converted into rods of hyaline cartilage. About the 8th week of its intra-uterine life, when the foetus is about one inch long, due to the influence of some of the internal secretions (anterior pituitary and the thyroid glands), hyperaemia and increased blood supply takes place about the middle of the long bones and calcium salts are deposited. This is the appearance of the primary centre of ossification and the beginning of the formation of the bones. This grows on all sides more specially towards its ends and forms a cylindrical piece of bone at the expense of the cartilage. At the time of birth the limb has the shaft or middle portion made up of the bone and two ends which are still cartilages. After the birth of the child the ends receive their centres, called the secondary centres, and are transformed into bones, the period being different for the different bones. Therefore, during early years of life the so-called bone consists of the rod or shaft of bone in the middle formed from the primary centre, a piece of bone at each end formed from the secondary centre, and a piece of cartilage in between the two where the growth in length of the bone takes place. After a certain number of years this cartilage disappears having been replaced by bone, union having taken place between the two, thereby completing the growth of the bone. After all the long bones are united, growth in length of the person ceases. The object of x-ray is to see the condition of this cartilage, whether it is present, what is its thickness, whether it is wholly or partly replaced by bone, etc. I have told you before that this age of union of the different long bones varies very much between Indians, Europeans and Americans. Now I shall tell you of the practical difficulty that I used to find in my daily work in determining the ages of girls sent to me. Those who have

worked on the bones for finding the ages of union have worked on girls of *known* ages and have given us the ages at which they found the bones have united. But what happens to us? A girl of *unknown* age is sent to us. We thoroughly examine her and examine some of her long bones with *x*-rays, and note the stage of the ossification of the bones especially of the intervening cartilage. Now comes the question of interpretation. Let us take an example. Suppose we may find that the lower end of the radius is not yet united. We ask when is this going to be united? It may be one to four years before it is united. There is no fixed standard. A girl may be one or two years younger or older than another girl whose bone presents the same *x*-ray appearance. It has been suggested that the conditions of endocrine balance created by a super-abundance of ultra-violet radiation and warmth tend to produce a condition whereby a greater proportion of the calcium intake is assimilated and made available for the formation of bone tissue. The same conditions of ultra-violet radiation and warmth of different quantity also affect the formation of bones. Also the normal endocrine balance, if upset by pathological states, can produce remarkable variation from the normal rate of formation and union of bony centres. Hence the age we give is only approximate and the mistake may be anything between one to three years if the opinion is based on the bones only.

I may mention here two cases in point. First, a man aged 32 had all the appearances, physical and radiological, of a boy 12 to 14 years of age. Second, a man aged 20 had the appearance and radiological characteristic of a boy of 12.

VII. *Degenerative changes*.—Namely, wrinkles, grey hair, arcus senilis, etc. These, as you know, are useless for our purpose. I have seen comparatively young fellows with grey hair and wrinkles, and I know a man who is only about 38 and has got an arcus senilis.

Conclusion

I will sum up by saying that the various data we have are useless, *if taken individually*, but when considered together and backed by experience of the examiner we can give a fairly approximate idea of the age of the individual, the mistake being only about 6 months this or other side of the real age.

I give here some of the bones and the ages of their union. If only these are *x*-rayed and taken into consideration it ought to be enough for our purpose.

A Mirror of Hospital Practice

A CASE OF PULMONARY MYIASIS ?

By D. H. BHATT, M.B., B.S. (Bom.)

Assistant Surgeon, In-Charge Vadali Dispensary

On 10th November, 1941, a man was brought to the dispensary for treatment. He complained of fever, difficulty in breathing and occasional bleeding from the nose of dark red blood, and stated that small blood clots had been coming out, on blowing the nose, for the last three days.

The skin over the nose and upper lip was inflamed and swollen, the lower eyelids were oedematous, teeth were dirty and carious, the nares were a little larger than normal, and breath was foul smelling. On further inquiry the patient stated that his mouth always remained a little open during sleep.

On closely looking into the nostrils white dots—the terminal ends of the larvæ embedded in the submucous tissue—were seen.

The features of the case were typical of nasal myiasis. The patient stated that a couple of 'worms' had dropped out of his nose in the last two days.

The treatment—instillation of turpentine—was resorted to, and tinctura ferri perchloridi was painted on the inflamed parts. A few larvæ about 1 cm. long and 2 mm. broad, resembling a screw were picked out every day. For three days the above treatment was continued without any relief to the patient and the infection extended to the frontal sinuses. This was apparent from the skin in that region becoming inflamed and swollen and the upper eyelids oedematous.

As this subject has never been satisfactorily dealt with in the literature, there being no definite line of treatment I decided to use a mixture of creosote, beechwood oil and oil eucalyptus in equal parts instead of turpentine and I sprayed it in the nostrils with a De Vilbiss atomizer.

This mixture was irritating to the larvæ which were wriggling after the spray and it was easy to dislodge and remove them. This new mixture also stimulated coughing and the patient coughed out a couple of larvæ coated in sputum which was blackish. This led me to spray again until the patient had another spasm of coughing and eventually two more larvæ came out covered in sputum. The same evening (the spray was used twice a day) the patient stated that he had had a very troublesome cough throughout the day and about fifty worms were expelled mixed with sputum, besides some escaping from the nose.

This encouraged me to continue this treatment with addition of tinctura iodi mitis 0.5 c.cm. intravenously and seven and a half grains of sulphanilamide (P. D. & Co.) *t.d.s.* The injection was repeated on the fourth day.

With this line of treatment about 60 to 80 larvæ a day were coughed up for three days. Then the number gradually dwindled with steady improvement in the patient's condition. By the end of the week he was completely free from the disease.

From the beginning of this illness the patient had used *neem*-vapour inhalations—*neem* bark and *neem* leaves boiled with water and the steam coming therefrom inhaled—which were continued throughout the course of treatment.

During convalescence cod-liver oil mixture was administered.

Comments

Passing remarks have been found in the textbooks on the destructive activities of this type of parasite on subcutaneous tissues and bones, and meningitis is mentioned as a possible complication.

Mention of intestinal myiasis as a separate entity is also found, but nowhere is pulmonary myiasis mentioned as a separate entity or as a complication of nasal myiasis.

The following possibilities are of interest:—

Can the above case be considered one of pulmonary myiasis? Is it a complication of nasal myiasis? But this is unlikely because the patient never experienced any sensation or discomfort which he should have had during the passage of the parasites from the nose down through the larynx and trachea to the lungs.

Did the infection start simultaneously in two regions because the eggs of the responsible flies laid in the nostrils were inhaled and carried to the lungs?

[Note.—This is a clear case of nasal myiasis probably caused by *Chrysomya bezziana*. Though Patton has laid considerable stress on the destructive action of their larvæ on soft tissues and bones as well, Strickland and Roy have recently reported that even in cases of infestation by biontophagous larvæ, generally no particular symptom is produced. Although some protease is normally excreted by larvæ with their faeces, it is extremely doubtful if it is qualitatively and quantitatively strong enough to act on healthy tissues, whether soft or hard.

Regarding treatment, it may be stated that it is not easy to dislodge first- and second-stage larvæ from wounds but when they are mature, there is a natural tendency for them to leave the wound and drop on the ground for pupation. At this stage there is, generally speaking, a rapid response to local treatment whatever may be selected for this purpose.—EDITOR, I. M. G.]

TRANSPPOSITION OF HEART AND VISCERA

By K. P. ABDUL KHADER, D.M.S.
S. I. Railway Hospital, Trichinopoly

A MAN aged 25 years.

Occupation: Fireman, Trichinopoly Junction.

Chief complaint: Vague pain in front of chest. He stated he has had similar pain on previous occasions.

Duration: Three to four days.

Present history: The onset was sudden. The patient noticed one morning some vague pain in front of his chest and it grew in intensity and hence he sought medical aid at the hospital.

Previous history: Nothing of interest.

General examination: A well-built man of about 25 years; not anæmic; no clubbing of fingers or toes; no stunted growth.

Systematic examination: Temperature normal. Pulse rate 75, regular, full and bounding.

Cardiac system—contour of chest normal.

(a) Inspection: Apex beat visible in the fifth right intercostal space $\frac{1}{2}$ inch below and $\frac{3}{4}$ inch medial to the right nipple.

(b) Palpation: Apex beat in the right fifth intercostal space.

(c) On percussion, the borders of the heart were:—Right—1 inch lateral to right nipple line. Left—1½ inches medial to left nipple line.

(d) Auscultation: Heart beat, well audible in the fifth intercostal area on the right side, no murmur; both sounds audible, rate normal, no accentuation.

Blood pressure: 100/65 (sitting).

Respiratory system: Normal.

Digestive system: (a) Inspection: Abdomen normal, moves with respiration; no distension.

(b) Palpation: Liver and spleen not palpable.

(c) Percussion: Liver dullness elicited on the left side corresponds to that usually found on the right side in a normal individual.

Nervous system: Normal.

Diagnosis.—Clinically a case of dextro-cardia with complete transposition of all abdominal viscera.

The pain which the patient complained of was of muscular origin only with no relationship to his developmental condition. His pain disappeared after 2 to 3 days of routine treatment with soda salicylas mixture and he was discharged cured.

Skiaigraphy.—The diagnosis was confirmed by x-ray picture of the heart, and the barium-meal fluoroscopy of the gastro-intestinal tract revealed complete transposition of the abdominal viscera with normal motility and otherwise normal function.

Discussion.—In this case, the patient was leading an active and normal life without any outward symptoms; the case being found out during the routine examination.

Apart from the anatomical curiosity, the rarity of such cases is considered to justify its publication as it is the only case of dextro-cardia we have seen in the course of handling a large labour force.

Acknowledgment

My thanks are due to Dr. Jas. K. Manson, Chief Medical Officer, South Indian Railway, Trichinopoly,

for his assistance which enabled me to come to a conclusive diagnosis and for his permission to report this case.

PROLAPSE OF RECTUM CAUSED BY VESICAL CALCULUS

By G. C. PATTANAYAK, M.B., B.S., D.T.M.

Orissa Medical Service, Kendrapara

A MIDDLE AGED labourer was admitted into hospital for prolapse of the rectum about 4 inches in length, with discharge of mucus, tenesmus and incontinence of urine for the past 1½ years. His main complaint was the continuous dribbling of urine. A tentative diagnosis of chronic bacillary dysentery, which had caused the rectal prolapse, and a reflex irritation of the bladder causing incontinence was made. Prolapse was easily reduced and rectal lavage with warm saline was given. The prolapse recurred as easily as it was reduced. Rectal lavage and rest having produced no effect, the bladder was examined with metal sounds and a fairly large vesical calculus was sounded. A rubber catheter could not be introduced for bladder washing. Any attempt at introducing irrigating fluid into the bladder immediately produced an involuntary straining and rectal prolapse. Rectal examination was very difficult, due to reflex straining.

Suprapubic cystotomy was performed and a large stone was taken out with difficulty. No cystitis being found, the wounds in the bladder wall and the parietes were sutured, with a small drainage tube under the skin. The patient made an uneventful recovery. There was no further recurrence of rectal prolapse.

The calculus.—The stone was phosphatic in nature and oval in shape. It measured 2 inches from tip to tip; 4 inches in circumference in the middle, and 5 inches in the tip to tip circumference. It weighed 105.5 drachms.

Discussion.—The calculus being large, it probably occupied almost the whole of the bladder cavity and no urine could be retained, causing the continuous dribble of urine. It also pressed upon the rectum. The straining for urination caused rectal straining for a long period. Continued straining for urination and the reflex straining of the rectum at the same time favoured the prolapse. When the original cause, namely, the stone was removed, the rectal prolapse was cured.

A CASE OF MENSTRUATION THROUGH THE UMBILICUS AS WELL AS PER VAGINAM

By SRI. A. G. PEREIRA, L.M. & S.

District Medical Officer, Coimbatore

A FEMALE Hindu, aged 28 years, was admitted into the Government Headquarters Hospital, Coimbatore, on 8th January, 1942, with the following complaints:—

For the last one year she was having pain in the lower part of the abdomen, and during the menstrual period the pain increased and she was passing blood through the umbilicus as well as per vaginam. She had also vomiting, on and off, for the last two months.

Previous history.—She had two children; the first was a forceps case and the child died; the second was a Caesarean section about 7 years ago and this child died after 5 months.

Her periods were regular.

On superficial examination there was the scar of the Caesarean section (lower median incision extending beyond the umbilicus on its right side). There were a few pin-point holes in the umbilicus but no probe could be passed. On vaginal examination the uterus was ante-verted, fornices very tender, but no mass was felt. There was tenderness in the appendicular region. On barium-meal examination nothing characteristic was noted.

On 8th February laparotomy was done. The uterus was found connected by a strong band to a loop of small intestine and from a little beyond this attachment a fairly big sized mesenteric band was connecting with the peritoneal surface of the umbilicus. The uterus was also adherent to the anterior abdominal wall. The band connecting the uterus to the intestine was divided at both the extremities. The band connecting the intestine to the umbilicus was also divided between the ligatures. The raw surface under the umbilicus was obliterated by bringing together the peritoneum on both sides.

She had an uneventful convalescence. Sutures were removed on the 10th. On the 25th February she had her periods through the normal passage, and was discharged cured on 3rd March.

A CASE OF GIARDIASIS

By H. S. ANDLEIGH, B.Sc., M.B., B.S., D.T.M.

Resident Pathologist, Medical College, Agra

R. S., Hindu, male, aged 30 years, was admitted into the medical wards of the hospital on 5th March, 1942, for the following complaints:—

- (1) Passage of mucus with stools.
- (2) Constipation.
- (3) Marked loss of weight—30 pounds in 1½ years.
- (4) Abdominal discomfort, specially below the umbilicus.
- (5) Gurgling in the lower abdomen.

All the symptoms were for about 1½ years.

Towards the end of the year 1940, he was stationed in a rural development dispensary in the district of Budaun, U. P. Once while on tour, he was by chance detained in a small village situated between the two currents of the river Ganges. There he had to depend upon the Ganges water for drinking purposes. He stayed there for three days and when he returned to his station, he felt a severe heaviness in his stomach with gradual and progressive constipation and loss of appetite. This condition continued for about a week when the constipation became very obstinate. He took a dose of saline which resulted in 3 to 4 motions. This purgation was followed by severe colicky pain which had to be relieved by two doses of atropine and morphine. This was followed by a period of quiescence of symptoms for about six months, except for mild abdominal pain and loss of appetite. He again got severely constipated for which he took a dose of castor oil, which resulted in several stools with large amounts of mucus, and were followed by a severe type of abdominal pain. This happened in the month of February 1941 and since then the passage of mucus with stools has been continuous. It increases now and then to a large amount. His stools were examined

twice in the month of April, but nothing abnormal was reported. As he was rapidly losing weight, he got himself admitted to the Thomason Hospital for systematic investigation and treatment. I examined his stool here and found it full of cysts of *Giardia intestinalis*. Other examinations carried out here were as follows:—

(1) Opaque enema—caecum and ascending colon have irregular outline and general mottling; no meal in the ileum.

(2) Gastric analysis—free HCl and total acid within normal limits.

(3) Sigmoidoscopic examination—nothing abnormal found.

(4) Blood picture showed only a slight degree of anaemia.

He was given a course of atabrin tablets, one tablet thrice a day for 5 days.

I again examined his stools on 17th March, and found no cysts of *Giardia intestinalis*. There was also no mucus in the stools. He has been relieved completely of his symptoms. His appetite has increased and he is no more passing any mucus with his stools. He has already started feeling much better and is gaining in weight; and I hope he is completely cured.

My thanks are due to Dr. G. N. Vyas, M.D., M.R.C.P., professor of medicine, for allowing me to report this case.

A CASE OF TETANUS

By MOHAMMED ASGHAR FAROOKI,

M.B., B.S. (Pb.)

School Medical Officer, Sialkot City

M. B., Muslim female, aged 25 years, wife of a doctor and sister of a doctor, on my friendly visit to her family on 6th April, 1942, told me that she had been having a slight temperature between 99° and 100°F. for four days. She had no other complaint except a little pain in the abdomen, especially in both sub-costal regions. I told her not to worry, thinking that it was only an attack of sandfly fever.

The same midnight she woke up with a terrible pain in the abdomen under both costal margins and could not sleep. She was given potassium bromide, grains 15, followed by luminal grain 1/2, half an hour later, with no effect. An hour later, she was given morphia grain 1/6 and atropine grain 1/100 subcutaneously as a result of which she slept quietly.

7th April.—She was sleeping till late morning and was awakened with difficulty; she was quiet and drowsy, and answered questions slowly. Cold sponging of the face brought about only a little improvement. The pupils were normal and reacting to light. It was thought that this sleepy condition might be due to morphia and would pass off soon. For the little distension she had, she was given glycerine enema, pituitrin, and flatus tube with good effect. At noon she became stuporose and developed lock-jaw. Previous history and examination of the patient revealed no wound, injury or scratch on the body. She had been delivered of a male child three months back, by a dirty *dai* before the lady health visitor could arrive. In the afternoon she was absolutely unconscious. We were still pondering over the co-existence of lock-jaw and unconsciousness, when she got her first typical tetanic convulsion, followed by another in a few seconds. There was convulsion of the whole body with cyanosis, foaming in the mouth, *risus sardonicus* and opisthotonos.

Anti-tetanic serum was given immediately, 30,000 international units intravenously and 30,000 international units intramuscularly. Lumbar puncture was tried but could not be done, due to severe opisthotonos and the parents did not like resorting to chloroform anaesthesia. Other general treatment was given in the shape of exclusion of foreign stimuli. Her temperature was 99°F., pulse 96, and respiration 24 per minute. Chloral hydrate, grains 30 and potassium bromide, grains 60, were given per rectum, which controlled the spasms in number and severity. We did not like to give more hypnotics, as by now the pupillary reflex had completely disappeared.

8th April.—Patient was still unconscious with no corneal reflex and no pupillary reaction. Feeble tetanic convulsions appeared occasionally. Temperature shot up to 104°F., pulse 122 and respiration 28 per minute. Hydrotherapy was done, which lowered the temperature to 101°F. Anti-tetanic serum, 15,000 international units was given intravenously and 5,000 international units intramuscularly. Ten c.cm. of 20 per cent magnesium sulphate solution, 25 c.cm. of 25 per cent glucose, and 5 c.cm. of 10 per cent soluseptasine, were given intravenously and were repeated six hourly. At noon she again developed severe convulsions (in spite of the deep coma she was in) which were controlled by morphia grain 1/6, hyoscine grain 1/100 and atropine grain 1/100 hypodermically. Respiration was quiet till evening when it became periodic and failing. All hopes were lost. In a desperate attempt to keep up the respiration, 3.4 c.cm. of coramine intravenously and 1.7 c.cm. intramuscularly were given. The improvement was marked and the respiration became normal in 15 minutes. Paraldehyde 2 drachms and ether 1 drachm in 3 ounces of olive oil were given per rectum at night, and there was no necessity to repeat it afterwards.

9th April.—The respiration was quiet, smooth and 26 per minute, pulse 140 per minute, and temperature 101°F. The heart sounds were weak and first sound softened. Digitalin grain 1/100 was given, anti-tetanic serum 20,000 units intravenously, soluseptasine and glucose were continued as before. Glucose saline per rectum was also given four hourly. The patient was still deeply comatose. Convulsions still appeared though mild. She died that evening as a result of circulatory failure.

Points of interest

1. Tetanus developed in a woman three months after delivery and there was no discharge per vaginam.
2. Although the incubation period was prolonged to as much as three months, the disease itself was of a very fulminating type.
3. Pain under both costal margins was probably due to irregular spasms of the diaphragm and appeared many hours before lock-jaw.
4. The mind was peculiarly cloudy to start with, but this soon passed into coma and she remained so throughout the course of the disease.
5. Coramine was most efficient in controlling respiratory failure.
6. Death was due to circulatory failure and exhaustion.

My grateful thanks are due to Dr. C. L. Sahni, M.B., D.P.H., D.T.M. & H., municipal medical officer of health, Sialkot city, for kindly allowing me to report this case.

AMOEBIASIS SINE DYSENTERY

THE word amoebiasis was used by some of the earliest investigators on amoebic dysentery—and it is usually attributed to Clegg and Musgrave—but it is only during the last twenty years, during the inter-war period, that it has come into common use, and that the general practitioner has become conscious of the potentialities of amoebiasis *sine* dysentery.

Let us consider what are the facts and what are the theoretical deductions regarding *Entamoeba histolytica* and the lesions it produces.

(i) In the first place, its pathogenicity has been established beyond reasonable doubt; the trophozoite forms of the amoeba are shown to be parasitic, and to ingest red blood and other tissue cells; these trophozoite forms are found buried in the tissues of the walls and bases of the ulcers, they are often the only living organisms in a liver abscess, and, whilst they are still there, the ulcers will not heal. Therapeutically, it has been shown that emetine has a direct action on these amoebae, that when this drug is given parenterally to an infected person it acts on the amoebae in the tissues and destroys them, and that in patients so treated the ulcers heal. Experimentally, the amoebic infection has been transmitted to man and certain animals, and typical lesions, from which the amoeba have been recovered, have been produced, whereas it has been shown that in similar circumstances *Entamoeba coli* will not produce ulceration of the colon.

(ii) Amoebic dysentery, together with its most serious complication, liver abscess, is a tropical and sub-tropical disease. Many cases have been reported amongst returned sojourners in the tropics and amongst their close associates in their homes in temperate countries, but very few instances of locally acquired sporadic amoebic dysentery or liver abscess ever occur in temperate countries, and, when they do, they are usually considered worthy of separate report in the medical press.

(iii) We know that minute ulcers may be present in the colon in the absence of clinical dysentery, or even of any other symptoms referable to the bowel. In these cases, *Entamoeba histolytica* cysts will be passed in the stools, and active amoeba will be found in the ulcers. There is considerable evidence that, although these ulcers may not produce dysenteric symptoms, they allow the entry of bacteria and/or of unchanged or partially-digested food substances directly into the blood stream, and thereby cause septic and/or allergic disease.

The evidence in favour of this sequence of events gains much support from the fact that the administration of amoebicidal specifics will cause the disappearance of both the cysts from the stools and the patients' symptoms.

(iv) Emetine given parenterally will usually cure amoebic hepatitis dramatically and will arrest the process of abscess formation; it will also cut short the dysenteric process in its early stages, but in the later stages, when the patient is passing cysts only and also in the carrier, oral administration of emetine bismuth iodide, or other amoebicidal drugs, such as yatren or carbarsone, are usually considered to be necessary to eradicate the infection.

(v) *Entamoeba histolytica* produces cyst forms that are now distinguishable by certain definite criteria from other non-pathogenic amoebae that inhabit the intestinal tract of man.

(vi) World-wide investigations during the last twenty years have shown that not only do a large percentage of the inhabitants of the tropics and sub-tropics, and of soldiers and others who have returned from the tropics and sub-tropics, pass *E. histolytica* cysts in their stools, but that a considerable percentage of residents of temperate climates, Great Britain, Canada, and the United States, also pass morphologically identical cysts in their stools; in the last group, the percentage is variable and varies according to the degree of sanitary advancement of the area and of the community from which the individuals are drawn.

Faust (*Amer. J. Trop. Med.*, **22**, 93) has suggested that in the United States, on an average, 20 per cent of the population pass *E. histolytica* cysts in their stools.

So much for the facts: now it has been deduced from the above facts and other evidence that *Entamoeba histolytica* is an obligatory parasite, that the presence of *Entamoeba histolytica* cysts in the stools of an individual is definite evidence that that individual has small ulcers in his or her colon which are potential, if not actual, portals of entry for bacteria and/or allergens, that such persons are a potential danger to others and should never be employed as food handlers, and that they are themselves liable to suffer from the innumerable ills that have been attributed to these small ulcers, and also that if their resistance is lowered they may suddenly become victims of frank amoebic dysentery, and that they should therefore undergo a course of treatment for eradication of this infection.

How do these facts and deductions tally? We will first consider the last of the facts. What is the evidence that one in every five residents of the United States has small ulcers in his or her bowel mucosa? How often have these small ulcers been seen in the tens of thousands of *post-mortem* examinations that are performed annually in that country? It is suggested that these ulcers are very small and superficial and heal rapidly; even then they should be found quite frequently.

Then the question arises, why, once having obtained a footing, should the amœbæ be so rapidly overcome by the local tissue resistance? Is it a matter of individual susceptibility? We can understand how in one person only small superficial ulcers are found, in another extensive ulceration, and in yet others the amœbæ reach the liver and cause hepatitis in one case and liver abscess in another, but why in one country should all individuals enjoy a high degree of immunity whereas in another they enjoy a varying amount? Is it a matter of racial immunity, or of the climatic factor? If the former, why does this immunity break down so readily when the same individuals go to the tropics, or in either case how can one explain the Chicago outbreak of 1933?

In this incident, 1,400 people, who had stayed in Chicago at one or other of two hotels which had a common water-supply that was later shown to be badly contaminated, developed acute amœbic dysentery and about 70 of them died. What suddenly happened to the immunity in these 1,400 people? And why if 1 in 5 of them already had a *histolytica* infection, was this super-infection from the water-supply necessary to precipitate an acute dysenteric attack?

Why under the various strains and stresses that man is subjected to does the resistance of these so-called *histolytica* 'carriers' practically never break down in temperate countries and produce frank dysentery and/or liver abscess? Even if we depart from the teaching of the protozoologist, and assume that *E. histolytica* can sometimes live as a saprophyte in the intestine of man, we still want to know what determines its invasiveness.

It is not clear why, if emetine given parentally will destroy the amœba in the ulcers in a case of frank amœbic dysentery, it will not also destroy the amœbæ in the small ulcers in the carrier, and thus prevent the formation of cysts, and/or how drugs, such as carbarsone and yatren, which are designed to act on the pre-cysts forms of amœbæ in the lumen of the gut, also destroy the parent amœba buried in the tissues and thereby prevent further cyst formation; in the latter case, it is probable that they are absorbed and act *via* the blood stream just as emetine does, but, if this is so, why should they not then be equally efficacious in acute amœbic dysentery and in amœbic hepatitis; in the latter, they are certainly not.

Thus, the story as it is told in the textbooks to-day does not apparently present the whole truth. How can these apparent inconsistencies be reconciled?

One rather revolutionary suggestion is that the amœba is not the true causative organism, but only a secondary invader. This can, we think, be negatived, not only by the pathological evidence and the experimental work that has been done with this organism, but by the fact that so much ulceration of the bowel occurs on

to which the ubiquitous amœba does not become engrafted.

Another suggestion is that a normally saprophytic amœba is stimulated in some way to become pathogenic, possibly by the synergistic action of some other micro-organism. There is, as far as we know, no experimental evidence in favour of this, but the ubiquity of the amœba and the limited distribution of amœbic dysentery could be explained on these grounds.

Finally, is it possible that we have accepted too readily the majority protozoological opinion regarding the identity of the cyst that is found in 1 in 5 of the stools of the inhabitants of the United States with the pathogenic *Entamœba histolytica* that causes amœbic dysentery and liver abscess in the tropics? The evidence is mainly morphological, but how far can we trust morphology? Confusion has reigned in the epidemiology of cholera until quite recently through failure to identify the true cholera vibrio; we might well be faced by a parallel position here. Many of the apparent anomalies could be explained on the assumption that there is a non-pathogenic race of amœbæ which produces cysts morphologically identical with those of the true pathogenic *Entamœba histolytica*, and that in the tropics we have both, whereas in temperate countries only the former is normally prevalent, although the latter may occasionally appear, e.g. the Chicago incident. At least, we feel, it is time that the subject was re-examined by the protozoologist.

The subject is one of much more than academic interest; in fact, it is one of vital importance to the clinician, for the list of diseases that are attributed to amœbiasis *sine* dysentery is already formidable and continues to grow. It includes all allergic diseases, many skin diseases, both allergic and septic, many chronic eye diseases and in fact the whole range of diseases in which a 'septic focus' is suspected as an ætiological factor. The physician who is groping about blindly for an allergen or septic focus finds the stool examination an easy and inexpensive procedure, and if his patient happens to be one of the 1 in 4 who passes *E. histolytica* cysts in this country (the incidence is higher than in the U.S.A.), he has found something positive and he either recommends a course of carbarsone or yatren, or ignoring modern teaching—or perhaps, questioning it as we have done above—he gives his patient six or more emetine injections—often, we fear, neglecting to warn him to rest during this treatment—or to make assurance doubly sure, he prescribes the double treatment. Now and then, this procedure, which is a perfectly rational interpretation of the amœbiasis-*sine*-dysentery hypothesis, appears to be brilliantly successful, for in this country we know that the dysentery-and-liver-abscess-producing *Entamœba histolytica* is prevalent and there is no question also that emetine has a non-specific beneficial action in hepatitis, but how often does

it make not the slightest difference to a patient? In view of the high incidence of these cyst passers amongst the apparently healthy members of the community, have we any right to attribute so much ill to these cysts, or rather to their parent amœbæ, and to waste valuable drugs—of which an acute shortage is threatened—without more clinical evidence that they are indicated?

The pathologist complains quite rightly that the physician does not take full advantage of

laboratory science and, for example, treats all anæmias with liver extract when 75 per cent of them would do much better with the far cheaper iron, but he should be sure that he himself does not sometimes mislead the physician into practising a pseudo-scientific quackery. In the matter of the significance of *E. histolytica* cysts, we feel that he cannot be too certain, and we therefore issue a plea for the re-examination of the whole subject, and for further experimental work if necessary.

PART III

Physiological action of alcohol

ALCOHOL has the peculiarity of being absorbed from the stomach in considerable quantities. After administration of ordinary doses as much as 25 per cent is taken up from the stomach and the balance is absorbed from the upper part of the small intestines. It appears in the blood in 5 minutes after it is taken by the mouth, its concentration reaching the maximum in about 1½ hours and then slowly declining. The maximum concentration in the blood is somewhat higher than in other tissues. Even the kidneys have not the power of concentrating alcohol as its percentage in urine is about the same as that in venous blood. In those who are accustomed to its use nearly the whole quantity taken is broken up by the tissues, only about 2 per cent usually being excreted by the breath and urine, and not more than 10 per cent in any case. Concentration of alcohol in the blood can be approximately calculated by dividing the quantity absorbed, by the body weight. Strong alcoholic drinks produce somewhat higher concentration in the blood than diluted drinks. A concentration of 0.055 per cent in blood produces slight mental disturbance; marked symptoms appear even in habitual drunkards when the concentration reaches 0.25 per cent.

According to Clark (1937) 0.025 to 0.1 c.cm. in 100 c.cm. of blood produces euphoria, impaired speed and inaccuracy; 0.1–0.2 produces disorder of conduct, minor inaccuracies and slowing down of movement; 0.2–0.5 appeared to produce intoxication, coma and gross inaccuracy of motor reactions.

Tolerance to alcohol in those habituated to its use is due to tolerance in the central nervous system. It is feeble than that produced by other drugs. That the brain functions are modified in alcoholics is shown by the fact that sudden stopping in such individuals leads to delirium tremens, which is then checked by moderate doses of alcohol. The gastric mucosa and the liver do not acquire tolerance but undergo progressive degeneration. In chronic alcoholism all the body tissues are devitalized and the will power, moral sense and mental capacity are greatly impaired.

Two of the commoner fallacies that need to be discussed under this heading are the use of alcohol

as (a) a stimulant and (b) a warming agent of the blood and tissues when taken after exposure to cold.

(a) *The use of alcohol as a stimulant.*—The popular belief pertaining to this particular effect of alcohol is precisely the opposite in its actual action. Alcohol acts primarily on the nervous system and its action is largely narcotic or sedative. The apparent stimulation is actually the direct effect of this narcotic which dulls the drinker's perception of his unpleasant feelings and makes him feel better. Effects such as increased loquacity and gesticulation, produced by alcohol, which are commonly attributed to its stimulant action, are also in reality narcotic effects resulting from the partial loss of the control exercised by the higher nervous centres. Ordinarily this control renders an individual self-critical and prevents him from the freer expression of his feelings. The removal of this control and the decrease of critical self-consciousness are, in fact, the most common and characteristic effects of alcohol, whether in a moderate dose, which diminishes restraint and 'nervousness' and imparts courage to the diffident speaker, or in larger doses when diffuse and incoordinated muscular movements of drunkenness are produced. The action of alcohol on the brain has been tested by a number of workers and they are all agreed that alcohol decreases the speed and accuracy of reflex response.

The popular belief that alcohol is a direct stimulant of the heart does not bear any scientific justification. Such value as it may have in heart diseases depends on its being a readily assimilable food, on its direct and reflex power to weaken the excessive check on the action of heart exercised by the nervous centres, and on its sedative influence on the higher centres of brain. The cumulative effect, inducing a sense of comfort and relief of mental anxiety, may be useful in selected cases of heart diseases, but it is actually the very opposite of stimulant effect. When an alcoholic drink appears to promote recovery from simple fainting it probably acts reflexly, like smelling salts, by virtue of its irritant effect upon the mucous membrane of the mouth and nose. Since the beneficial effect appears almost immediately and long before any appreciable amount of alcohol could have been absorbed and carried to the heart, the action must be local and indirect. The administering of spirits in the treatment of fits of unconsciousness is to be deprecated, for even in simple fainting alcohol is unlikely to do much good, and if the unconsciousness results from apoplexy or a head injury it may do positive harm.

The effect of alcohol on blood pressure is also of importance because of its supposed action as a circulatory stimulant. When administered by the mouth in concentrated form it stimulates the sensory nerve endings in the mouth and produces a reflex rise of blood pressure by exciting the vasomotor centre. After absorption, however, it produces dilatation of the blood vessels, particularly those of the vessels of the skin; this fact is probably due to its action on the heart-regulating centre, thus causing a lowering of the blood pressure.

(b) *The use of alcohol as a warming agent of the blood and tissues after an exposure to cold.*—Alcohol depresses the activity of the heart-regulating centres and therefore acts as an antipyretic. The temperature of a person under the effect of alcohol can be more easily lowered than that of a normal individual. It is probably owing to this effect on the heart centres that alcohol causes dilatation of blood vessels of the skin and a subjective feeling of warmth. It is therefore more inadvisable to take it either before or during exposure to severe cold because, although it produces a temporary feeling of warmth and comfort, it diminishes the power of the body to conserve heat.

Alcohol is popularly believed to have a warming action on the human system when it is taken after a chill. It is to be emphatically stated that the so-called 'warming up' action of alcohol is not a physiological process and the sensation of warmth it causes is purely due to the flushing of the skin surface. This flushing does undoubtedly lead to relief of the unpleasant sensation of 'feeling cold', but this may itself, in some cases, be disadvantageous for, under exposure to cold, the unpleasant sensation urges the individual to protect himself suitably and thus assists the maintenance of body temperature by creating an impulse towards muscular exertion, so that the production of heat is accelerated. These effects of alcohol also form a part of the explanation of its supposed therapeutic value when taken in early stages of a common cold, but it may also have a more definite pharmacological action in such cases by assisting in the diffusion of blood to the vessels of the skin and thereby relieving partially the congestion of the internal organs, as well as promoting respiration. It must, however, be recognized that against the symptomatic benefits that may be derived from taking alcohol when the patient is in a warm bed at the outset of a 'cold', alcohol when taken habitually in excess decreases the body resistance to bacterial infection.

Pharmacological action of alcohol.—Alcohol has a stimulant effect on the taste nerve-endings, increases the flow of saliva and stimulates the psychic secretion of gastric juice. Flavouring agents in alcoholic beverages such as bitters in beer and ethereal esters in spirits intensify these actions. Alcohol directly stimulates the functions of the stomach and in this way stimulates the secretion of gastric juice. Concentrated solutions of alcohol produce gastric irritation which, after a preliminary stimulation, lead to inhibition of secretion. Continued use of such drinks may produce chronic gastritis and total loss of acid from gastric juice.

The action of alcohol as a circulatory and respiratory stimulant is not powerful enough to be of any great therapeutic value.

Alcohol as food.—A large amount of experimental work has been done to show that the value of alcohol as food is very limited. It undoubtedly does enter the blood and is oxidized by the tissues at a constant rate, yielding energy, but the supply of energy is fixed and cannot be adjusted according to the needs of the body; it particularly cannot be increased to meet a sudden emergency nor can it be stored as a reserve. It also does not, unlike other foodstuffs, cause increase of basal metabolism.

Alcoholism as a cause of neuritis and cirrhosis of liver.—The researches of various American authors—Welsler, Minot, Strauss and Cobb, Joffe and Jolliffe and others—have shown that the form of peripheral neuritis which characteristically occurs in chronic alcoholics is not due, as was formerly supposed, to the toxic action of alcohol on the nerve tissues, but to the deficiency of the B vitamins, and especially of vitamin B₁, in the diet of the alcoholic. 'Alcoholic neuritis' is to be regarded as a nutritional disorder closely related to beri-beri, the more acute manifestation of vitamin-B₁ deficiency, which is seen in certain tropical countries. There is some evidence also that other morbid effects of chronic alcoholism, notably the gastric changes and the 'alcoholic heart', may be due,

at least in part, to vitamin-B₁ deficiency. The action of alcohol in such cases is indirect rather than direct, but its rôle as an aetiological factor should not therefore be regarded as of small importance. The fact that the 'alcoholic' type of neuritis, and the related lesions, occur most frequently in chronic alcoholics cannot be disputed, and apart from their significance in regard to treatment, the main interest of the new findings lies in the light they shed on the actual method by which alcoholism may lead to harmful effects in the tissues. The process by which alcoholism may lead to vitamin-B₁ deficiency is still somewhat obscure; but among the factors responsible are probably decreased intake, due to the habitually poor appetite of the alcoholic, and to the fact that he can obtain his working energy from alcohol instead of from other foods, and possibly to increased utilization of the vitamin in such cases. The absorption of this vitamin may possibly be decreased on account of the catarrhal condition of the gastro-intestinal tract.

From the point of view of treatment, this new work has great value, for it has been shown that alcoholic neuritis formerly regarded as a very chronic and intractable disease, will in some cases respond quite rapidly to adequate doses of vitamin B.

Recent work has shown that cirrhosis of the liver is not due to the direct effect of alcohol on the parenchyma of the liver but it is in all probability due to its damaging effects on the intestinal mucosa, which leads to absorption of abnormal quantities of products of intestinal putrefaction.

Alcohol in health.—Taken in moderate quantities (e.g., a large peg of whisky or a pint of beer) alcohol acts as a mild hypnotic and therefore renders the brain less active and less accurate; this effect may last for several hours. It reduces the accuracy of movements and eventually increases fatigue and the power of prolonged endurance to severe muscular exertion is reduced. As a food it is inferior to carbohydrate and fats and is a very expensive source of energy.

The consumption of alcohol in Great Britain has decreased enormously during recent years. The annual consumption per head was 4.54 gallons in 1900 and the convictions for drunkenness were 200,000 annually. In 1930 these figures had fallen to 1.98 gallons per head and convictions to 53,000.

Intoxicant effects of alcohol.—According to Clark (1937) symptoms of slight intoxication, recognizable without any special tests, commence when the blood concentration reaches 0.1 per cent or 1 mg. per c.c.m. of blood or 0.125 per cent vol./vol. (as the specific gravity of alcohol is nearly 0.8). The quantity of alcohol needed to produce this result is shown in the following table (after Clark 1937):—

TABLE VII

Drink	Concentration of alcohol per cent vol./vol.	Quantity supply 60 c.c.m. alcohol producing 1.0 mg. per c.c.m. concentration in 50 kilo. individual
Whisky (35 degrees under proof).	37	160 c.c.m. or 5 oz.
Port	2.0	300 c.c.m. or $\frac{1}{2}$ pint.
Natural wines ..	9-15	670-400 c.c.m. or 1 to $\frac{1}{2}$ pint.
Strong beers ..	7	8.50 c.c.m. or $1\frac{1}{2}$ pints.
Light beers ..	4-5	1,500 c.c.m. or $2\frac{1}{2}$ pints.

It will be seen from this that country beers, which contain even smaller percentages of alcohol, will require 4 or 5 pints to produce intoxicating effects (Clark, 1937). Alcohol even in sub-intoxicant doses is

probably one of the most important causes of motor accidents.

Are alcoholic beverages abused in India?

Country beers. (a) *Tari*.—The harmful effects of the abuse of alcoholic beverages were realized from very early days. Tipu Sultan found drunkenness from *tari* so prevalent that he ordered all *tari* trees to be cut down. Sir Brown Ellis gave similar orders, for the same reason, with regard to date palm trees growing on the Government waste lands in Bombay Presidency. The Excise Commissioner in Bengal in 1884 found that much of the drunkenness attributed to outstills was really due to *tari*. Our own inquiries in parts of Bombay and Madras Presidencies, from old alcoholics, show that before the introduction of control, it was not uncommon to find the entire village, including men, women and children, drunk with *tari*. This state of affairs is sometimes met with even in these days in remote areas, in forests where Government control is not efficient, for instance, in the Agency Tracts of Madras, the Panch Mahals of Bombay and the areas inhabited by the Maria Gonds in the Chanda district of the Central Provinces. In certain parts of Bihar, which are populated by aborigines, and the mining areas of Bengal, there is a certain amount of difficulty in keeping women or servants sober.

(b) *Pachwai*.—Drunkenness due to drinking *pachwai*, which is a mild drink, also exists in certain parts of India. Some of the aboriginal races drink this beverage to a stage of intoxication, when they get an opportunity. Among the hill tribes in Chota Nagpur, Bengal and Assam there is a tendency to take large quantities of *pachwai* if it can be had ready-made in shops, but on account of the paucity of the supply of rice they do not manufacture it in their own homes. Drunkenness due to *pachwai* is not uncommon in the mining areas in Bengal and Bihar. The evidence in favour of *pachwai* being taken mostly for its nutritive effects is also not so strong as in the case of such beers as *zu* and *laopani*, as the rice in the former becomes unpalatable and bitter after fermentation, and is not consumed but thrown away.

Among the hill tribes in Assam the beers ordinarily consumed are weaker and the manner of their consumption is also different, the beverage being taken in the form of a thick gruel and rice eaten with it. It is a part of the dietary of the inhabitants of the whole range of hills right up to Tibet and Burma. These tribes, who have a fine physique and are hardy, use as much as 25 per cent of their rice crop for this purpose. This in itself is proof that this beer cannot be very harmful and probably is not abused. Drunkenness of a convivial nature, however, does occur among these tribes and many individuals may become incapacitated for days together after drinking bouts. Amongst the tea garden coolies the state of affairs is much worse and

there is considerable drunkenness from this source. The coolies get so accustomed to the use of beers that they will starve themselves in order to get rice for brewing *laopani* or *zu*. In the United Provinces the evidence we have collected goes to show that excessive use of beer and drunkenness is confined chiefly to festive occasions. In Jaunsar taluk *pachwai* and *rabra* are chiefly used on such occasions as New Year's Day, Dewali and certain other festivals. In the Punjab, although evidence of drunkenness and even of debauchery was produced before the Excise Committee, *lugri* drinking usually is only conducive to merry-making of a harmless type. In South India beers are used to a much smaller extent, there being only one or two small areas where they are still consumed.

It has sometimes been urged that the use of such beverages should be totally stopped. On the other hand, there are authorities who think that any attempt to restrict their production would do more harm than good and would encourage drinking of stronger liquors or the resort to narcotics such as opium or hemp. The use of beer to the extent of producing uncontrollable intoxication is rare. Repeated doses of these beverages in excess may produce a state of intoxication similar to that commonly produced by stronger forms of alcoholic drinks. The accompanying recklessness of danger and the feeling of bravery induced in such cases is partly the result of the temperament of these more or less primitive races, and also in many cases it is due to a state of mental confusion induced by poisons such as dhatura, aconite and nux vomica with which the beers are not infrequently adulterated.

There is no doubt, however, that in a few instances drinkers of country beer intoxicate themselves, simply for the purpose of inducing a state of intoxication. These gross instances of producing motiveless drunkenness from country beer corresponding to the excessive drinkers of alcohol in the West; they are fortunately not common. Very large quantities have to be taken before such a condition can be produced, and this is often beyond the means of the drinkers.

Effects of different alcoholic beverages

We have analyzed the statements of individuals who were in the habit of regularly taking different forms of alcoholic beverages as to whether their general health was improved after their use or not. The following observations summarize the views expressed :—

(A) *Effects of tari*.—Over six hundred cases were examined in different parts of the country, taking different quantities of this beverage in different stages of fermentation. It was found that the intoxicating effects of *tari* were comparatively mild and that in 80 per cent of this series the stage of intoxication, if it occurred at all, lasted only for short periods not exceeding half an hour. The remaining 20 per cent (some

of them being very reliable persons holding responsible positions) stated that the beverage had no intoxicating effect at all and that it was a wholesome, refreshing and invigorating beverage with marked nutritive properties. They believed it to be the least harmful of all the alcoholic beverages used in this country. Owing to divergence of opinion we decided to go into this question in more detail.

The term *tari* includes both the unfermented and fermented juice of all kinds of palm tree. According to an analysis carried out in the laboratories of the Bengal Government, its ordinary strength was found to be about 95°U.P., which can be compared to the weakest description of *vin ordinaire*. The Excise Commissioner of the United Provinces puts its strength at 98.1°U.P., and another authority repeats the assertion once made in the House of Commons that it is little stronger than home-made ginger beer. It must be presumed that in *tari*, fermentation sets in rapidly because the solution is favourable for fermentation and the pot in which the juice is collected is almost invariably coated with fermenting material. The rate of progress of fermentation varies according to the kind of palm tree tapped and the temperature at which it is kept. For instance, in cooler climates, the alcoholic content may be negligible or entirely absent after a few hours; while in warmer climates fermentation occurs rapidly, unless certain chemicals are used to prevent it, the most common method being coating the inside of the pot with lime. If the alcoholic content is low, the percentage of unfermented sugars is high, and vice versa. It appears, therefore, that opinions regarding the harmlessness of fresh *tari* are justified, so far as they relate to *tari* in which the fermentation has not commenced or has only slightly advanced. In the authors' opinion they relate to only 30 per cent of the cases examined, in the remaining 70 per cent careful enquiry showed that fermentation was far advanced or nearly complete. A series of analyses of these specimens of *tari* showed that the average strength in Bengal and Madras was 89.20 U.P., which compares well with almost all mild alcoholic beverages used in the West.

As regards the effects of other harmful ingredients, it was found that the ordinary *tari* consumed in shops contained, bulk for bulk, nearly the same proportion of fusel oil as an equal amount of spirit of 60 U.P.; this is nearly four times as much in proportion to the alcohol content. Besides alcohol these specimens contained a large proportion of acids, which are believed to be the chief cause of indigestion, diarrhoea, dysentery and rheumatism which accompany its excessive use. As regards their nutritive value, these specimens contained a fair amount of sugars and albuminoids. It would appear, therefore, that *tari* on the whole has low alcoholic content, and comparatively greater nutritive value than many of the other alcoholic

beverages in use. The nutritive value, however, is of importance only in the case of moderate consumers of this beverage, who take it in a comparatively fresh state. When it is taken in large quantities, the percentage of some of the impurities consumed is much greater than would be the case if the same amount of alcohol was taken in the form of distilled liquors. It should be remembered that the nutritive factors are of little advantage to the consumer, who drinks in order to get drunk, and that large quantities of *tari* consumed have injurious effects. There is a popular saying that the confirmed *toddy* drinker soaks, he becomes bloated and lethargic, while the drinker of country liquor is soon under the effect of alcohol. There is moreover a large amount of medical and other evidence on record to show that considerable injury results from drinking of stale *tari*, which is described not only as a powerful intoxicant but, on account of its acid content, as highly productive of such metabolic disorders as gout, and is detrimental to health in other ways. Thus from observations in the field extending over prolonged periods in different parts of India, we are inclined to believe that the unfermented *tari* is the least harmful of all the beverages consumed in this country. If its use is in any way restricted, we have no doubt that people will be driven to more harmful beverages. In moderate quantities there is little harm; excessive drinking is very detrimental to health.

(B) *Effects of country beers (fermented beverage).*—There is a great deal of difference of opinion as to whether country beers are wholesome or harmful. The effects produced by them are somewhat similar to those of ordinary malt beer, commonly used in the West. The immediate effects in habitual consumers are refreshing and stimulating; they alleviate fatigue and give rise to a sense of pleasure and general comfort (euphoria), accompanied by a feeling of vigour, and capacity for work. According to those who take them habitually, these beers remove restlessness, induce forgetfulness and soothe the nerves. Drinkers are at first inclined to be silent, but they soon begin to talk, become happy, courageous and even hilarious. They become sociable, the eyes brighten up and the usual depressing effects of alcohol on the higher centres become apparent. With larger doses the symptoms observed are similar to those seen after strong alcoholic drinks. As regards the production of harmful effects with these beers, our experience is very much the same as that of the witnesses who appeared before the Indian Excise Committee. These liquors are not always innocuous and sustaining as is sometimes claimed, and they undoubtedly lead to much waste of food material. Cases of excessive drinking are not uncommon, and even deaths have been recorded after heavy indulgence.

We have carefully studied the question of the fatal effects produced by the use of these

beverages and have come to the conclusion that, even if inordinately large quantities are consumed, it would be difficult to take sufficient alcohol to produce stupor, coma or death from drinking the ordinary rice or *mandwa* beers. Most of the cases of poisoning were undoubtedly due to the use of adulterated or drugged beer. The allegation of adulteration of country beer has been made in most of the provinces and, although in the case of distilled liquors and *tari*, evidence has been wanting, it has certainly been obtained with regard to country beers. In quite a number of the fatal cases, *dhatura*, *nuxvomica* or *aconite* have been detected in sufficient quantities to produce death by over-indulgence. Some of these poisonous substances have actually been detected in the fermenting cakes known as 'bakhar'. These drugs are surreptitiously added with the idea of giving the beverages a bitter taste and also with the object of increasing their intoxicating effects. From the data we have collected it is clear that habitués may be grouped into two classes with regard to the effects produced.

In the first group are included the tribes inhabiting Assam Hill Tracts right down to Burma, who use beer as an article of dietary or as a bland and mildly-stimulating drink. The Nagas, as we have stated, drink beer in lieu of water, and they are noted for their fine physique, in spite of drinking large quantities. We have not been able to detect any mental and physical deterioration in those who take such beer habitually.

To the second group belong those who use beer primarily for the intoxicating effects produced by the alcohol contained in them. To this category belong most of the races living in the plains and low-lying hill area which have a high rainfall.

Both classes undoubtedly contain a certain number of psycho-neurotic individuals who are unable to bear the strain and stress of life and resort to these drinks, but the number of persons among the tribes who use beer is very small indeed.

The witnesses who appeared before the *Indian Excise Committee* (Thomson *et al.*, 1907) expressed the opinion that even excessive use of these beers is less harmful than that of strong spirituous drinks, so long as the liquor drunk is not adulterated with deleterious substances. Bedford carefully studied the question of the alcoholic content and by-products contained in these beers. In point of by-products he found that they undoubtedly contain a high percentage of acidity and a much higher proportion of fusel oil. The quantities of fufurool present, however, was less than in country spirits. Beer drinkers, therefore, consumed comparatively small quantities of alcohol but very much larger quantities of the by-products. The general consensus of opinion was, and this is borne out by our own observations during recent years, that fermented liquors are very much less harmful

in their effects than spirits containing a high percentage of ethyl alcohol.

A large amount of experimental work was carried out by Bedford (1906) and by Chopra (1927) on both animals and men, regarding the toxic effects of alcohol and the various by-products of fermentation. The conclusions arrived at by these observers are in accord. These are:—(a) That alcohol alone is at least as injurious as alcohol plus by-products; (b) that while the by-products are undoubtedly noxious and the amount far exceeds that found in potable liquors, in the relatively small quantities found even in the worst samples of the liquors analysed, their action would appear to be unimportant and negligible, and (c) that spirit-drinking is more noxious than the drinking of fermented liquors, because the amount of alcohol necessary to produce toxic effects is more quickly reached and more easily exceeded. Alcohol and not the by-products is chiefly responsible for the toxic effects produced by potable spirits. Any evil effects observed were attributable more to the excessive quantity of alcohol consumed than to any action of the by-products.

From the experimental data we have obtained and from our observations in different areas, we are in a position to state that these fermented liquors do not produce any special harm, when the concentration of alcohol is low and the consumption is not excessive. The age-long experience of the hill tribes in India points to the fact that fermented beers are on the whole less harmful than distilled spirits. The by-products are not harmful in the concentrations in which they are present in these liquors, unless very large quantities are taken for prolonged periods. During the course of our inquiry we have not found any greater preponderance of cirrhosis of the liver or any of the other conditions usually attributed to the excessive use of alcohol among these races, than are ordinarily found in races who do not use these liquors.

An altogether different factor, responsible for ill health in the consumers, is the insanitary conditions under which the beer is produced; the utensils used are not properly cleaned and impure water is often used in their preparation. To these facts might be attributed the occurrence of diseases such as dysentery, diarrhoea, cholera, tuberculosis, typhoid, etc. Finally it must be mentioned that beer after storage may taste stale and sour on account of bacterial contamination, when by-products, such as acetic acid and lactic acid, are formed in abundance. The harmful effects of these drinks, therefore, appear to be due to the unsatisfactory methods of preparation and storage rather than to the actual effect of alcohol contained in them.

(C) *Effects of stronger alcoholic beverages such as country spirit and other liquors.*—There is considerable difference of opinion with regard to the ultimate effects of alcoholic drinks on the human system. These differences are probably due more to the quantity and character of the particular liquor used rather than to error of observation or analysis. The wide range of environmental conditions and the personality types is clearly responsible for some of these variations. According to some authorities, who have observed alcohol addicts amongst the native population in India, the abuse of alcohol produces permanent ill effects and disease during periods varying according to the physical powers of the individual. The most common

symptoms described are dyspepsia and emaciation in the case of country spirit, but fattening in case of beer, accompanied by diarrhoea, gastritis, cough, vertigo, cirrhosis of liver, neuritis, loss of mental power, tremors and some believe even epileptic type of fits. The chief alimentary disorders among those indulging in excessive quantities of alcohol are dyspepsia, gastritis and impairment of hepatic function. Congestion of liver and even fatty degeneration are not uncommon. No relation between chronic alcoholism and atrophic cirrhosis of the liver could be traced in our series of cases. We carefully examined the histories of all cases of atrophic cirrhosis and ascites in two of the largest hospitals in the Punjab. Only in very rare instances could any definite alcoholic history be traced. The cardio-vascular and respiratory systems are not markedly affected in chronic alcoholics in this country. In a series of 200 cases examined no marked changes were detected; the central nervous system undoubtedly bears the brunt.

Chronic alcoholics can be recognized in a number of ways. Many exhibit an unsteady gait and hasty behaviour, sometimes with an exaggerated degree of politeness. Excessive *tari* drinkers neglect their clothes, and their eyes are usually congested; the eyelids are swollen and oedematous in the same way as in nephritis. Some addicts described a wonderful feeling of exaltation and physical strength. If the abuse is persisted in it leads to indigestion, wasting of the body, cough, depression, melancholia, impotence and finally drowsy. The individual is reduced to beggary and serfdom and becomes an outcast from society, and not infrequently his career terminates in insanity.

Mental disorders and alcohol

A statistical survey of such conditions has been made in the mental hospitals at Ranchi, Lahore, Madras, Nagpur and Yeravda. These observations were made by the authors in collaboration with the superintendents of these institutions, and the authors are grateful to these officers for the valuable help and suggestions given them in this work. The observations we have made show that abuse of alcohol is a causal factor in the development of insanity in many cases. There were altogether 875 cases labelled as toxic insanity in these hospitals, who gave history of alcoholism before their admission into the hospital.

1. *Minor mental disorders.*—Our observations in this connection were also made on habitual consumers who were not inmates of mental hospitals but were persons at large in the towns and villages. Most of them were doing their daily work and were earning their livelihood; a few even held positions of responsibility and trust. Minor changes in mental faculties may take place even from moderate habitual use of alcohol. The following are the common changes that have been observed:—

(a) *Minor impairment of mental faculties and judgment.*—In a series of 250 alcoholics examined, 20 per cent showed these symptoms. The degree of mental enfeeblement was sometimes so small that it was difficult to detect, but information could only be obtained through friends and relatives who could compare the past of the individual with his present condition and who could observe definite deterioration.

(b) *Progressive loss of memory.*—This was observed in individuals after 40 years of age, and in 15 per cent of this series such changes were discernible. These were associated with other senile degenerative changes such as arteriosclerosis, premature greyness, and diminution of sexual desire, etc.

(c) *Hallucinations and delusions.*—These were observed in 2 per cent of cases and were generally delusions of persecution. Auditory hallucinations were more common, and if care is not taken this may lead to paranoia.

(d) *Sexual depravity.*—This was met with in 4 per cent of the cases, most of the individuals being below the age of 30 who were given to life of debauchery. A gradually increasing suspiciousness and paranoid attitude develops with a pronounced increase in sexual excitement.

II. *Transient mania.*—The most common form seen in Indian asylums is an acute mania of short duration which was found in 10 per cent of cases labelled toxic insanity produced by alcohol. The onset is sudden and invariably follows a drinking bout; it is more common amongst persons who have a particular susceptibility to alcohol. There are instances on record where half a pint of country liquor rendered a person aggressive and violent with homicidal tendency. These persons sometime showed signs of exaltation and a sense of well-being in the beginning, followed by restlessness, noisiness and disorderly conduct. There was a tendency to commit wilful damage, often followed by complete forgetfulness of the entire incident.

III. *Hallucinations.*—These were observed in 3 per cent of the cases of toxic alcoholic insanity. Hallucinations and delusions were of frequent occurrence, when alcohol was abused for prolonged periods. This condition could be distinguished from delirium tremens by the fact that it was mostly of a coherent type, and particular hallucinations followed particular delusions. The delusions seen were mostly of suspicion and persecution and often led to acts of violence.

IV. *Delirium tremens.*—This syndrome has been rarely observed in Indian alcoholics, although it is perhaps the most common of all the mental disorders attributed to abuse of alcohol in the West. The distinguishing features are presence of delirium and tremors which are rarely present together in any other disease. It is believed by some authorities that the syndrome is a withdrawal symptom of the drug during an acute illness. This belief is supported by the fact that rapid improvement often follows the administration of alcohol during early stages of the disease. Others believe that it is toxic in nature, as excessive indulgence in alcohol produces an antitoxin which enables tolerance to be established and that delirium is caused by an excess of this antitoxin. It has also been

claimed that the serum of confirmed alcoholic addicts yields a toxin which is capable of producing delirium in dogs. The reason why delirium tremens rarely occurs among Indians is that it is only in very rare instances that such large quantities of alcohol as are imbibed by habitués in the West are taken by Indian habitués.

V. *Paranoic conditions*.—Four per cent of cases with history of alcoholism in the mental hospitals were labelled as paranoia (not true paranoia). The disorder starts with delusions of suspicion, and rapidly reaches a paranoic state. Hallucinations of hearing are frequent, and delusions generally referring to persecution by enemies. Such patients are often homicidal, and are very difficult to control. The duration of disease is usually shorter than in true paranoia. Dementia often follows and may change the picture to a considerable extent. Sometimes, when cases are mild and the drug is withdrawn early, the individual may become a useful member of society but he should be carefully guarded all the time. Most of these persons were below the age of 30 and were given to a life of debauchery and prostitution. A gradually increasing suspiciousness and paranoid attitude develop with a pronounced increase in sexual excitement.

VI. *Korsakoff's syndrome or polyneuritic psychosis*.—This is a toxic disorder which may also be due to other toxic factors such as diabetes mellitus, septic poisoning or chronic poisoning with metallic substances, such as arsenic, lead and mercury. Long-standing alcoholic intemperance is the most common cause of this disorder. The usual symptoms of the disorder are peripheral neuritis associated with the loss of memory for recent events. There may be extreme dissociation of thoughts and ideas. Alcohol probably influences both the cortical nerve cells and the peripheral nerve fibres, therefore the symptoms vary according to the region first affected. Not only memory but the self-critical faculty and sometimes the general intelligence suffers.

Alcohol in relation to crime

The relation between alcohol and incidence of crime was also studied by the present authors. In the central districts of the Punjab, for example, in Amritsar, Lahore, Gurdaspur, Ludhiana and Ferozepore, which are inhabited by Sikhs who consume alcohol in larger amount compared with other parts of the province, the incidence of crime is decidedly higher than in the rest of the province. Similarly, the incidence of crime rose in certain districts of the United Provinces and Madras and Bombay Presidencies, when the consumption of alcohol went up. Of all kinds of alcohol used in this country, it was found that country spirits were more instrumental in leading to a criminal mentality than any other kind of alcoholic liquors. Next in

order come *pachwai*, foreign liquors and *tari*. We tried to trace a history of alcoholism among 150 addicts tried for murder in these areas, and found that country spirit was the contributory cause in 12.5 per cent.

As regards the relationship between alcohol and crimes of a sexual nature, it was found that, in 120 cases charged with rape and other sexual offences, there were 50 persons who frequently indulged excessively in alcohol. Criminals sometimes take to alcohol to overcome the sense of inhibition and the association of alcoholism with prostitution is often for the same purpose.

We have already referred elsewhere in this paper to the relation between mental disease and alcoholism. Insanity might lead to drunkenness, and *vice versa*. The typical crime committed in *mania a potu* is one of violence, and the terrifying hallucinations of delirium tremens might be responsible for murder, suicide, violent assault, or damage to property. In the more chronic forms of insanity, theft, fraud, and sexual offences were not uncommon. Crimes of violence might be due to hallucinations or to delusions. Sexual offence, thefts, embezzlement, or vagrancy might be caused by mental deterioration favoured by the abnormal mental condition produced by drunkenness apart from insanity. The impairment of reason, the lack of appreciation of the consequences, the emotional disturbance, the divorce from reality, the loss of inhibition, and the consequent unleashing of personal predilections were responsible for many crimes committed by alcoholics.

There was a tendency in some alcoholics to repeat their previous crime, thus resemblance might be accentuated if there were no subsequent recollection of the crime; and if an epileptic had taken alcohol before committing a crime, the diagnosis between alcoholic and epileptic automatism might be impossible. It is also important that after certain illnesses, such as head injury, brain disease, or a previous attack of mental disease (especially delirium tremens), the offender might be more susceptible to alcohol than formerly—the so-called pathological drunkenness.

Medical News

PROFESSOR SIR RAM NATH CHOPRA AND GROWTH OF PHARMACOLOGY IN INDIA

ON 16th November, 1941, Professor Sir R. N. Chopra decided to retire from Government service and with this the long association, with Calcutta, and with Calcutta's premier medical research institution (School of Tropical Medicine), of a great pioneer figure in Indian experimental medicine came to a close. Besides being distinguished for his many notable contributions in his chosen fields, Professor Chopra will be long remembered as the 'Father of Indian Pharmacology' and a founder of a school of pharmacologists. Those with whom he came into intimate contact will never forget his magnetic yet simple personality, his high idealism, his unbounded enthusiasm and devotion for work, and, above all, his remarkable capacity to promote collaborative effort amongst various groups of scientists in extending the bounds of medical knowledge.

Chopra's academic background fitted him admirably for a career in the field of medical research. As a promising scholar of the Punjab University, Chopra so ably impressed his professors that his father was advised to send him after graduation to England for higher studies. Early in 1902, Chopra proceeded to England and enrolled himself in Downing College, Cambridge. Here he stayed for six years obtaining his Science Tripos in 1905, L.R.C.P., M.R.C.S. (Eng.) in 1907 and M.B., B.Ch. (Cantab.) in 1908. British medicine and physiology was at the zenith of reputation at this period under such internationally renowned exponents as Barcroft, Langley, Gaskell, Nuttall, Dixon, Horder, Clifford Albutt, Osler, Langdon-Brown, etc., and he had the good fortune of coming under the inspiring influence of some of these teachers. Deciding to take up medical research as his life's career, Chopra entered the laboratories of Professor Dixon and took up specialized study in that field of advanced physiology which deals with the action of chemical agents on biological tissues (pharmacology). Under the direction of the late Professor Dixon, he prepared a thesis entitled 'Action of drugs on ciliary movement in the respiratory tract', which later won him the degree of Doctor of Medicine in 1912. Knowing however that he will have to earn a living, and realizing the lack of full-time opportunities in scientific medicine in India nearly 35 years ago, Chopra entered the St. Bartholomew's Hospital while still enrolled at Cambridge, and towards the latter part of 1908, competed for the I.M.S. examination standing third in order of merit. As a young I.M.S. officer he saw active service first in East Africa and later in the Afghan War, for nearly 12 years. For a man of Chopra's temperament and keenness for research and academic work, it must have been a great relief when the School of Tropical Medicine was established through the untiring efforts of Sir Leonard Rogers and he was chosen to occupy the chair of pharmacology at this institution in 1921. After a roving life of well nigh 12 years, during which the only outlet for his genius was stereotyped medical and surgical practice in the army, luck and chance placed him in his real element and once he got his mooring, he stuck to it with his characteristic zeal and tenacity until his retirement 20 years later.

In 1921, pharmacology as a science was unknown in India. Excepting the sporadic efforts made by a group of workers to study the value of indigenous anthelmintic remedies under the guidance of Father F. J. Caius of Bombay, no systematic study on the basis of animal experimentation was being undertaken in any of the university laboratories or medical institutions. Pharmacology was not included as a subject for study in the medical curriculum of Indian Universities. It was therefore no easy task for

Colonel Chopra to organize and equip a laboratory for modern experimental pharmacological work for the first time in India. As he used to admit freely to his students in later years, the task of arranging all details at the very outset of experimental work, where none had been performed before and where no practical guidance of any kind was available, offered difficulties which could not have been successfully surmounted but for the ready help of late Colonel H. W. Acton, C.I.E., I.M.S., then professor of pathology and bacteriology at the School of Tropical Medicine, and the advice and guidance from Cambridge of his professor, late Professor W. E. Dixon, F.R.S. His first paper on 'Therapeutics of Emetine' was published in 1922 in collaboration with Professor B. N. Ghosh (now professor of pharmacology at the Carmichael Medical College), more than a year later from the time he started work at the School, and this probably was the first paper published in India where the toxic effects of repeated doses of emetine injections on the cardiac musculature were demonstrated on experimental animals, and which, incidentally, served as the first note of warning in India against the dangerous practice of employing heroic doses of emetine in the treatment of all types of dysenteries and liver complications. Since then, a steady stream of researches on various aspects of tropical medicine, experimental pharmacology and therapeutics, drug addiction, indigenous drugs, drug standardization, clinical medicine, etc., emanated from Chopra's laboratory and Chopra spared no pains, whenever opportunity presented itself, in training up a band of young workers to carry on his field of studies.

Chopra's contributions to medical science cover a wide range of subjects. Space will not permit any detailed analysis or evaluation of his work. The main theme which seems to have attracted his attention early and to which he returned again and again was the study of Indian indigenous drugs—their chemical composition, the physiological action of their active principles on living tissues *in vivo* and *in vitro*, and the biochemical and bio-physical changes brought about in mammalian organisms on the administration of these active principles. The aim and scope of the work, as he conceived it as early as 1922, was as follows:—

- (1) To make India self-supporting by enabling her to utilize the drugs produced in the country, by manufacturing them in a form suitable for administration.
- (2) To discover remedies from the claims of Ayurvedic, Tibbi and other indigenous sources suitable to be employed by the exponents of western medicine.
- (3) To discover the means of effecting economy, so that these remedies might fall within the means of the great masses in India whose economic condition is very low.
- (4) And eventually, to prepare an Indian Pharmacopœia.

Such a comprehensive and ambitious approach to a complicated problem could not naturally be managed single-handed and Chopra realized from the very beginning, as Sir Leonard Rogers did, that collaboration with botany and chemistry was essential in tackling such problems. Here started a partnership between him and Professor S. Ghosh, professor of chemistry at the School of Tropical Medicine, which was destined to last all through his career at the School and which, like the partnership between Sir Henry Dale, F.R.S., N.I., and late Professor G. Barger, F.R.S. of London, yielded very fruitful and far-reaching results in the field of Indian indigenous drugs. Practically all the indigenous drugs that are now being used by the medical profession in India in place of imported drugs may be said to be the outcome of the researches emanating from the Chopra-Ghosh school of workers. From scientific and academic viewpoints, the work on indigenous drugs has set up a high standard of medical and chemical research in India and has focused international attention to it. Its value from the economic viewpoint is no less

worthy of note, as it has given a definite fillip to the Indian drug industry. Chopra's book on 'Indigenous Drugs of India' and 'Medicinal and Poisonous Plants of India' (2 vols.) will stand as lasting monuments of his enthusiasm and endeavour in a field which has seldom been trodden by scientific medical workers.

There was, however, another side of Chopra's interest in pharmacology which manifested itself in a large number of his published papers and in his books on 'Tropical Therapeutics' and 'Anthelmintics'. He was one of those, like the late Professor A. J. Clark of Edinburgh, who wanted to bridge the gap between pharmacology, therapeutics, and clinical medicine. He belonged to that group of scientists who were trained to study and appreciate the whole field of experimental medical science, particularly its 'applied' side as distinguished from 'fundamental and basic' concepts. Most of his work therefore leaned heavily towards studying problems of 'practical' utility to professional medical practice in the tropics. This is the reason why he moved his interest frequently from investigations pertaining to the field of tropical medicine such as asthma, lathyrism, epidemic dropsy, amebic dysentery, helminthiasis, malaria, etc., to problems of drug standardization and adulteration, the scientific study of the effects of habit-forming drugs, e.g., opium, cannabis, alcohol, chloral hydrate, cocaine, etc., on laboratory animals and human beings, the effects of chemotherapeutic remedies on mammalian system, the devising of laboratory tests for the diagnosis of kala-azar in outdoor clinics and in the field, etc., etc. In the apparent 'diversity' of topics dealt with by Chopra and in the very wide range of his scientific contributions, there is evident to critical observers a 'latent central theme' and that is, his effort to always interweave and interdigitate the work of the laboratory and the hospital. Though essentially a laboratory man with a preferential liking for experimental therapeutics, Chopra's later experience at St. Bart's Hospital, at the Carmichael Hospital for Tropical Diseases, and in the Army Medical Service rounded off his university training in pharmacology and served to extend his knowledge and interest to the science of disease as a whole, and he became ultimately a combined product of the laboratory and the clinic. Judged from this angle, Chopra's contributions are undoubtedly very significant and give clear evidence of the range and versatility of his mind.

The pioneer work of Chopra in building up Indian pharmacology, and in giving an impetus to medical and scientific research on 'applied' problems of peculiar interest to India, soon marked him out as an outstanding Indian in the field of medical research. One instance of his consuming desire to put India in the map of international medical and scientific research is provided by the fact that he never yielded to the attraction, so commonly seen in many foreign-trained scientists, of publishing his research papers in foreign journals. The writer recalls one instance when one of his British friends asked him to publish the results of one of his investigations in the *British Medical Journal*. Chopra politely wrote back saying that the *Indian Medical Gazette* would serve the purpose all right and he would send reprints to all the persons in England interested in that question. Chopra was fortunate in having an enterprising spirit coupled with admirable patience and grit, which made him an ideal administrator, a stimulating teacher and a sympathetic office-master. He exercised a great influence on many pupils, assistants and others who came in contact with him during the course of his long scientific career. None of the many who at one time or another were privileged to work in his laboratory failed to profit by his intense enthusiasm for research, his youthful outlook on science, his tremendous optimism even in the face of problems which seemed incapable of solution, and above all, his courteous dealings at all times with even his laboratory attendants. Despite his great absorption in his administrative and book-writing work in later years, the door of his room was always open

to any worker in his or other laboratories of the School or to any former pupil or scientific friend. When one came for advice, one found a man who seemed to be working against time, but nevertheless, prepared to stop to listen to him attentively and give whatever advice he could to a younger assistant or colleague. In this way and by other sterling qualities of the head and heart, Chopra unconsciously served to build up a school of Indian pharmacology in the comparatively short space of 20 years from almost nothing but descriptive materia medica and non-scientific teaching of older days. If Chopra did not do anything else but this, his name would remain to posterity. As 'Father of Indian Pharmacology' in India, Chopra's position may be compared to those of Oswald Schmiedeberg of Germany and John Jacob Abel of America. Professor Schmiedeberg*, who is credited with the establishment of the first properly equipped pharmacological laboratory in a University, had nearly 40 pupils who occupied important chairs in almost all countries of Europe and America. The international character of the school developed by him can be judged from the following representative pupils:—Abel (Michigan and Hopkins); Meyer (Vienna), Magnus (Utrecht), Gottlieb (Heidelberg), Heffter and Heubner (Berlin), Cloetta (Zurich), Pohl (Prag), Morishima (Japan), Maogori (Padua), Cushny (Michigan, London and Edinburgh), Baldovi and Gagli (Rome), Mosso (Genoa), Poulsson (Christiana), Bock (Copenhagen), Santesson (Stockholm), Kobert (Dorpat), Harnack (Halle), Dresser (Elberfeld), Wallace (New York) and Stockman (Glasgow). Professor Abel is also credited with training nearly 25 pupils who are now teaching pharmacology all over America, Japan, and Korea. During the last 20 years, Chopra had succeeded in developing an all-India School of Pharmacology and had, in collaboration with Professor S. Ghosh, trained more than 45 workers in the chemistry and pharmacology of drugs including indigenous drugs. A few names would indicate the representative character of the school developed by him:—Professor B. N. Ghosh (Calcutta), Paranjpe (Bombay), Nanda (Lahore), David (Madras), Iswariah (Andhra), Dikshit (Bombay), P. De (Calcutta), Venkatachallam (Madras), Grewal (Lahore), Chakravarty (Agra), Das (Nagpur), Mukerji (Calcutta), Sharma (Amritsar), Gupta (Calcutta), I. C. Chopra (Kashmir), B. C. Bose (Calcutta), Ratnagiriswaran (Madras), Chowhan (Meerut), N. K. Bose (Delhi), Chatterjee (Calcutta), G. S. Chopra (Karachi), Miss Chaudhuri and Miss Vethavanum (Delhi), Dutt (Calcutta), Kahili (Rangoon), Muthanna (Karachi), A. Chatterjee (Darjeeling), N. De (Bangalore), etc., etc.

Honours, both in appreciation of his contributions to medical science, and for all his activities in connection with medical and public health organizations and in connection with the initiation and development of the drug control organization in India, came to him from all quarters—from his *alma mater* (Cambridge University), from the University of Calcutta and other scientific bodies in India, Great Britain, Europe and America, and from the Government under which he served for a long period. When he retired last November to take up the duties of the Director of Medical Services and Drug Research in Jammu and Kashmir State, his hair was seen to be grey but his head remained as before—still sympathetic and approachable, still keen to work in his chosen field of Indian drugs as long as physical powers would permit, never to flag until Nature would demand it. It did not fall to his lot to make epoch-making discoveries, but his was the glory of a pioneer 'blazing the trail' in a field (study of indigenous drugs) so far untrodden and neglected in India but, nevertheless, a field pregnant with possibilities. A worker in his very core, Chopra's many pupils, friends, and acquaintances cannot help

* Festschrift to Professor Schmiedeberg. *Archiv. f. exper. Path. u. Pharmacol.*, 1908 (Supplementary volume).

but feel the loss of his genial company and inspiring leadership, but can be reconciled to it by his long life of accomplishments and by the fact that he is still happily 'in harness' in a better climate at the Kashmir State and is actively engaged in building up another research centre in Northern India.

B. MUKERJI.

MALE NURSES FOR MILITARY HOSPITALS

THE Government of India have decided to recruit 'male nurses' for employment in military hospitals during the present emergency. These men will be enrolled as warrant officers, class II, in the Indian Medical Department.

Men offering for this service must be registered as 'male nurses' with a provincial nurses registration council. Persons in government service, who wish to volunteer, will also be eligible.

Besides salary and allowances, men employed as 'male nurses' will be entitled to free rations and accommodation.

THE TUBERCULOSIS ASSOCIATION OF INDIA

TUBERCULOSIS NEWS

Hassan Masud Suhrawardy Memorial Anti-Tuberculosis Challenge Shield Competition

ENTRIES for the Hassan Masud Suhrawardy Memorial Anti-Tuberculosis Challenge Shield Competition on the basis of work done by the respective tuberculosis organizations during the year 1941 have been invited up to the 15th July, 1942.

The competition is open to any corporation, municipal council, municipal committee or district local authority in British India or in an Indian State doing anti-tuberculosis work or to any other organization, private or aided, which is doing anti-tuberculosis work and which the central committee of the Tuberculosis Association of India may from time to time admit to be eligible for the competition.

In awarding the shield full consideration will be given to the efforts made and results achieved in the prevention of tuberculosis during the year 1941.

The winning body will be entitled to hold the silver shield for one year, and its name will be inscribed thereon.

Special Tuberculosis Number of the 'Indian Medical Gazette'

At the request of the Tuberculosis Association of India, the editor of the *Indian Medical Gazette* has agreed, as in the past, to publish a special tuberculosis number of the *Gazette* in October this year. This will be published on the lines of previous numbers issued since the year 1937.

Articles on any aspect of tuberculosis—clinical, medical or preventive—for the forthcoming number have been invited from tuberculosis workers by the middle of July.

Lady Linlithgow Sanatorium, Kasauli

The following have been appointed members of the sanatorium managing committee for one year:—

The Chairman, Tuberculosis Association of India.

The Vice-Chairman, Tuberculosis Association of India.

The Honorary Treasurer, Tuberculosis Association of India.

Mr. D. N. Mitra, C.B.E., Solicitor to the Government of India.

Mr. U. N. Sen, C.B.E., Managing Director, Associated Press of India.

Sardar Bahadur Teja Singh Malik, C.I.E., I.S.E., Chief Engineer, C. P. W. D.

Major-General J. Taylor, C.I.E., D.S.O., I.M.S., Director, Central Research Institute, Kasauli.

Mr. D. D. Anand, M.A., Executive Officer, Kasauli Cantonment.

The Medical Commissioner, Tuberculosis Association of India.

Medical Commissioner, Tuberculosis Association of India

Dr. C. Frimodt-Møller, the first Medical Commissioner of the Association, had unfortunately to resign his appointment owing to failing health at the end of March 1942.

Dr. Frimodt-Møller was on medical leave since the 11th of August, 1941, and Dr. P. V. Benjamin, Medical Superintendent of the Union Mission Tuberculosis Sanatorium, officiated for him for about five months from the end of October last.

The affiliated provincial and state tuberculosis associations have been asked to recommend names of suitable candidates for the post. The candidates are expected not only to have the necessary academic qualifications in the special subject but should also have had wide experience in both the administrative and clinical fields.

New Tuberculosis Institutions

Her Excellency the Marchioness of Linlithgow laid the foundation stone of the Lady Linlithgow Tuberculosis Hospital, Patiala, on the 3rd March, 1942.

ROSE HIPS FOR ORANGES

TWO HUNDRED tons of rose hips gathered from the hedges of England and Scotland last autumn have been turned into syrup for the older children in Britain who cannot get a regular supply of oranges.

Like the orange, rose hips are a rich source of vitamin C, the anti-scurvy vitamin.

Before the war it never occurred to anybody to use rose hips, but when the supply of oranges dwindled a small army of Boy Scouts, Girl Guides, teachers and Women's Institute members turned out into the lanes with their baskets.

Even housewives who were expert jam makers found it difficult to keep the hip hairs out of the syrup and the hips were therefore sent off to nine factories which have now produced from them 600,000 bottles of syrup. Young children are sipping it with relish at the rate of one teaspoonful a day. Two teaspoonsful in the twenty-four hours give all the vitamin C which older boys and girls require.

Britain's Ministry of Health are so pleased with the result that they are hoping for a much bigger collection of rose hips when autumn comes round again.

RHEUMATISM IN CHILDHOOD AND ADOLESCENCE*

WE are pleased to receive a copy of this reprint. It is an outcome of an endowment founded to commemorate the memory of Dr. Elizabeth Mathai—such endowments for furtherance of medical science are relatively few in Indian Universities. The subject is well chosen, in view of the condition that the lectures should be definitely connected with some aspect of diseases of children and women. This series of three lectures, apart from confirming the established fact about the prevalence of rheumatism in this country, presents the available local material admirably, and insists on the importance of early detection of cases and their organized supervision.

*Rheumatism in Childhood and Adolescence. By P. Kutumbiah, B.A., M.D., M.R.C.P. (Lond.). (Reprinted from *Indian Journal of Pediatrics*, Vol. VIII, Nos. 30 and 32, 1941.)

Public Health Section

THE HEALTH STATUS OF A BENGAL VILLAGE: ALL-INDIA INSTITUTE OF HYGIENE AND PUBLIC HEALTH STUDENTS' SURVEY*

For the past three years the D.P.H. students of the All-India Institute of Hygiene and Public Health, Calcutta, have been carrying out a survey of the health conditions of a rural Bengali community, including such data of socio-economic significance as can be included within the limitations of a period of five days. The survey has a twofold purpose: (a) to train the students in survey methodology including collection, analysis and interpretation of data, and (b) to give opportunity for the students to secure some first-hand acquaintanceship with rural conditions. A survey was made of Ratanpur in February 1942 and the essential data collected by the students are summarized below:—

Physiography

The village Ratanpur is 22 miles from Calcutta and is situated to the north-east of Singur in the Hooghly district. The village itself has developed in a ribbon fashion along the foot-path connecting Singur to Chandernagar and extends over nearly a mile and a quarter. There is no planning either in house-building or in village extension. The river Damodar situated about 14 miles to the west of the village and the river Hooghly situated about 9 miles to the east, run from North to South. The natural drainage of the tract has been interfered with or impeded by the following factors:—

(1) The silting up of the connecting channels, viz, the Kananadi, Kana Damodar between the Damodar and the Hooghly and of the river Saraswati.

(2) The construction of the left embankment of the Damodar and other embankments in connection with the railways and roads.

With the decay of the river system there was an urge for the construction of the Eden Canal for supplying people with drinking water. This canal with its distributary system was modified later for the purpose of irrigation as well. One of such distributaries connecting the Kananadi with the Saraswati, runs through the Ratanpur village. But it has failed to serve both the purposes mentioned above.

Climatology

The climate of the place is similar to the major part of the Western Bengal. The year

can be divided into three distinct seasons—winter, summer, and the rainy season. Winter lasting from November to February is pleasant with little rainfall. During the summer months from March to June the temperature varies from 80°F. to 105°F. but the humidity does not fall below 60 per cent. The average annual rainfall is 59 inches, much of it occurring between July and October when the humidity is as high as 90 per cent.

Water supply

Water supply can be grouped into two headings: (1) for irrigation, facilitated to some extent by the Eden Canal; (2) for domestic purposes. Water from the *dobas* and from the dying tributaries is also utilized for irrigation.

For domestic purposes water is obtained mainly from two sources. The four tube-wells in the village, of which one requires immediate repair, supply water for drinking purposes while the numerous *dobas* are used for ablution, bathing, washing and also for cattle. Approximately each tube-well serves a population of 250, which is adequate under normal conditions; but in view of the ribbon development of the village, people have to go a long way for obtaining drinking water. Two new tube-wells were constructed by the students themselves during their survey and fitted with pumps and impermeable aprons and platforms and should alleviate to some extent the difficulty in getting good drinking water supply. The water in the Eden Canal is also used by those living near it, as others use *doba* water.

There are three dug-wells in the village of which one is *pucca*. Water from these is used both for drinking and other domestic purposes. No bacteriological examination was done to determine the quality of water from the tube-wells and the dug-wells.

Disposal of excreta

There are two houses with latrines of which one has a hand flushing closet with a septic tank. These are only used regularly by the female members of the house. There are no public latrines except for the two bore-hole latrines constructed by the D.P.H. students. The animal excreta, valuable as manure, are usually dumped in a corner near the house and converted into cakes for use as fuel.

Disposal of refuse and garbage

The refuse and garbage from the houses and cattle-yards are collected and heaped in manure-pits behind the houses. These pits are fairly distant from living quarters so as not to cause any nuisance to the inmates. Though there is no public agency responsible for the disposal of

* Arranged by Dr. C. Chandra Sekar and Dr. B. Mukerjee, of the Section of Epidemiology and Vital Statistics.

refuse, one is struck by the general cleanliness of individual houses.

Housing conditions

Fifty-seven houses were surveyed for their conditions regarding (1) openness, (2) approach, (3) materials, (4) cleanliness, (5) dampness, (6) over-crowding, (7) ventilation and lighting, (8) kitchen and food, (9) bathing and washing facilities, (10) refuse collection and disposal, (11) latrine accommodation, (12) water supply and (13) other defects including nuisance from live-stock, flies, etc. The standards used for appraising the various items were purposely made lenient on account of rural conditions and even then only one house out of 57 could be classed as 'satisfactory' in every respect. However, the houses were not equally defective with regard to all items. With regard to openness, approach, materials, cleanliness and over-crowding at most only 25 per cent houses were below standard.

Most of the houses have open spaces, and are detached or semi-detached with fairly good approaches. The walls are massive and are either built wholly of mud or of mud over bamboo frame-work. The roofs are thatched. Few houses are white-washed. The floor is also of mud, well raised above the surrounding ground yet about 25 per cent of the houses are reported to be damp during the rains. Although most of the houses are provided with sufficient windows for ventilation, the lighting is poor due to the absence of white-washing of the walls. The kitchens are generally separate from the living rooms. Invariably the kitchens are well-kept and food is kept covered. Bathing and washing

breeding is prolific especially in wet weather. Mosquitoes are found in plenty especially in eowsheds and many villagers use mosquito-curtains.

Vital statistics

The population of the village at the time of survey was 1,071, the population 6 months before the survey as estimated by the natural increase method and used for the calculation of rates being 1,054. The population density works out to 5.4 persons per acre, reckoned on the area of Ratanpur, excluding only the paddy fields.

The age and sex distribution of the village compared to that of Bengal according to the 1931 census is given in Table I.

The crude birth rate for the year preceding the survey was 49.5 *per mille* and resident birth rate 48.5 *per mille*. The birth rate is much higher than that of Bengal which according to the D.P.H.'s report for 1939 is 32.0 and which even after allowing for incomplete registration of births cannot be much more than 42.0 *per mille*. Considering the fact that women in the reproductive age group at Ratanpur are lower than those in Bengal, the higher birth rate reflects on the higher fertility rate of the women in this village. It is not, therefore, surprising that the general fertility rate for women of 12 to 50 years of age works out to 209 *per mille*.

The crude death rate of the village is 18.03 *per mille* and the resident death rate 17.07 *per mille*. It should be observed that in spite of a larger proportion of individuals below 10 years of age and over 40 as compared to Bengal, the crude death rate of the village should be actually

TABLE I

Age group in years	RATANPUR				BENGAL			
	Number		Percentage of total		Number in '000s		Percentage of total	
	Males	Females	Males	Females	Males	Females	Males	Females

facilities are almost non-existent inside houses. The same applies to drinking water supply. Most of the houses have eatsheds on the premises which are kept fairly clean. Pigs and poultry are not found in the houses. Though manure-pits are not close to the houses, fly

lower—the crude death rate of Bengal in 1939 being 21.9 *per mille*.

The low death rate and high birth rate lead to a high value for the vital index which is 284 for the village compared with 147 for Bengal in 1939.

The infant and neonatal mortality rates of the village as compared to Bengal are as follows:—

	Ratanpur	Bengal (1939)
	<i>per mille</i>	<i>per mille</i>
Infant	78.4	146.6
Neonatal	39.2	86.3

The above rates for the village are based on small numbers and as such *much reliance cannot be placed on them for comparative purposes*. Yet the low figures for infant mortality do arrest attention, especially as only 4.2 per cent deliveries receive the attention of certified midwives whereas 85.0 per cent are conducted almost completely by the conventional *dais* and the rest are supervised by relatives and friends.

Judging from the pregnancy history of the women in the village, the still birth rate is 38.3 per 1,000 live and still-births (39.8 per 1,000 live-births), the rate for Bengal in 1939 being 41 per 1,000 live-births. Abortion rate is 7.5 per 1,000 pregnancies.

The specific mortality rates by age groups are as follows:—

Age groups	Rate <i>per mille</i>	Age groups	Rate <i>per mille</i>
Below 1 year ..	78.4*	20-40 years ..	14.0
1-5 years ..	30.3	40-60 " ..	14.1
5-10 " ..	16.9	60 and over ..	32.8

* Infant mortality rate.

The specific mortality rates by causes are:—

Causes	Rate per 100,000	Causes	Rate per 100,000
Typhoid ..	284.6	Chickenpox ..	94.9
Dysentery and diarrhoea.	284.6	Pneumonia ..	94.9
Tuberculosis ..	189.8	Diphtheria ..	189.8*
		Others ..	664.1

* 1,111.1 per 100,000 for children under 5.

There were no deaths due to cholera or smallpox during the year under discussion. Diarrhoea and dysentery and enteric group of diseases are the commonest causes of death. These and malaria are also common causes of sickness as brought out by the following table giving morbidity rates:—

Morbidity rates per 100,000 population:—

Causes	All ages	Children under 5
Cholera	189.8	..
Typhoid	1,518.0	..
Pneumonia	284.6	..
Smallpox	284.6	..
Chickenpox	94.9	..
Dysentery and diarrhoea ..	1,043.6	..
Tuberculosis	284.6	..
Other respiratory diseases ..	94.9	..
Malaria	2,941.2	..
Ankylostomiasis	189.8	..
Diphtheria	284.6	1,666.7
Whooping cough	94.9	555.6
Measles	284.6	1,666.7
Others	4,838.7	..

The intestinal diseases are responsible for about 23.7 per cent of the morbidity figures. This high incidence is no doubt to be attributed to the unrestricted pollution of water sources especially *dobas* and to the absence of fly-control measures. The gravity of this problem is further brought out by the results of stool examination for hookworm ova by salt-floatation method in which out of 400 samples 233 were positive. The hookworm infestation was manifested equally by both sexes.

Though there were two cases of cholera and three of smallpox there were no deaths from these causes.

Health of the community

A general health examination was made and the individuals classified into four categories: (1) well, (2) acutely ill, (3) chronically ill, and (4) indifferent health. All persons whose state of health permitted them to carry on their normal duties efficiently were classified as 'well' while those who complained of vague ill-defined ailments which though not holding them back from their work yet interfered with the proper execution of it were classed as being in 'indifferent' health. The terms 'acutely ill' and 'chronically ill' were used in the accepted sense of the terms. The result of the examination showed that 87.6 per cent individuals were well, 0.4 per cent acutely ill, 0.8 per cent chronically ill and the rest 11.2 per cent in indifferent health. Both amongst males and females 88 per cent. were well. The percentages of persons classified as well, in the different age groups, are as follows:—

Age groups	Percentage well	Age groups	Percentage well
0-1 ..	77.1	20-40 ..	91.4
1-5 ..	85.6	40-60 ..	84.7
5-10 ..	91.1	60 and over	79.0
10-20 ..	88.8		

The above figures indicate that more than one-tenth of the community is either acutely ill or in

indifferent health at any given time, infants and old people being the worst sufferers.

Examination of the condition of the heart showed that in 96.5 per cent individuals the heart was normal whereas in 3.0 per cent there was functional disease and in 0.5 per cent organic disorder was present.

Examination of the lungs indicated that in 1.0 per cent individuals there was abnormality and these could be divided into three groups as follows:—

Abnormalities of lung	Frequency
	per cent
Congestion ..	0.4
Catarrh ..	0.3
Chronic disease ..	0.3

Examination of other organs revealed the following percentages of defects:—

Organs	Percentages found defective	Organs	Percentages found defective
Eye ..	19.9	Subcutaneous tissue.	13.0
Nose ..	19.3	Bones ..	0.5
Mouth ..	25.9	Lungs ..	1.0
Teeth ..	35.1	Circulatory system.	35.1
Throat ..	18.6	Abdomen ..	7.7
Ear ..	2.2	General ..	7.5
Hair ..	4.8		
Skin ..	28.6		

The organs in which the defects are commonest are teeth, circulatory system, skin and mouth. Defects in eye, throat and nose though less common are quite considerable.

The hæmoglobin percentage of the community as determined by Tallqvist method is below standard and almost all the circulatory defects are perhaps due to the anæmic state of the population.

Hæmoglobin percentage	Males	Females
	per cent	per cent
-50	2.2	2.6
-75	73.6	84.0
-100	24.2	13.4

The women are more anæmic than men. The cause of such widespread anæmia is not very clear especially in view of the fact that only 2.4 per cent of persons exhibited an enlarged spleen, while out of 897 persons examined for the presence of malarial parasite in the blood 0.1 per cent proved positive.

During the survey there were 28 pregnant women in the community. The table below

gives the number of pregnant women according to parity:—

Parity	Number	Parity	Number
1	4	6	2
2	5	7	2
3	5	8	1
4	4	9	1
5	4	10	1

Of the above 71.4 per cent were healthy, 7.1 per cent complained of pain, another 7.1 per cent complained of headache and the rest had minor complaints. In only 20 cases inclusive of the 4 primiparae could the risk to the mother and child be ascertained. Of these in 3 cases of multipara the risk to the mother was moderate while in one case each of the multipara was there 'moderate' and 'grave' risk to the infant. None of the pregnant women attended the clinic attached to the Health Unit at Singur. In nearly 60 per cent of the cases the women had not been visited by health visitors.

Early marriage amongst girls is common, though not the rule, as 39 per cent girls between 12 and 15 years are reported as unmarried. Since the median age at marriage of all the women in the village is about 11 years there is an indication that the age at marriage for girls is on the increase. There is usually a time lag between the age at marriage and age at cohabitation with the result that out of 269 married and widowed women in the village only 15 have had their first pregnancies before 14 years of age.

Due to lack of standards it is not possible to comment on the state of development of the infants. All the infants between 5 and 6 months were over 10 pounds in weight and one infant 9 months old was more than 20 pounds. The average heights at different months is given in the following table:—

Age in months	Average height in inches	Age in months	Average height in inches
0-	18.2	5-	22.5
1-	18.5	6-	20.8
2-	21.3	8-	25.3
3-	22.5	10-	26.3
4-	24.1		

Regarding dentition it may be mentioned that no infant below 8 months had any teeth erupted and of the infants above 8 months, 6 had not developed any tooth at all while the others had on an average 5 teeth. None of the infants had been weaned though some of them received solids even after the fifth month. Fresh milk and cereals are regularly supplemented to mother's milk after the sixth month. It is the exception rather than the rule for infants to get fruit juice and none is given egg, fish or meat.

The average weight of pre-schools between 1 and 2 years of age is 20.3 pounds for males

and 18.7 for females. The same for the age-group 2-5 years is 26.5 pounds for males and 24.0 for females. The heights in inches in the different age groups are:—

Age groups	Males	Females	Age groups	Males	Females
1-2	29.0	27.2	2-5	34.8	33.3

Of the 21 pre-schools aged between 2 years 6 months and 2 years 9 months, 18 had cut 20 teeth. All the pre-schools above 2 years and 9

milk obtained is sold to supplement the family income. The food of the villagers is very deficient in animal proteins. Vegetables are usually grown in the courtyards and used by the family. The villagers eat fish, though not regularly.

The general under-development of the community directs attention to the nutrition question. A diary method of nutritional survey of 100 families for four days gave the following figures *per capita* consumption: the standards used for comparison are based on the recommendations of the Food Committee, British Medical Association and the Technical Commission of the League of Nations:—

Essential food component	Per capita consumption per day	Per capita requirement per day	Adequate or not, if not by how much?
Animal protein	6.9 gm.	50.0 gm.	43.1 gm.
Vegetable protein	58.1 gm.	50.0 gm.	Adequate
Fat	31.6 gm.	50.0 gm.	68.4 gm.
Carbohydrate	598.3 gm.	425.0 gm.	Adequate
Calories	3,088.0 cal.	3,000.0 cal.	Adequate
Calcium	0.45 gm.	0.75 gm.	0.30 gm.
Phosphorus	1.96 gm.	1.00 gm.	Adequate
Iron	31.33 mgm.	10.00 mgm.	Adequate
Vitamin A	924.00 µg.	1,000.00 µg.	76.00 µg.
Vitamin B	2,390.00 µg.	900.00 µg.	Adequate
Vitamin C	157.00 mgm.	50.00 mgm.	Adequate

months had 20 teeth. It is surprising that 12.5 per cent children between 4 and 5 years and about 50.0 per cent children between 2 and 4 years have not been weaned. The strain on maternal health due to delayed weaning though considerable is not fully appreciated by the villagers.

The average weight and height for age groups greater than 5 years are given below separately for males and females:—

Age groups	WEIGHT IN POUNDS		HEIGHT IN INCHES	
	Males	Females	Males	Females
5-10 ..	38.1	38.9	42.4	43.6
10-12 ..	57.4	60.0	50.8	52.0
12-15 ..	66.2	66.7	54.3	54.2
15-20 ..	84.8	82.4	61.3	57.0
20-40 ..	102.8	90.4	62.6	57.7
40-60 ..	109.0	87.2	63.6	57.9
60 and over	90.9	84.6	62.7	57.0

The weights and heights had they been recorded for individual ages between 5 and 10 years would have provided a sensitive index to judge growth. Yet the table above shows clearly that the average weight is below par.

Nutritional state

Rice is the staple food of the population. Though each family has a cow, the bulk of the

The diet is deficient with regard to animal protein, fat, calcium, and to a slight extent in vitamin A. Considering the diet of the pre-school children only 5.3 per cent receive more than 10 ounces of milk per day, 8.3 per cent get fruit twice a week, 3.8 per cent get eggs twice a week and 1.5 per cent get meat twice a week. 74.3 per cent get cereals daily. No wonder that with such deficiencies in the important food elements intimately connected with growth, the community should be below par in physique.

Epidemiological factors

Under-nourishment may affect community health by lowering resistance to infection. Yet it is felt that even in the absence of facilities for immediate improvement of the economic condition and thus the nutrition status of the community, such communicable diseases as smallpox, typhoid and cholera can however be checked by control measures only. So a study of the epidemiological factors of the community with respect to such diseases merits attention.

The community being mostly agricultural, there is hardly any movement of the population from in and out of the village. An occasional visit to relatives may take the villager away just for a few days. Aggregation and dispersal of any magnitude takes place only on two days in a week when the villagers visit the bazar in Singur. Occasionally big *Jatras* are arranged locally which are attended by large groups of people from neighbouring villages. The population thus being practically closed, it should not

be so difficult to keep away communicable diseases.

As already stated intestinal diseases are the commonest cause of morbidity. The unclean habits of the community in the indiscriminate pollution of the surroundings, the absence of tube-wells within easy reach offering an inducement for the use of *doba* water for cooking, etc., no doubt are the major factors responsible for this. The fairly loose and always moist soil, the high temperature and humidity and the shade given by rank vegetation favour the development of the hookworm larvæ, which infest and undermine the general health of the community.

During the year under review, there have been cases of easily controllable communicable diseases as smallpox, cholera, and typhoid. This is undoubtedly a reflection on the state of artificial immunization against these diseases. No attempt at immunization against typhoid and cholera appears to have been made before the outbreak of these diseases. Even then the population protected is very small, being only 0.4 per cent for typhoid, the figure being still poorer for cholera. With regard to smallpox immunization figures are high as an intensive campaign for vaccination has been undertaken recently after the occurrence of two cases of smallpox. 95.2 per cent of the population have been vaccinated at least once, the percentage for males and for females being 94.6 per cent and 95.9 per cent respectively. Re-vaccination is less common, 40.1 per cent males and 29.6 per cent females being re-vaccinated. Vaccination amongst infants is fairly high; 17.9 per cent of infants under six months and 75.0 per cent infants over six months bearing marks of successful vaccination. In the age-groups 1-2 years and 2-5 years the percentages of vaccinated are 92.5 and 94.6. The table below gives the vaccination and re-vaccination results for different age groups by sexes :—

Age in years	PERCENTAGE VACCINATED		PERCENTAGE RE-VACCINATED	
	Males	Females	Males	Females
0-	44.4	38.1	7.4	4.8
1-	91.3	94.1	17.4	0.0
2-	90.6	100.0	15.1	15.4
5-	100.0	96.8	38.1	33.3
10-	97.3	100.0	46.0	42.9
12-	97.0	100.0	54.5	26.1
15-	95.8	95.7	58.3	28.3
20-	100.0	99.3	49.0	34.7
40-	94.9	100.0	41.6	35.8
60-	100.0	97.0	48.3	24.2

Malaria surveys

Before 1911 this area was free from malaria. Afterwards the disease spread into this area from the Burdwan side and the 1926 malaria survey revealed a fairly high spleen rate of 14.5.

The following figures of spleen rate for a few years show how fluctuating the values can be for different years :—

Year	Spleen rate	Year	Spleen rate
1930	16.6	1941	28.3
1940	33.3	1942	8.3

Past experience shows that the disease manifests itself in epidemic form once in about six years, one of the determining factors being heavy rainfall in the preceding year.

Results of survey.—Ninety-eight breeding places consisting of 4 tanks, 89 *dobas*, 1 pit and 4 irrigation channels were examined for larvæ. In all the 4 tanks, 3 channels and 36 *dobas*, larvæ were found; the species found being *A. vagus*, *A. hyrcanus*, *A. barbirostris*, *A. annularis*, *A. culicifacies*. The local carrier species, *A. philippinensis*, were not found in any of these breeding places.

Ninety-five places consisting of 53 cow-sheds and 42 houses were examined for the presence of adult anophelines. The species found and the number of each species caught are given below :—

Species	Number found	Species	Number found
<i>A. annularis</i> ..	205	<i>A. pallidus</i> ..	7
<i>A. hyrcanus</i> ..	14		
<i>A. vagus</i> ..	9	<i>A. barbirostris</i>	1

No adults of the local carrier species were found. Of the 302 children between 2 and 12 years examined, only 6 showed enlarged spleen, the average enlarged spleen being 8.8.

Judging from past history it is doubtful if the present malaria status will continue for long and to study the importance of the malaria problem at least one more survey during the malaria season is called for.

Socio-economic factors

Intimately connected with any effort at Public Health Organization is the question of finance and the extent to which a community can bear the expenditure on public health. Intermingled with the economic question and oftentimes acting as a drag on progress by its conservatism are the habits and mode of living of the community. As these factors have also to be taken into consideration in appreciating the epidemiological picture of a community, a brief discussion of the socio-economic factors at Ratanpur will now be made.

Except for a few cottage industries like net making for fishing and other purposes, agriculture is the mainstay of the population, the chief crop grown being paddy. Vegetable gardening is popular and helps to supplement the income from agriculture.

The villagers lead a hand to mouth existence and being mainly agricultural and so entirely dependent on the vagaries of nature for their very existence often run into debt. It was difficult to obtain from the villagers information on family earnings though they were very co-operative in supplying detailed monthly expenditure under various heads. As such it is difficult to assess exactly as to what proportion of families were able to run the household without running into debt.

The *per capita* monthly expenditure is Rs. 8.4 and this meagre amount can hardly provide anything more than the bare necessities of life like food and clothing.

Table below gives the percentage spent on the different items by families classified according to their monthly expenditure:—

Family expenditure in rupees (monthly)	Average monthly expenditure <i>per capita</i> (in rupees)	Food	Light and fuel	House rent and house tax	Clothing, bedding and foot-wear	Toilets	Furniture	Education	Medical advice and medicines	Travelling	Ceremonies	Debt discharge	Others
-20	6.7	78.8	5.2	1.2	7.0	0.9	0.0	0.4	1.6	0.8	0.8	3.2	0.1
-30	6.7	78.6	5.1	1.3	6.4	0.9	0.0	0.6	3.4	1.0	0.4	2.2	0.1
-40	8.9	79.1	4.8	1.1	6.7	0.7	0.0	0.3	2.5	1.5	0.5	2.7	0.1
-50	8.0	78.0	4.8	1.6	7.8	0.8	0.0	0.5	2.1	0.7	1.0	2.3	0.4
-75	8.0	79.1	4.3	1.5	7.1	0.5	0.1	0.6	1.6	1.4	1.5	1.8	0.5
-100	10.2	77.7	4.1	1.0	7.9	0.8	0.0	0.7	1.1	0.9	1.4	4.4	0.0
-150	9.2	75.0	5.2	3.0	6.8	0.8	0.4	0.4	3.0	1.0	1.6	2.2	0.6
-200	12.0	75.0	3.5	1.0	10.5	1.0	0.0	1.0	2.0	1.0	1.0	4.0	0.0
200+	12.4	81.0	1.0	1.0	10.0	3.0	0.0	1.0	1.0	1.0	1.0	0.0	0.0

The bulk of the expenditure is spent on food, clothing and house rent and house tax. On an average an individual spends about Re. -[3]- per month for private medical help.

Education

There is a lower primary school in the village with 90 students on its roll but the benefit derived from it is questionable. The condition of the school is deplorable, the thatched roof having nearly given way. This school has to be run from the grant given by the District Board and the fees from the students except for small donations, but it appears that the grant from the District Board has been very irregular for the last one year. The apathy of the paid teachers caused by such treatment is reflected in the efficiency of the school.

The percentage of literacy amongst males over 15 years of age is 52.5 and amongst females of the same age group it is 3.1, literacy being defined as the ability to read and write a letter.

Agriculture and animal husbandry

The population is mainly agricultural and as in other parts of India the methods used are those handed down for generations. There is no

central organization to supply the villagers with selected strains of paddy for cultivation or to educate them in such agricultural principles as the rotation of crops, etc.

Animal husbandry is non-existent. Any public agency which would help to introduce animal husbandry and pisciculture in the villages and thus improve the economic condition and the dietary of the population would be doing a very great service.

Communal activities : public health administration

Apart from the usual facilities of the Bengal Government, the village has the advantage of coming within the sphere of activity of the Singur Model Health Unit which is financed by the Government of Bengal and the International Health Division of the Rockefeller Foundation.

The *per capita* expenditure of the health unit is about Re. -[11]- per year and its activities include—(1) environmental sanitation, (2) public health education, (3) collection and checking of vital statistics, (4) maternity and child welfare services (domiciliary and clinical), (5) school medical inspection, (6) control of communicable diseases and (7) training of public health personnel.

Considering that only 2 out of 52 births during the past year were conducted by the midwives of the health unit, the benefit that the villagers derive from this organization is questionable. The ante-natal cases in the village are also not often contacted by the health visitors. This is mostly because the villagers have all along been strangers to trained service though they are slowly overcoming their shyness.

There is no medical unit in the village. The nearest hospital is at Singur where there is an indoor hospital with 14 beds, with separate accommodation for males and females. This curative organization and the health unit meant for preventive purposes are managed by two different bodies. Only by co-operation between these two organizations can the public health problem of the area be solved efficiently.

Very few social agencies are present in the village. The existence of a primary school though not in good condition has already been referred to. There are no co-operative societies or other social welfare organizations. Even recreational facilities are limited only to the religious side of life, there being one *Bhajan Mandir* in Ratanpur.

Recommendations to improve the welfare of the villagers

(1) Environmental sanitation should be improved. Not only are tube-wells needed but an agency to maintain them in good condition is a greater necessity. The expenditure for sinking and maintenance could be considerably reduced if the village labour is utilized. Only supervision would be needed and the sanitary inspectors of the Bengal Health Department could be trained for this purpose. Periodical bacteriological examination of water supply is also desirable. Provision of suitable latrines is an urgent necessity. For the latter object village labour should be utilized.

(2) Effective control of communicable diseases by disinfection, immunization and better facilities for notification and isolation of cases, should be attempted.

(3) All the persons infected with hookworm should be treated and restored to normal health.

(4) The villagers should be made more conscious of public health by propaganda and the measure of success obtained should be judged by the extent to which they enjoy the facilities

of the Rural Health Unit at Singur, especially for maternity and child welfare services.

(5) The economic condition and the dietary of the people should be improved at least by the introduction of pisciculture, if not of animal husbandry. It is fully realized that in their present economic position they cannot afford to embark on this scheme by themselves. Monetary assistance in the beginning of every year for at least a couple of years would be needed and the advance should be made by co-operative banks on condition that the money advanced with a nominal interest should be returned at the end of the season. One can safely assert that if the villagers find the occupation profitable there will be no more need for persuasion.

(6) Improved strains of paddy should be introduced and a scheme for the rotation of crops should be recommended. The impetus should come from public bodies.

(7) An efficient system for the collection and checking of vital statistics should be introduced and the villagers made to appreciate the utility of early reporting of the vital events.

(8) No amount of money spent or services done can leave a lasting effect if the villagers are not genuinely interested in public health activities. Their interest can be roused and kept up only by education. So no useful attempt at improving the welfare of the villagers can be made without trying to educate the children of to-day, who shall be the citizens of to-morrow.

Current Topics

To Defeat the Typhus-bearing Louse

(From the *Lancet*, Vol. II, 29th November, 1941, p. 688)

THE Ministry of Health puts us on our guard against the possible arrival of louse-borne typhus in this country, in company with refugees, prisoners of war and returning travellers. The body-louse and the head-louse are both probable vectors. Diagnosis depends on the sudden onset, high temperature, the appearance on the 4th or 5th day of a rash which spares the face, and a torpid or maniacal mental state. The Weil-Felix reaction can be obtained by the end of the first week and sometimes earlier. A strong reaction in a dilution of 1 in 80 or 1 in 100, obtained by a naked-eye reading, may be taken as positive, and during the later stages of the disease the titre rises to 1 in 1,000 or even higher. At the other end of the scale, any increase in the agglutinating power of the serum, established by examinations at 2-day intervals, is significant even at a titre of 1 in 50. A vaccine against infection is available but its value in the field has not been tried. It is to be used at present only by those working on typhus teams and is to be given in three doses of 1 c.cm. at weekly intervals. If typhus does reach this country it is most liable to break out in crowded areas. Several of the large cities have been asked to organize typhus teams, each of which is to include the medical officer, 4 nurses, 1 ambulance driver, 1 ambulance attendant and 1 or more sanitary

inspectors and trained disinfectors. The team should be duplicated so that absentees can be replaced.

Figure shows one-piece suit for use by hospital and ambulance personnel. It is closed by means of a Zipper behind, elastic round the wrists, and a tape round the face, tied under the chin.

All team members are to be provided with protective clothing consisting of a one-piece garment with a hood fastening down the back, preferably with a Zipper. A tape runs round the face aperture of the hood and ties under the chin, and tapes and elastic draw the

sleeves closely round the wrists. Gum-boots and long fabric gloves are also to be worn, and masks if desired. Protective clothing is absolutely necessary for members of the team, since any of them may come into contact with typhus-infected lice. During removal to hospital the patient should be enveloped in a large sheet, and should travel in a vehicle which is easy to free from lice. The staff engaged in admitting the patient to hospital are particularly exposed to danger, and the greatest care of all should be taken during this time. The patient must be admitted to a special bathroom, stripped, deloused and clad in hospital clothing before being taken to a ward set aside for the purpose. Delousing must include not only complete disinfection of the patient's clothing but careful delousing of his person, close cutting of the hair, shaving where necessary and careful bathing. He must be thoroughly soaped all over and cleansed in such a way that all lice are destroyed. In the hospital a room must be provided where the staff can change into protective clothing. After use the clothing must be left there for disinfection; the staff must pass next to a bathroom and finally to the room where their ordinary clothing is kept.

Officers with experience of typhus in the medical department of the Ministry of Health or in the L.C.C. will help to advise on diagnosis, and arrangements have been made for a mobile team from the American Red Cross—Harvard Field Hospital Unit—to give help in diagnosis and control in any part of England or Wales. Medical officers of health are advised to arrange for beds to be available in the larger isolation hospitals. The origin of infection must be carefully traced and all those who have been exposed to risk must be deloused and kept under observation for three weeks. Heavily infested people may have to be deloused a second time after an interval of ten days to ensure destruction of lice hatched from surviving eggs.

Scabies "the Itch"

(Summarized from a paper by P. A. BUXTON in the *British Medical Journal*, Vol. II, 20th September, 1941, p. 397)

THIS is a contagious disease caused by the presence on the skin of the itch mite *Sarcoptes scabiei* de Geer.

Ætiology.—All ages are susceptible to this disease and both sexes are equally affected. In peace time children are the worst sufferers. They get the infection from other children at school and then spread the disease to their families. Next to the children, people attending to the animals—horses, sheep, pigs and dogs—get the infection from the animals, and spread the disease through their families. The disease spreads rapidly in places where there is overcrowding. Amongst labourers and troops the disease is brought from families and spread amongst the fellow workers and troops.

***Sarcoptes scabiei*: Appearance.**—The female mite is about 0.390 mm. long and the male 0.225 mm. The general outline of the itch mite is oval: it is convex above and flat below and of dirty white colour. The adults and nymphs have four pairs of legs and the larvæ three pairs. The anus is terminal. The legs are short; in the female the first and second legs terminate in suckers (ambulacra), in the male there are similar suckers on the first, second and fourth legs. The male has large and elaborate genital organs lying on the ventral surface between the fourth pair of legs. Anatomically the mites attacking man, horse and the common pets are not to be distinguished.

Life cycle of the *Sarcoptes scabiei*.—Much of the life cycle is passed beneath the surface of the skin of the host. The adult female usually lives in the burrows made by the nymph, but removed from her burrow she is capable of burying herself again completely in a very brief period. Usually the burrows are made in the parts of the body where the skin is thin, for example the webs between the fingers, the flexor surfaces of the wrists, etc. Once beneath the skin the

mite rests if the body is cold and continues to excavate its burrow only if the skin is warm. It is when the mite is wandering on the skin that the itching is felt so it is worse in the night when the patient's body is warm under the cover of the blankets. Within 24 hours of maturing the female lays the first egg.

The duration of the successive stages from the hatching of the egg to the emergence of an adult female is as follows:—

Eggs—2½ days or more; larva—1½ to 3 days; nymph—1½ to 2½ days; immature female—2 to 4 days. The shortest period from the deposition of eggs to the emergence of adults may be just short of eight days. The larva quits the burrow of its parent in which it hatched from the egg and makes its own burrow. The nymph in its turn makes its own burrow. It is not known whether the males and the immature females make their own burrows or continue in that made by the nymph. The adult female does not normally move though she can start a fresh burrow if she is forcibly removed from her burrow.

The itch mite cannot survive long outside the skin burrow of the host and it seems probable that she lays rather more than two eggs daily to a total of about forty to fifty.

Hosts.—Mites similar to that of *S. scabiei* of man causing itching and mange occur on the horse, dog, sheep, rabbit and other animals. Anatomically these mites are not separable from one another and it is customary to speak of varieties such as *S. scabiei* var. *hominis* on man, var. *equi*, *canis*, *suis*, *ovis*, on the horse, dog, pig and sheep and so on.

Transmission.—There is no doubt that one human being is normally infected from another, the itch generally spreads through a family or a group of man living together. Scabies infection has also been traced to domestic animals such as horses, dogs, cats and rabbits. Its spread through the fomites has not been proved definitely, but for all practical purposes the fomites are recognized as a source of infection and should be treated as such.

The severity of the scabies acquired by man from animals differs greatly with circumstances. Mites derived from camels appear to be particularly irritating. Some of the cases of crusted scabies in man may be derived from animals.

Medical importance.—It is very important to detect scabies, segregate the patients and treat them effectively in order to stop further spread of the disease. In conditions of war its spread among labourers and troops should be prevented because it causes loss of time and impairment of efficiency in the men due to lack of sleep owing to the intense irritation at night. Its spread amongst school children is very rapid and causes a good deal of suffering.

Symptoms.—The cardinal symptom is the intense itching especially at night. The mites wander about in the night to make fresh burrows when the body surface is warm, that is when the patients cover themselves with blankets. In the tropics patients complain of itching both in the day and night but the irritation is always worse at night. The scabietic child looks pale, heavy-eyed and is irritable. Left untreated for some time the lesions become infected with secondary pyogenic organisms such as strepto- and staphylococci and an inflammatory condition supervenes. The hands, feet and buttocks become covered with painful pustules and there is often inflammation and fever. Nephritis is a frequent sequela due to a large skin surface being infected with streptococci.

Crusted scabies or Norwegian crusted scabies.—This is a distinct clinical condition with thick crusts and callosities on the various parts of the body, especially the limbs. The crusts which are stratified may project 2 to 3 mm. above the surface of the skin and consist of dead epithelium, dried exudate and enormous numbers of sarcoptes of all stages. Generally the condition requires at least a year for its development and when fully established gives the appearance of sarcoptic mange such as one sees in the dogs. The hands are more affected than other parts. The condition is very

rare. It is more common in lepers. Diverse views are held as to the cause of this condition. Many authors regard the disease as normal scabies which has been neglected perhaps because it occurs in insensitive lepers or in careless patients. The alternative view is that the mites in crusted scabies are derived from animals. From the reports on the mites from a crusted scabies in a Chinese leper it was clear that these mites differed in several important characters from the ordinary human variety. It may be that both the above views are correct.

Treatment.—A. The traditional treatment for scabies is the unguentum sulphuris B.P. 1 dr. to 1 oz. Its effectiveness is indisputable and it is very well suited for treatment in the outpatient department where large numbers of patients have to be dealt with economically and because of the simplicity of the method of application.

The patient is given a good wash with soap and warm water—the skin surface is scrubbed well with a hard brush or a rough flannel; the wash is given preferably towards evening. He is then given a quantity of the ointment sufficient to cover his whole day (about 3 ounces of ointment is required for one application for every adult); this he rubs in vigorously for twenty minutes to half an hour and then puts his clothes on and goes to bed.

This process is repeated for three consecutive nights and on the morning of the 5th day he gets a good bath and wears fresh clothes and the treatment is complete. His clothes and bed-sheets that he was using during the four days of treatment should be thoroughly sterilized by boiling.

This method of treatment though simple and efficient is not without some disadvantages, such as (1) The use of an ointment spread thickly over the body means that underclothing and bedding become soiled by the grease. (2) Greasy ointment combined with its pungent smell is objectionable to many people. (3) All the burrows must be opened by preliminary scrubbing otherwise the ointment cannot penetrate. (4) There is likelihood of sulphur dermatitis.

B. Sulphur soap method.

The application of sulphur incorporated in a soap has been used in America fairly extensively in recent times with good results. It is a cleaner method than the messy ointment and the actual quantity of sulphur used for each case being less than that in the ointment. It gives less chance of sulphur dermatitis and it helps the saving of sulphur.

The technique is as follows:—Sulphur in the strength of 18 per cent is mixed with a bland soap (in America soft soap is being used) and made up into tablets of 4 grammes each—which is the amount of soap required to cover the body with lather. (1) The patient is given a good hot bath and scrubbed well with a nail brush or harsh flannel. (2) Then the body is lathered all over with the soap, the foam being produced by rubbing the tablets between the nurses' wet hands. (3) The lather is allowed to dry. (4) Clean clothes put on. (5) This procedure is repeated on two successive days. (6) The clothes and bed-sheets are boiled. (7) If any irritation or excoriations are present unguentum zinci, B.P. or calamine ointment is given to apply for the next few days.

This method though quite effective and clean requires an intelligent person to carry out the instructions, which is not possible in a large outpatient clinic.

C. Benzyl benzoate emulsion.

This method of treatment is very well suited for mass treatment as in the army. The technique is as follows:—Each patient receives a hot bath and the body is well lathered with soap and scrubbed. When the skin is dry the whole body surface from the neck to the toes is covered with an emulsion containing equal parts of benzyl benzoate, soft soap and aethylated or rectified spirit (Proscabin-Bayer) applied with a brush. Parts badly affected receive a second painting immediately after the first has dried. The previously worn clothing is then put on. Bath and painting is given on the second day and clean

underwear used. The patient is advised to have the clothes and bed-sheets changed and disinfected. The crusted or pustular areas of secondary infection are treated with 1 per cent ammoniated mercury ointment after completion of the benzyl benzoate treatment. Each patient is examined after 4 days or 1 week and if necessary a second course of treatment is given, as above. This treatment requires the help of another man or a nurse and hence only suitable for inpatients in the hospital and for the army.

L. M. GHOSH.

Reviews

EXERCISES IN ELECTROCARDIOGRAPHIC INTERPRETATION.—By Louis N. Katz, A.B., M.D. 1941. Henry Kimpton, London. Pp. 222. Illustrated with 128 engravings containing 189 electrocardiograms. Price, 25s.

In this book the author has presented an outline of the manner in which to study and interpret an unknown electrocardiogram, and this has been followed by a series of 90 case records. The description and interpretation of each appears on the page opposite to the electrocardiogram and a brief clinical history and series of electrocardiograms taken at different intervals when necessary, are set forth, so that the reader may compare his own interpretation with the author's and correlate the clinical aspects of the cases with electrocardiographic patterns.

The interpretations are based on the teaching in the author's book on electrocardiography. The tracings are well chosen and represent a wide variety of cardiovascular disorders.

The book will be found very useful by the student of cardiology in that it will provide a guided practice in reading and interpreting electrocardiographic records.

P. C. S. G.

ELECTROCARDIOGRAPHY INCLUDING AN ATLAS OF ELECTROCARDIOGRAMS.—By Louis N. Katz, A.B., M.D. 1941. Henry Kimpton, London. Pp. 580. Illustrated with 402 engravings, including 806 electrocardiograms. Price, 45s.

It is almost a century since it was first observed that twitches of the rheoscopic frog-muscle preparation accompanied the contractions of the heart. Since then, there has been a gradual evolution in the methods of recording and interpreting these cardiac action currents, until the electrocardiogram came into clinical prominence. More recently, a new era has begun with the introduction and development of the clinical use of chest leads, and in the diagnosis and management of coronary disease.

Here is a comprehensive treatise on electrocardiography with an admirable presentation of the subject, emphasizing all its practical aspects along with enough theoretical background to facilitate an intelligent interpretation.

The book is divided into three sections. The first section deals with the theory of electrocardiography with brief accounts of galvanometers, available types of electrocardiographic machines, equipment and technique. In discussing the chest leads the author has presented the recommendations of the joint committee of the American Heart Association and the Cardiac Society of Great Britain and Ireland. Ordinarily, he prefers to take two chest leads CF₁ and CF₂, labelled '4' and '5' in the records for information not ordinarily demonstrable in limb leads. In discussing the place of electrocardiogram in clinical practice, the author says 'the electrocardiograph is not a tool for the unscrupulous or a plaything for the erudite, nor is it an instrument of precision which replaces the ordinary clinical examination. . . . It is as much of an

error to expect too much from this tool as to ignore the valuable information that it can give'.

The second section describes the normal electrocardiogram and the range of its variations. The normal U wave is considered in the present state of knowledge to be of unknown clinical significance. Table I is a very useful one depicting the characteristics of the normal electrocardiograms. This is followed by discussions on abnormal electrocardiograms which include the changes that occur during administration of drugs and in various diseases, acute or chronic. The changes due to coronary disease have been dealt with in detail.

Section three is devoted to systematic description of the electrocardiogram in the arrhythmias.

Each section is followed by an extensive bibliography. There are numerous excellent, well-chosen and explicit illustrations which, along with the legends beneath each, serve almost as an atlas on the subject. The book is of a high standard and the cardiologist will find it an invaluable aid in his practice.

R. C.

SURGERY OF THE HEART.—By E. S. J. King, M.D., M.S., D.Sc. (Melb.), F.R.C.S. (Eng.), F.R.A.C.S., Major, R.A.M.C. 1941. Edward Arnold and Company, London. Pp. xii plus 728. With 268 illustrations. Price, 50s.

THIS is a book of rare merit and is a timely publication. It may be included in the surgery of modern warfare.

The text is divided into two main sections, of which the first deals with the anatomy, histology and physiology of the heart with a brief review of electrocardiographic and radiological methods of investigation. The other section, dealing with the treatment of cardiac diseases, is divided into three parts: (i) general methods and principles of surgical approach, (ii) experimental work, and (iii) diseases and their treatment.

This monograph is based on the Jacksonian essay of the Royal College of Surgeons for the year 1938. Surgery of the heart is a very difficult subject but the author has succeeded in compiling a great work, which is assured of a ready welcome. No one will dispute the statement that the surgeon who would attempt the treatment of diseases of the heart must have the courage and optimism of the explorer and be equipped to justify their exploitation. The printing, get-up and illustrations are all excellent. The book is provided with a large bibliography and an adequate index, which will be greatly appreciated.

P. N. R.

THE PROBLEM OF TUMOURS—AN EXPERIMENTAL INVESTIGATION.—By J. C. Mottram, M.B. (Lond.). 1942. H. K. Lewis and Company, Limited, London. Pp. vii plus 91 with 9 tables and 33 illustrations. Price, 7s. 6d. (Paper boards).

PERHAPS no branch of scientific medicine is more perplexing and fascinating than the problem of tumours. At the same time the subject is extremely important because the number of fatalities and invalidism is enormous. Up to the present day the explanation for causation of tumour formation is a mystery; from time to time various theories were advanced but they all remained in the domain of conjectures.

In this small volume Dr. Mottram has put forth the observations as seen in the course of experimental investigations of tumour formation. He has observed the phenomenon of photo-dynamic activity of benzopyrene on paramecium and its power of increased cellular proliferation. This has opened a new field of investigation, viz, the factors that can cause increased cellular multiplication. The physico-chemical processes as described by the author are highly interesting and perhaps continued researches on this line might throw some light on the explanation of tumour formation. It is gradually becoming evident that the

medical biologists will have to look forward to the chemists and physicists for the solution of their problems. The experiments of Dr. Mottram will be keenly watched by the scientific world with great expectations.

Abstracts from Reports

ANNUAL REPORT FOR 1941 OF THE BENGAL BRANCH OF THE BRITISH EMPIRE LEPROSY RELIEF ASSOCIATION

WORK DONE

THE chief lines of work followed during the present year have been as follows:—

Leprosy survey.—In the past leprosy survey work has been of the nature of sample surveys and covering large areas in a limited time.

During recent months, attempts have been made to organize survey work of a more thorough nature in limited areas in such a way as to give accurate information. Such surveys have been carried out during the present year in the following districts: Tippera, Hooghly, Bankura, Malda, Rangpur and Birbhum. Work is now being done in Rajshahi.

Training of doctors.—Under the auspices of the Bengal Branch a special post-graduate course in leprosy lasting for eleven days and attended by 18 doctors deputed by the district authorities in Bengal was held in the Leprosy Department of the School of Tropical Medicine, Calcutta, under Dr. Lowe. Three short courses have been held by Dr. B. N. Ghosh, the leprosy officer, during this year, one in Midnapore and two in Rangpur. These three courses have been attended by 47 doctors. Other similar work has been planned in Rajshahi in December. Three days' instruction was also given for clinic assistants in one district.

Visits to clinics.—There are about 139 leprosy clinics in the districts of Bengal and visits from our staff help to maintain a reasonable standard of work in these clinics.

Detection of cases of leprosy in school children.—During the year, 10 teachers' training schools with 864 students and 41 other schools with 9,102 students have been visited, and the staff and students of these schools have been examined. During this work 44 cases of leprosy have been detected giving an incidence of approximately 0.44 per cent. Lectures on leprosy have been delivered in 23 of the schools visited.

Examination of the police.—At the request of the district authorities in two districts our staff examined the police force of these districts, the total number being 1,598. Among these, 39 cases of leprosy had been detected giving an incidence of 2.4 per cent. Practically all the cases detected, however, have been of very mild type which does not progress, is not infectious and causes no serious disability.

Leprosy in jails.—At the request of one district authority the jail prisoners were examined numbering 906. Among these 19 cases of leprosy were detected giving an incidence of 2.2 per cent, most of the cases being mild.

Propaganda work.—A complete new set of slides for popular lectures has been prepared and a lecture drafted to go with them. New models illustrating the main points about leprosy from the public health standpoint have been devised. New pamphlets on leprosy for use among general public and in schools have been prepared and are being produced in English, Hindi and Bengali. The work included lectures on leprosy, health exhibitions and a radio talk.

Arrangements have been made with the Director of Public Instruction and the Director of Public Health,

Bengal, for the development of leprosy propaganda in high schools throughout the province. The work done this year in schools has already been mentioned.

Study of leprosy in Calcutta.—It has been felt desirable to obtain more information about leprosy and the spread of leprosy in the general population of Calcutta. One of the assistant leprosy officers has therefore been deputed to study this problem. The findings of this work so far indicate that while leper beggars in Calcutta and neighbourhood may number 1,000, the number of cases in the general population is probably at least ten times this figure, that a considerable number of the cases are infectious, and that a considerable number of persons have acquired the disease in Calcutta.

Study of leprosy in women and children.—For the detection of cases in females—a woman assistant leprosy officer has been appointed under the Branch.

DISTRICT BRANCHES

The following local organizations in Bengal are affiliated to the provincial branch:—(1) Bankura district leprosy council, (2) 24-Parganas district branch, (3) Silda Peddie leper clinics (Belpahari, Midnapore district), and (4) Murshidabad district branch. There are other anti-leprosy organizations in Bengal and their affiliation to this Branch is being encouraged.

FINANCE

The audited accounts of receipts and payments for the year 1941 show that payments have exceeded receipts by about Rs. 2,300 and that the balance has been reduced from Rs. 16,684-12-3 to Rs. 14,382-9-0. Nevertheless the financial position of the branch remains sound; but if the work is to be continued on the present scale, additional income will be needed later.

REPORT OF THE WORKING OF THE PUNJAB MENTAL HOSPITAL, LAHORE, FOR THE YEAR 1941

Total population.—The year 1941 opened with 1,128 patients (902 men and 226 women) and closed with 1,169 (929 men and 240 women). The total number of patients treated in the hospital during the year under report was 1,416 as against 1,366 in 1940 and the daily average strength rose from 1,090.84 in 1940 to 1,143.43. It has been possible to reserve

accommodation up to 100 patients for military insanes belonging to this province.

Admissions and discharges.—The number of admissions and re-admissions was 252 (204 men and 48 women) and 36 (29 men and 7 women) respectively as against 289 (236 men and 53 women) and 42 (38 men and 4 women) in the preceding year. The total number of discharges was 195 (165 men and 30 women), viz, 89 cured, 59 improved, 29 not improved and 18 otherwise as against 117, 27, 42 and 21 respectively in the preceding year. The total number of deaths was 52 in 1941 as against 31 in the previous year. The percentage of deaths on the daily average strength and on admission was 4.54 and 4.51 as against 2.84 and 2.42 respectively in 1940.

Health of patients.—There was no outbreak of an epidemic nature and the general health of patients during the year under report was satisfactory. The chief treatment for mental disorders done in the hospital is with cardiazol, ammonium chloride, and sulphosin. These treatments were carried out with encouraging results. The occupational therapy such as agriculture, gardening, weaving, munj matting, etc., continues to be the main feature of treatment.

Of the total number of 288 admissions 155 were Hindus (122 men and 33 women), 114 Muslims (97 men and 17 women), 1 European, 10 Indian Christians (6 men and 4 women), and 8 others (7 men and 1 woman) as against 166 Hindus, 151 Muslims, 8 Indian Christians and 6 others in 1940.

The principal types of insanity among the patients treated in 1941 and 1940 are compared below:—

	1941	1940
(1) Manic depressive insanity ..	344	349
(2) Schizophrenia including dementia præcox ..	358	358
(3) Secondary dementia ..	136	143
(4) Mental deficiency ..	138	129
(5) Epilepsy and epileptic insanity ..	136	119
(6) Mania ..	95	67
(7) Paranoia and paranoid states ..	68	63
(8) Cannabis indica psychosis ..	51	50
(9) Melancholia ..	39	45

General.—The non-official visitors took keen interest in the welfare of the patients, especially Mrs. Bharucha whose name is worthy of special mention in this connection.

Correspondence

LOCAL CHEMOTHERAPY OF WOUNDS

SIR,—For the last six months I have been trying sulphanilamide locally, either in powder form or sometimes in the form of a 3 to 5 per cent ointment with sterile vaseline, mostly in dressing infected wounds with a fair amount of sloughs in them. I had a mind all along to assay properly the merits of topical application of sulphanilamide, *vis-à-vis* the acriflavine ointment dressing, in these cases. Of course, till very recently sulphanilamide in my hand could not prove to be the better substitute, though verily it was never a failure either.

Recently for about a month I have made a little alteration in its mode of use by adding cod-liver oil (pure) to my usual formula of its ointment, whereby now I find its bactericidal effect definitely enhanced in comparison with its previous result.

Lately, apart from suppurating wounds I have tried it with very encouraging results in a good many cases of impetigo contagiosa, pustular eczema, and some obstinate cases of paronychia that baffled practically all other methods of local treatment.

In all my cases treated so far, I have used only 'septanilam' brand of sulphanilamide in the following prescription:—

R Septanilam	grs. 20
Oil morrhua	drachms 2
Lanoline ad	1 ounce
<i>Fiat unguentum</i>

CHEMOTHERAPY IN BACILLARY DYSENTERY

SIR,—I read with interest Dr. D. Lapping's article on 'Chemotherapy in Bacillary Dysentery', in the last February copy.

I have had the chance of treating eleven cases of bacillary dysentery with Dagenan, with no mortality

and highly satisfactory results. Some cases were very toxæmic on admission. On the second day of treatment the patients generally felt better and rapid cure followed. The general line of treatment followed here is Dagenan 2 tablets, *i.d.*, for adult and children proportionately; with free alkaline *cum* glucose drink. Bael Sherbet in the early morning was supplied, as this is noted to turn the stools formed early. A dose or two of Dover's powder were needed for the bad cases.

THE ASSESSMENT OF VITAMIN NUTRITION

SIR,—In his article on 'The Assessment of Vitamin Nutrition' published in the *Indian Medical Gazette* of March 1922, Dr. N. C. Datta writes (line 10, p. 157, column 1), 'They found the daily excretion of most of the normal individuals whom they examined to lie between 150 to 240 mg. Westenbrink and Goudsmit (1938) are of opinion that individuals excreting over 100 mg. of vitamin B₁ are saturated with the vitamin' (*italics mine*).

I am surprised to read this statement and should be interested to learn the diet that these normal people consumed. So far as I know, no dietary in the world supplies such large amounts of vitamin B₁ and even the most liberal standard of the human requirements of this vitamin lies somewhere between 2 to 3 mg. Obviously, what is meant is international units and not milligrams in the above statement. But the error does not appear to be a misprint or a mere slip of pen, for, in column 2 line 20, we read, '... a value of 4.5 mg. per 100 c.cm. or less for human blood is considered to be significantly low' (*italics mine*).

Even at best, this is a careless statement and I should not have thus protested but for the fact that similar errors had also crept in Sir R. N. Chopra's article which appeared in the February number.

PANCHKUWA, AHMEDABAD,
28th April, 1942.

TRICHLORETHYLENE

SIR,—I am made to understand by medical colleague of mine that trichlorethylene is as useful if not more pleasant as tetrachlorethylene or carbon tetrachloride. But no suggestion of such drug is being seen in your editorial of March 1942.

I shall be pleased if you will kindly reply me whether 'trichlorethylene' is advocated in the latest edition of Manson-Bahr.

C. MATHAI.

KADAMANKULAM ESTATE,
MUNDAKAYAM P. O.,
S. INDIA,
18th April, 1942.

[Note.—Trichlorethylene is used in industry as a fat solvent and numerous cases of intoxication have been reported from workers exposed to the vapours of this compound. Cases of acute poisoning have been reported in men using trichlorethylene to remove grease from machinery.

Animal experiments with this compound have shown that it has very little action against hookworms (Wright, W. W., 1932, *Amer. Journ. Hyg.*, 16, 2, 325).

Probably this letter refers to the editorial of March 1941 in which hookworm infection was discussed, and not to that of March 1942 which was on industrial hygiene. Was our correspondent's mistake an inspired

one, because trichlorethylene appears to be more important from an industrial hygiene point of view than from an anthelmintic?

This drug is advocated in the last edition of Manson's Tropical Medicine.—EDITOR, I. M. G.]

KNOWLEDGE OF SEX

SIR,—The comments on the sociological importance of sexual knowledge of Indians by Lieut.-Colonel O. Berkeley-Hill, I.M.S. (Retd.), in his article 'A Case of Mild Hypopituitarism' appearing in March 1942 number of the *Indian Medical Gazette* have neither been based on facts nor fairly drawn. It appears obvious that the author has tabooed Indians unjustly.

Although he has not given out what is the importance of sexual knowledge but it is true that procreation is the chief object and that its natural instinct common to mankind, irrespective of colour, creed and climate. It is the primitive quality of mankind, none having monopoly over it, unaffected hitherto by any sort of influence from any quarter.

India's population, according to last several censuses, has shown continuous increase. In spite of anxiety of the author, Indians are not dissatisfied with their ideals of plain living and high thinking. Would it be too much to expect that authors will save the trouble of making needless comments on racial knowledge of sex when they can easily do without those.

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL G. H. MAHONY, I.M.S. (retired), is temporarily appointed as Civil Surgeon, Darjeeling, for a period of 1 year, with effect from the 3rd February, 1942.

His Excellency the Governor of Bengal is pleased to appoint Lieutenant-Colonel G. H. Mahony, I.M.S. (retired), Civil Surgeon, Darjeeling, as Honorary Surgeon to His Excellency at Darjeeling, with effect from the 3rd February, 1942.

On reversion to military duty of Lieutenant-Colonel V. R. Mirajkar, O.B.E., Professor of Surgery, and Principal, K. E. Medical College, Lahore, Lieutenant-Colonel S. N. Hayes, Professor of Midwifery, assumed collateral charge of the office of Principal of the College on the afternoon of the 15th April, 1942, and Lieutenant-Colonel A. S. Fry, Professor of Operative Surgery, assumed charge of the office of Professor of Surgery in addition to his own duties on the hour and date mentioned above.

On return from leave Major F. R. W. K. Allen resumed charge of the office of Civil Surgeon, Raipur.

INDIAN LAND FORCES

(Emergency Commissions)

The undermentioned Lieutenants (on probation) are confirmed in their rank, with effect from the dates specified:—

M. Alam. Dated 1st August, 1940.
S. K. Ghosh. Dated 2nd December, 1940.
A. R. Biswas. Dated 25th March, 1941.

B. K. Sheorey. Dated 23rd June, 1941.
The undermentioned appointments are made :—

To be Lieutenants

James Elliott Moncreiff Melville. Dated 29th November, 1941, with seniority from 29th November, 1940.

Hugh Rosborough Swanzy Harley. Dated 29th November, 1941, with seniority from 29th November, 1940.

Owen Clarke. Dated 20th December, 1941, with seniority from 20th December, 1940.

Duncan MacAulay. Dated 20th December, 1941, with seniority from 20th December, 1940.

Archibald James Sinclair. Dated 20th December, 1941, with seniority from 20th December, 1940.

Kenneth James Langlands Scott. Dated 20th December, 1941, with seniority from 20th December, 1940.

William Francis John Maxwell Thom. Dated 20th December, 1941, with seniority from 20th August, 1940.

George Edwin Spear. Dated 20th December, 1941, with seniority from 20th June, 1940.

Norman John McQueen. Dated 20th December, 1941, with seniority from 20th June, 1939.

Alastair Colon Mackenzie. Dated 20th December, 1941, with seniority from 20th June, 1940.

Danier Crawford Logan. Dated 20th December, 1941, with seniority from 20th June, 1940.

PROMOTIONS

Lieutenant-Colonel P. D. Chopra (now on military duty) has been advanced to the higher position of his rank, with effect from the 14th October, 1941.

Lieutenant-Colonel A. S. Fry, Professor of Operative Surgery, K. E. Medical College, Lahore, has been advanced to the higher position of his rank in the increased pay admissible, with effect from the 22nd November, 1941.

Captain F. V. Stonham has been promoted to the rank of Major, with effect from the 1st February, 1942.

INDIAN LAND FORCES

RETIREMENTS

Lieutenant-Colonel K. S. Thakur. Dated 2nd April, 1942.

Lieutenant-Colonel H. S. Anand. Professor of Physiology, K. E. Medical College, Lahore, who was

on military duty since 15th July, 1941, has been invalidated out of the service, with effect from the 13th February, 1942.

The following retirement, with gratuity, is permitted :—

INDIAN LAND FORCES

(Short Service Commission)

Captain C. Parkash. Dated 7th March, 1942.

Notes

CLINICAL EXPERIENCES WITH UREA SULPHAZIDE

We have received a copy of a brochure on *Clinical Experiences with Urea Sulphazide* by Union Drug Company, Limited.

It is a soluble azo-compound of the sulphanilamide group, in which sodium is replaced by urea.

The brochure is a collection of articles on the uses of the compound. Copies can be obtained free from Messrs. Union Drug Company, Limited, 285, Bow Bazar Street, Calcutta, by the members of the medical profession.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors *ask for them at the time of submitting their manuscripts*.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India; Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

INFLUENCE OF ANTI-ANAEMIC TREATMENT ON THE GASTRIC FUNCTION IN HOOKWORM DISEASE

By ROBERT HEILIG, M.D.

First Physician, Krishnarajendra Hospital, and Professor of Medicine, Medical College, University of Mysore
and

VISWESWAR, M.B., B.S.

Research Scholar, Medical College, University of Mysore

THE usual conception of the connection between anaemia and stomach function is that certain pathological conditions of the stomach cause anaemias. The inability of the stomach to form Castle's intrinsic factor which is necessary to build the anti-anaemic or anaemia-preventing factor from the extrinsic factor is one of the main mechanisms leading to pernicious anaemia. Deficiency of hydrochloric acid in the gastric juice is said to impair the utilization of the food iron, which is necessary to prevent the formation of normoblasts that are deficient in haemoglobin; in the absence of sufficient iron, hypochromic anaemias develop.

Which correlation exists the other way round? How is the stomach function influenced by changes in the blood condition? This question was touched on in one of the important investigations by Napier and Das Gupta (1935-37), which form in their totality a rich source of information. These authors examined the distribution of the different degrees of acidity among different kinds of anaemias and compared these findings with those in 'normal' Indians; but only in two cases was it possible to examine the influence of anti-anaemic treatment or of an improved blood condition on the stomach function. McRobert *et al.* (1940) performed similar investigations; they report that in four achlorhydric ancylostomiasis anaemias, free hydrochloric acid appeared after anti-anaemic treatment, whereas three other cases of the same kind remained achlorhydric; no figures of the gastric acidity are given regarding these cases. Finally, Napier, Das Gupta and Majumdar (1941) examined the gastric acidity of 28 cases of hookworm anaemia.

These papers supply valuable material for the comparison of the distribution of the various acidity levels in *untreated* hookworm anaemia with our cases; but in none of these investigations was the variation of the gastric function with the improving blood condition systematically followed up, so that practically nothing is known about the correlation between haemopoietic and stomach function in hookworm anaemia under anti-anaemic (iron) treatment.

The following working method was used to investigate this question in 51 hospital patients (43 men, 8 women) suffering

from hookworm anaemia; erythrocyte count, haemoglobin level (Sahli Haemometer, 'Amsco', U.S.A., 100 per cent = 15 g.) and gastric acidity with fractional test meal have been estimated on admission. From these 51 cases, 37 were selected for further investigation; the selection depended on the following points: the patient had to promise to stay at the hospital as long as required 'to kill his worms'; he had to be afebrile and clinically free from any other active disease; the haemoglobin content on admission had to be not more than 20 per cent (one case with Hb. 25 per cent was included). In these cases the same estimations (erythrocyte count, haemoglobin per cent and fractional meal with oatmeal gruel) have been performed simultaneously on admission and during anti-anaemic treatment at weekly intervals until a haemoglobin level of about 30 to 40 per cent (preferably 40 per cent) was attained; usually three to four weeks of treatment were needed to reach this haemoglobin level; only three patients out of this series left the hospital with a lower haemoglobin value. Then followed anthelmintic treatment. The anti-anaemic treatment uniformly consisted in iron medication (freshly prepared Blaud's pills, 90 grains per day); no other remedy was given and to avoid any external influence on the gastric function, the iron medication was stopped 36 hours before each test meal. Every sample of gastric juice, recovered before and in half-hourly intervals during the test meal, was unfiltered, titrated against $\frac{N}{10}$ NaOH with dimethylamidoazobenzol as indicator for the estimation of free HCl and phenolphthalein for the total acidity; whenever a sufficient quantity of gastric juice was evacuated, a simple and exact colorimetric method was applied to estimate the pH (Michaelis and Mueller, 1922).

The diet of the investigation cases was milk and bread during the first two weeks; later on, most of them were given, in addition, unpolished rice and buttermilk; a few of them also butter and eggs.

Among the 51 cases of hookworm anaemia examined on admission, 11 = 22 per cent are achlorhydric, 14 = 28 per cent hypochlorhydric (free HCl below 25), 13 = 25 per cent normochlorhydric (free HCl 25 to 45) and 13 = 25 per cent hyperchlorhydric (more than 45 free HCl); we do not calculate the percentage for male and female patients separately because the female group, containing eight patients, is too small to yield exact results.

The results of the examinations of the 17 followed-up patients are given in table I.

Calculating the distribution of acidity groups for the 37 investigation cases, 17 of which are reported in table I, we get the following results, taking the same group limits as for the total of 51 cases: achlorhydric 7 = 19 per cent, hypochlorhydric 10 = 27 per cent, normochlorhydric 11 = 30 per cent and hyperchlorhydric 9 = 24 per cent.

17	10	0/8	6/26	16	4/10	6/26	28	2/10	8/16	40	2/14	6/32

It was not determined whether the achlorhydrias are histamine refractory as this question is unimportant from the point of view of this investigation.

For the graphical presentation of the variations of the gastric function under anti-anæmic treatment with reference to the simultaneous blood condition, the investigated cases have been placed in three groups: achlorhydria (7 cases), hypochlorhydria (10 cases) and normo- plus hyperchlorhydria (20 cases). The curves are condensed from the test meal results of all the cases belonging to the same group; thus figure 1 (a) was traced by calculating the mean value of

acidity of the resting juice and of all the following samples, respectively, recovered during the fractional test meal on admission from the seven achlorhydric cases. Similarly figure 1 (b), (c), (d) and (e) are condensed from the fractional test meal curves of the same seven cases, after one, two, three and four weeks of anti-anæmic treatment. The broken horizontal line in each of these figures marks the hæmoglobin percentage average value of the same cases at the same stage of treatment at which the fractional test meal was examined.

Correspondingly, figure 2 (a) to (e) represent the condensed curves of free HCl and total

TABLE II.

acidity of the ten hypochlorhydric cases on admission and after one to four weeks of anti-anæmic treatment respectively; figure 3 (a) to (e) show the variations, week by week, in the normo- plus hyperchlorhydric group of 20 cases.

The figures in table I and the comparison of the charts belonging to one and the same group make it equally probable that the gastric function is independent of the improved blood condition. To make this point quite clear, we condensed the five charts of each group, which represents the mean values of the weekly fractional test meal, to one main curve for each of the three groups in the following way: from each of the 'week-curves' the mean value of the free and total acidity, respectively, was calculated; in such a manner we got one value for the free and one for the total acidity (for each of the three groups) on admission, one for each of them after one, two, three and four weeks

Fig. 4.—Achlorhydria.

Hæmoglobin % ————

of anti-anæmic treatment; the mean hæmoglobin values on admission and at the end of every week of treatment constitute the third curve (broken line) in the figures 4, 5, 6 which

permit an immediate comparison and evaluation of the correlation between blood condition and gastric acidity. The figures resulting for each group in this way of condensation are given in table II.

In the achlorhydric group, after four weeks of iron medication, the free HCl increases from 0 to 2, the total acidity from 6 to 10, whereas the hæmoglobin rises steeply from 14 to 39 per cent in the average of seven cases.

Anti-anæmic treatment of the same duration in the ten hypochlorhydric cases increased free HCl from 5 to 6, the total acidity remained constant at 15, the hæmoglobin content rose from 16 to 40.6 per cent.

The last group, which contains 20 normo- or hyperchlorhydric cases, shows under equal conditions of treatment, free HCl almost unchanged, varying only from 25 to 24, total acidity from 36 to 32; the hæmoglobin increased from 13 to 33.7 per cent.

Discussion

Before an evaluation of these results may be attempted, the distribution of the different groups of acidity among hookworm anæmias found in previous investigations,* has to be compared with that in our cases. Table III serves this purpose.

investigation cases separately, the normo-chlorhydrias are the strongest group (30 per cent), closely followed by hypochlorhydrias (27 per cent), at a greater distance by hyperchlorhydrias (24 per cent), and finally by the group of achlorhydrias (19 per cent). Our figures in the investigation group seem to be quite reliable (for Mysore) as they have been confirmed by all the following weekly examinations.

Napier and Das Gupta (1935-36) compared their Assam figures with those of 'normal' Indians from Bengal; they found almost the same mean HCl curve in women suffering from hookworm anæmia and in 'normal' females; the figures have been slightly lower for anæmic than for 'normal' men.

Due to the kindness of Dr. C. Srikantia, professor of chemistry, Messrs. S. Hiraniya, professor of physiology and L. Kantiengar, lecturer in chemistry, University Medical College, Mysore, we are able to compare the ratio of the various levels of acidity in hookworm anæmia in Mysore with that among 91 normal healthy Mysoreans (college students). In a personal communication these authors permitted us to use their figures. For easier comparison we put the results obtained in normal test subjects side by side with those of our hookworm

TABLE III

Comparison between the gastric acidity in hypochromic hookworm anæmia in different places.

* A wider range of normality adopted. † Figure of same range of normality as above is adopted.

Taking for a detailed comparison only the recent figures from Calcutta, one finds great differences between them and our results; whereas the hypofunction group (below 25 free HCl) of Napier *et al.* (1941) contains 26 per cent of the examined 28 cases, our corresponding group comprises 50 per cent of all examined and 46 per cent of the followed-up 37 cases; thus, in Calcutta the normo-hyperchlorhydric cases (74 per cent) are by far predominant, whereas in Mysore the border line of 25 free HCl divides into equal halves those below and those above it among 51 hookworm anæmias; taking the

anæmias. Though a difference between the gastric acidity of men and women is definite in the results of Srikantia, Hiraniya and Kantiengar (main free HCl in men only: 35.5, men + women : 32.1), we compare their total results with ours, for the reasons mentioned before.

The differences are striking; whereas the group between free HCl 20 and 49 contains 66.5 per cent of normal Mysoreans, it includes only 40 per cent of hookworm anæmias. Correspondingly only 22 per cent of the normal test subjects show free HCl below 20, but 42 per cent of hookworm anæmias are to be found in this group; still greater is the difference in the lowest range of acidity; 4.3 per cent of normal persons against 28 per cent of hookworm anæmias have free HCl values below 9. The normal figures of Srikantia

* The figures of McRobert *et al.* (1940) cannot be used for comparison because these authors include all kinds of anæmias in their 100 cases and remark regarding hookworm anæmias only, that among 77 cases 27 = 35 per cent have been achlorhydric.

TABLE IV

Comparison between the gastric acidity of 91 healthy college students and 51 hookworm anæmias in Mysore.

Free HCl	NORMAL		HOOKWORM ANÆMIA	
	Cases	Per cent	Cases	Per cent

10-19	16	17.6	7	14
20-29	28	30.8	6	12
30-39	13	14.3	5	10
40-49	18	20	9	18
50-59	10	11	5	9
> 60	2	2	5	9

et al. show more similarity with those found by Napier *et al.* (1941) among hookworm anæmia in Calcutta, than with our own results. However, the comparison of these two local groups proves that in hookworm anæmia a far higher percentage of low acidity is to be found than among the healthy population.*

Whether it is the anæmia or the hookworm infestation which is responsible for the gastric underfunction in a percentage twice as high as among normal persons is under investigation. But what can be stated definitely at present is that the improvement of the blood condition has practically no influence on the stomach function; the quantity of free HCl which appears in the achlorhydric and the increase of free HCl in the hypochlorhydric cases after four to five weeks of highly successful anti-anæmic treatment is so small that it does not change the efficiency of gastric function at all; equally the variations in the normo- *plus* hyperchlorhydric group are of no real importance for the digestive power. Similar facts are known regarding pernicious anæmia and 'idiopathic hypochromic anæmia'; the changes in the gastric function are irreversible in both these conditions, just as in hookworm anæmia (without deworming).

Another fact which becomes evident from our results is the independence of blood condition and blood improvement in hookworm anæmia from the gastric acidity. The average value of hæmoglobin on admission was the lowest in the normo- *plus* hyperacidity group (figure 3), 13.2 per cent against 16 per cent in the hypochlorhydric and 14 per cent in the achlorhydric patients. These differences might be accidental, except that the mean value of hæmoglobin reached after four weeks of iron medication was again the lowest in the normo- *plus* hyperchlorhydric group (33.7 per cent against 40.6 per cent and 39 per cent, respectively) proves beyond doubt that neither the

free HCl production nor the pH of the gastric juice are deciding factors for the utilization of inorganic iron; in fact the absolute increase of the hæmoglobin level in the average of the three groups was the highest in the achlorhydric group, namely 25 per cent, about the same—24.6 per cent in the hypochlorhydric, and only 20.5 per cent in the normo- *plus* hyperchlorhydric hookworm anæmias; consequently more patients in the last group needed longer anti-anæmic treatment than the usual three to four weeks in preparation for deworming than in both the other groups.

Conclusion

Among 51 hookworm anæmias in Mysore the percentage of those with a gastric acidity below 20 free HCl is twice as high (42 per cent) as among 91 healthy normal Mysoreans (22 per cent).

The blood condition of 37 hookworm anæmias was greatly improved by iron medication without deworming; the simultaneous variations in the gastric function have been negligible; none of the groups—achlor-, hypo-, normo-, nor hyperchlorhydrias showed any definite change of the acidity values before and after anti-anæmic treatment.

The improvement of the blood condition proceeded independent of the gastric acidity; it was achieved more quickly and more extensively in achlorhydric than in normo- *plus* hyperchlorhydric patients.

Summary

The gastric acidity of 51 patients suffering from hookworm anæmia was estimated. Their gastric function was compared with that of normal Mysoreans.

Thirty-seven of these patients have been investigated before and during anti-anæmic treatment; erythrocyte count, hæmoglobin content and fractional test meal have been examined at weekly intervals. The results are reported.

The influence of blood improvement on gastric acidity is presented in curves and tables.

The influence of gastric function on blood condition, blood improvement and iron utilization is discussed.

Our thanks are due to Dr. C. Srikantia, Messrs. S. Hiraniya and L. Kantiengar for their kind permission to use their results, personally communicated to us, before their own publication.

REPORT OF A CASE AND AN ANALYSIS OF TWENTY-TWO CASES OF BRONCHO- GENIC CARCINOMATA*

By M. V. BHAJEKAR, M.A., M.B., B.Ch. (Oxon.), F.R.C.S.E.
Honorary Assistant Surgeon, Sir J. J. Hospital, and
Ear, Nose and Throat Surgeon, K. B. Haji Bachoo Ali
Free Ophthalmic Hospital, Bombay

THE following case came to the out-door department of Sir J. J. Hospital and was subsequently under my care in the wards of the hospital. It was diagnosed tentatively as 'sarcoma of the scalp', but at the *post-mortem* examination it was discovered to be a secondary deposit from a carcinoma of the left bronchus.

A Hindu male, aged 35 years, reported at the out-door department of Sir J. J. Hospital, complaining of a swelling on the back of his head. He stated that five months ago, *i.e.*, in January 1938, he noticed a small nodular swelling in the occipital region. At that time it was painless and so he did not pay any attention to it, but during the two following months the nodule had grown in size and had become slightly painful. He therefore went to a hakim and had the tumour cut by him—some time in February 1938. As a result of this treatment, the nodule instead of subsiding began to grow with greater vigour, until it had attained its present size. During these past three months, while it had been growing in size, it had become ulcerated in places and painful, and had begun to discharge what the patient described as pus and serum. The patient had been suffering from cough and fever for the last one month only.

Examination.—There is a large swelling on the back of the head occupying the whole of the occipital and part of the parietal regions on both sides (figure 1). Approximately, the size of the tumour is 8 inches by 8 inches and it is raised for about 4 inches above the surface of the head. The surface of the tumour is nodular over its greater extent and in this area the growth is raw-looking and ulcerated in places. The ulcerated surface is discharging pus and sero-purulent material, and blood is seen to ooze out of a few of the ulcerated spots. In some places the area shows adherent sloughs. On more detailed examination each nodule appears to be studded on its exposed surface with coarse large granulations. The remaining part of the growth is covered with scalp which is normal in some places and undermined in others. In this region a few dilated veins can be seen.

On palpation, the feel of the growth varies in different parts. In some places, it is firm while in the area immediately surrounding the raw-looking nodular surface it is fluctuating, especially in both the parietal regions. The ulcerated and raw-looking surface is friable. The whole growth has a superficial mobility and gives the impression that it is adherent to the underlying bone. There are no palpable lymph nodes.

(1941).

Clinical examination of the lungs.—No impaired note on percussion, no bronchial breathing, but râles and rhonchi are present as adventitious sounds. Liver and spleen are not enlarged. The general condition of the patient is emaciated and toxic-looking. The patient was admitted for further investigation.

Clinical diagnosis.—Fungating sarcoma of the scalp. Under local anaesthesia a biopsy was performed. There was smart bleeding from the cut edge of the tumour which was checked by diathermy coagulation and firm pressure. **Report of tissue examination:**—'Loose texture, abundant lymph spaces, few epithelial

Fig. 1.

pearls. The greater bulk is connective tissue malignant tumour'.

Other investigations:—

Wassermann reaction—Negative.

Urine examination—

Albumin present.

Bence-Jones proteins absent.

Pus cells and red cells present.

Blood examination—

Red cells 2,400,000 per c.mm.

Leucocytes 6,000 " "

Differential count—

Polymorphonuclears 76 per cent.

Lymphocytes 18 " "

Eosinophils 3 " "

X-ray photographs—

(a) Skull—Malignant tumour eroding posterior part of skull (figure 2).

(b) Lungs—'Secondaries ribs and lungs'.

From the time of his admission, his general condition gradually grew worse every day, and in view of his general condition and the x-ray findings it was decided that the neoplasm had advanced too far to institute any curative or even palliative line of treatment. His pain and other discomforts were relieved with morphia. The patient died on 20th June, 1938.

Post-mortem report.—The body is that of a male aged about 45 years, considerably emaciated. There is a growth in the occipital region

about the size of an orange, ulcerated on the surface, nodular, and having a raw appearance. On opening the skull the growth is seen to have destroyed a greater part of the occipital bone below the occipital prominence, and to have pressed inwards the dura underlying this part.

Right lung—shows a few sub-pleural cellular nodules. Compensatory emphysema is seen at the margins of both lungs, but more prominent in the right lung.

Left lung—shows two abscess cavities one below the other at the apical region. The walls of the cavities are irregular and the contents muco-purulent. Near the hilum one of the bronchi shows infiltration, blocking its lumen.

Fig. 2.

Liver—shows a large growth at the right lobe, the size of a cricket ball. The growth is cellular with yellowish streaking along its surface. Two other small nodules are seen in the lower portion.

Left kidney—shows an irregular cellular growth on its convex margin about the middle, snow white in colour.

Right suprarenal—shows a nodule at its apex.

Stomach.—Normal.

Spleen.—Not enlarged, capsule thickened at places, and shows a calcified plaque in the capsule.

Other organs.—Normal.

Histological report of sections from post-mortem tissues

Three sections of lungs.—Two sections of the wall of the suspected tuberculous cavities show exuberant granulation tissue. No tumour cells detected. There is an exuberant growth of epithelioid tissue as well as tuberculous bronchopneumonia, with areas of caseation.

The third section shows sheets of large round or oval cells, irregular in shape, as well as narrower strands of the same situated more proximally, while there is an adenomatous proliferation of the same cells more distally. No evidence of tubercle.

On section of lymph gland (mediastinal, with bronchial cartilage and mucous glands).—One gland shows caseating tubercle while another shows marked congestion and hæmorrhage and partial disorganization of the architecture. No metastatic deposits.

One section of liver.—It shows secondary deposits: irregular sheets and strands. The pattern of the proliferation is not adenomatous.

One section of suprarenal.—More of adenomatous proliferation, less of irregular strands and sheets.

Earlier cases

A detailed study of the above case prompted me to look into the past records of the pathology department, Sir J. J. Hospital, of cases of tumours, particularly bronchogenic carcinomata, arising primarily in the thoracic cavity. By this is meant to include only those tumours which arise from the intra-thoracic respiratory organs and other tissues, excluding however the œsophagus, cardiac end of the stomach, heart and the pericardium.

The total number of cases is thirty, from the year 1886 to December 1938. Prior to 1886 there is a record of only one case mentioned in the catalogue of 1879 which runs as follows: 'Scirrhus tumour surrounding the lower end of the trachea and the commencement of the bronchi. The patient suffered from urgent dyspnoea and died of asphyxia'.

Histological sections cannot be traced of any of the cases that occurred between 1886 to 1908, nor is the material available for making fresh microscopic preparations. The information about these cases which number eleven is therefore obtained from recorded notes only. From 1908 to 1925 no case of intra-thoracic tumour is found in the *post-mortem* records of this period.

Out of the thirty cases, twenty-two are carcinomata, six are sarcomata, one is a hæmangioma of the pleura, and one gumma. For purposes of analysis all cases other than those of carcinoma are omitted, and the twenty-two cases of carcinoma which are analysed have apparently all arisen primarily from intra-thoracic portion of the respiratory tract—bronchogenic carcinomata.

It is fully realized that the number of cases is too small to draw any far-reaching conclusions; also in addition the recording of some of the cases is very incomplete. The total number of thirty cases is divided into the following three chronological groups:—

	Number of cases	Carcinomata
1. From 1886 to 1908 ..	12	9
2. From 1926 to 1937 ..	14	10
3. From Jan. to Dec. 1938	4	3
	—	—
TOTAL ..	30	22

Group I. 1886 to 1908

	Date	Sex	Age	Clinical history	Right lung	Left lung	Liver	Kidney	Bone or brain	Glands
(1)	11-9-1886	M.	48	Cough, pain in the abdomen, right lumbar and iliac regions. Attacks of hæmoptysis occasionally 2 months ago. Enlarged liver and swelling of ribs.	Lower half broken down and upper consolidated.	Infiltrated with growth.	Several large tumour masses.	Lumbar; growth in small intestine near ileocolic valve.
(2)	20-2-1887	M.	30	Sudden loss of power of right side.	Multiple nodules.	Multiple nodules.	..	Multiple nodules.	Multiple nodules in brain.	..
(3)	29-4-1892	M.	35	Painful swelling of the neck for five months and troublesome cough.	Two nodules.	Bronchial.
(4)	1-2-1898	M.	30	Clinical history not available.	..	Solid. Covered with pleurisy. Infiltrating nodules in base. Left bronchus stenosed.	Several nodules.	Posterior mediastinal.
(5)	31-3-1901	M.	50	Complaint of hæmoptysis.	Growth	Growth	..	Growth one kidney.	..	Gland in neck.
(6)	8-4-1905	M.	50	Fever, cough, pain behind the sternum and hepatic region. Sudden attack of paralysis.	Base	Left hemisphere just above Sylvian fissure.	At bifurcation of trachea and mesenteric.
(7)	28-6-1905	M.	40	Clinical history not available.	..	Bronchus	Nodule	Nodule in one kidney.	Spine and skull.	..
(8)	17-7-1908	M.	30	Clinical history not available.	Apex	Posterior mediastinal.
(9)	13-11-1908	M.	30	Cough and fever, pain and dullness in the chest.	Root of lung.

Group II. 1926 to 1937

(1)	12-2-1926	M.	30	Ill for 3 years. Pain left lumbar region for 1 year. Lump in left kidney region. Pain in chest 3 years. Sinus in region of left 4th rib. Dullness on left side of chest. Clinical diagnosis of primary lung tumour and secondary in the left kidney.	Right pleural sac.	Left pleural sac and pericardium, bronchus.	Nodule	Nodules in both kidneys.	..	Pelvic peritoneum.
(2)	20-6-1927	M.	37	Gradual dysphagia for 2 months. Hoarseness of voice, fœtid breath and sputum. No physical signs of aneurysm. X-ray shows shadow pressing on the œsophagus.	A lump between the œsophagus and trachea and at the bifurcation of the trachea.
(3)	6-10-1930	M.	50	Cough with muco-purulent expectoration. Loss of power of right half of the face.	Right lung	Surface of cerebellum.	..

Group II. 1926 to 1937—concl.

	Date	Sex	Age	Clinical history	Right lung	Left lung	Liver	Kidney	Bone or brain	Glands
(4)	29-12-1933	M.	50	Frequency of stools for 3 months. No blood or mucus. Pain in right hip; sprain 3 months ago. Marked wasting of gluteal muscles. Hip movements possible but painful. Thickening of ileum and greater trochanter. Clinical diagnosis Ewing's tumour.	New growth in bronchus extending from hilum into the right lung.	Ribs, vertebrae, skull and iliac bones.	..
(5)	24-1-1934	M.	35	Multiple sinuses in both groins. Difficulty in micturition. Prepuce and glans penis sloughed off.	..	Lung and bronchus. Bronchiectasis.	Glands both sides.
(6)	20-3-1935	M.	60	Severe pain in chest for 3 months.	Hilum tubercle infection.	Brain and meninges.	..
(7)	28-9-1935	M.	45	Clinical history not available.	Nodule in bronchus.	..	Many nodules.	Bronchial lymph glands.
(8)	12-6-1936	M.	18	Frequent stools 3 months. Macular syphilis 3 months.	..	Soft fleshy lump.
(9)	21-4-1937	M.	45	Unconscious with convulsions. Right sided hemiplegia, no conjunctival reflex, pupils react sluggishly.	Bronchus	Bronchus	Multiple nodules.	..	Skull and brain.	Large lump on left side of neck.
(10)	29-6-1937	M.	48	Pain all over for 2 months. Tubular breathing left side; interspaces sunken, clubbing of fingers.	..	Near the base.

Group III. 1938

(1)	23-4-1938	M.	45	Irregular fever 1 month. Cough. Pain in the chest when coughing. Diminished movements left side. Blood stained sputum. Vocal resonance diminished.	..	Infiltrated, also bronchus.	Nodule	Nodule in left kidney.	Brain	Glands near the head of the pancreas.
(2)	20-6-1938	M.	35	Cough with expectoration. Pain in chest both sides. Low fever for 5 months. Cough is unceasing.	Bronchus and pleura and tuberculous infection.	Brain	Bronchial glands.
(3)	31-6-1938	M.	35	Fungating growth scalp, occipital region. Cough and fever 1 month. Clinical diagnosis—sarcoma scalp. X-ray—eroded skull and secondaries in lungs.	..	Left bronchus and tuberculous infection.	Large mass.	Nodule and in supra-renal.	Skull	Bronchial glands.

Analysis

1. All the twenty-two cases occurred in males.

2. Clinical history is available in eighteen cases out of which thirteen cases, i.e., about 72 per cent, manifested signs or symptoms or both

which could be definitely referred to an intrathoracic disease; and out of these again 66.6 per cent complained of cough.

3. As regards the age incidence, 50 per cent of cases in this series occurred between the ages of 30 to 40 years and 40.9 per cent between the

ages of 40 to 50 years. In the series published by Brines and Kenning (1937) only 14.8 per cent occurred between the ages of 30 to 40 years and 26.4 per cent between the ages of 40 to 50 years. In the series published by Frissell and Knox (1937) only 10.8 per cent and 13 per cent occurred between the ages of 30 to 40 years and 40 to 50 years respectively. On taking the age period of 30 to 50 years in the writer's series 91 per cent of cases occurred in this age period.

4. In this series the right side appears to be more commonly affected than the left—54.5 per cent and 45.5 per cent. In statistics of 3,735 cases published by Fischer, 53 per cent occurred on the right side and 45 per cent on the left side.

5. As regards metastases in this series 77.2 per cent of cases had secondary deposits in one or more parts of the body. In the series published by Fischer, 80 per cent of cases had secondary deposits.

6. Of all the places in the body as sites of secondary deposits, the liver is found to be the commonest—36.3 per cent of cases, the next common site being the brain 31.8 per cent; and out of those cases which had secondary deposits in the brain more than 50 per cent exhibited signs referable to central nervous lesion.

7. Bones in themselves do not appear to be common as sites of secondary deposits, but out of all the bones, skull bones are those which are most commonly affected—in every case in this series whenever there were secondary deposits in the bones.

8. Association of tuberculous infection is found to be present in three cases.

Pathological and histological comments

Of the twelve cases—of intra-thoracic tumours—recorded from 1886 to 1908, three are sarcomata and the remaining nine are bronchogenic carcinomata, as judged from the study of recorded notes. One of these nine cases is histologically diagnosed as 'alveolar sarcoma'.

Of the eighteen cases recorded from 1926 to 1938, five are non-epithelial in origin: one a cavernous hæmangioma of the pleura, another a lympho-sarcoma of the mediastinal glands, two others are spindle-celled sarcomata of the lung, and one a sarcoma of the ribs. The remaining thirteen are carcinomata of the lungs, eleven hilar, one apical and one peripheral—all bronchogenic in origin, except the last which has a texture of an adenocarcinoma of the lung parenchyma. Of the eleven hilar, two are columnar-celled adenocarcinomata, one a columnar-celled carcinoma, one a mixed spheroidal and columnar-celled type with few areas of adenomatous texture; three are stratified squamous epithelial in type, and about the remaining two the cell type cannot be clearly determined. The apical one is a spheroidal cell carcinoma and the peripheral one an adeno-carcinoma. The associated tumour of the penis in one of these cases is a squamous-celled

carcinoma with secondary deposits in the inguinal glands on both sides.

Metastatic deposits recorded in the nine cases are seen to have bred true in all but one case—the one which was sent to the pathologist as a biopsy piece with a clinical diagnosis of a primary sarcoma of the scalp—the case described in detail at the beginning of this paper. This showed extreme differentiation, exhibiting the morphology of a rapidly-growing connective tissue spindle-celled mass with stray epithelial pearls. The growth later turned out to be a secondary deposit from a spheroidal and columnar-celled bronchogenic carcinoma with adenomatous proliferation in places. The epithelial pearls were apparently of local origin.

The association of tuberculous infection in three of these cases is verified.

Donald Owen, T. H. Hewer and P. H. Whitker draw attention to a statement made by Geschicter and Denison that bronchogenic carcinomata can be rigidly divided into two classes: (1) those arising at the hilum which are squamous, basal-cell or oat-cell in type; and (2) those arising at the periphery of the lung which are adeno-columnar, adeno-mucoid, or adeno-cubical. Their study of twenty cases of hilar carcinomata does not warrant such a clear-cut finding. The analysis of the above thirteen cases lends support to their contention.

Analysis in percentages.—Total number of cases 22.

	Per cent.
1. Right side involvement in 12 cases	.. 54.5
2. Left side involvement in 10 cases	.. 45.5
3. Both sides involved in 4 cases	.. 18.1
4. Secondary deposits in the liver in 8 cases	36.3
5. Secondary deposits in the brain in 7 cases	31.8
6. Secondary deposits in the kidney in 6 cases	27.2
7. Secondary deposits in the bones in 4 cases	18.1
8. Secondary deposits in the pleura in 1 case	4.5
9. Secondary deposits in the peritoneum in 1 case	4.5
10. Secondary deposits in the intestines in 1 case	.. 4.5

It is noteworthy that regarding secondary deposits in the bones, skull bones are involved in all the four cases, in some cases in addition to other bones.

Conclusions

1. The disease occurs in males.
2. The highest age incidence is between 30 to 50 years.
3. A large number of cases manifest signs or symptoms referable to an intra-thoracic lesion of which cough is the most prominent symptom.
4. A very large number of cases give rise to secondary deposits of which the commonest site is the liver, the next common site being the brain.
5. When secondary deposits occur in the bones, skull bones are the sites of choice.
6. The right side is slightly more commonly affected than the left.

AN ANALYSIS OF 356 CASES OF ENTERIC FEVER TREATED IN THE KING EDWARD MEMORIAL HOSPITAL, SECUNDERABAD, DECCAN

By RAO SAHIB T. D. RAJOO

Civil Surgeon and Assistant Medical Officer,
King. Edward Memorial Hospital, Secunderabad,
Deccan

THOUGH enteric fever is prevalent in Secunderabad every year and continues throughout the year, it broke out in an epidemic form about the end of August last year, and during its two months' virulence it carried away a good many young adults. The rush to the K. E. M. Hospital, Secunderabad, at that time was so great that a wing of the surgical section was utilized to accommodate the enteric cases.

The total number of cases treated was 356, out of which 284 were cured and 72 died, which included 19 cases admitted moribund and died within 24 hours and 6 cases within 72 hours.

The method of examination

As a routine all patients admitted for fever are examined for malaria and blood taken for

(Continued from previous page)

Summary

1. One case of bronchogenic carcinoma which had come under the writer's personal observation is described in detail.
2. All the records available in the pathology department of Sir J. J. Hospital of cases of bronchogenic carcinomata are reviewed.
3. The twenty-two cases are divided into three chronological groups.
4. All cases are analysed in a table and regarding some points a comparative view is given.
5. Conclusions arrived at from a study of these cases are given.

Acknowledgments

I must thank Prof. P. V. Gharpure for giving me facilities and all the necessary help during the search of these records. I am indebted to Dr. J. L. Saldhana, assistant professor of pathology, who has entirely written the histological section of this paper. I have also to thank the radiologist and the hospital artist for supplying copies of the radiograms and photographs. I must also thank the Superintendent, Sir J. J. group of hospitals, for allowing me to publish the case records.

General management

Absolute rest in bed, position is changed at frequent intervals, regulation of diet and careful nursing to prevent complications. Symptoms are treated as they arise. The temperature and pulse are charted four hourly. If the temperature rises above 103.5°F. the patient is given cold sponging and ice applied to the head. The body is sponged once daily. Special attention is paid to the skin, the back and pressure points being treated with spirit and powder twice daily.

The diet aimed at in this hospital is one consisting of *not less* than 2,500 calories. The patient gets 3 pints of buffalo milk, one pint coffee, one pint tea, two ounces glucose, two ounces sugar, eight ounces soup and juice of two lemons. Patients are allowed to supplement their hospital diet with one ounce of honey, one ounce cream, juice of six oranges or sweet limes, eight ounces of buttermilk and plain milk chocolate. Paying ward patients get in addition cream-soup, Chivers jelly and custard. Between feeds patients are encouraged to drink plenty of water. Those who can afford it are given in addition pure vitamin C in tablet form and some proprietary preparations containing vitamins A, B and D in liquid form. Solid food is allowed after the temperature has been normal for ten days and five days later if everything goes on well the patient is discharged. The above-mentioned diet could not be given to serious cases and nasal feeding had to be resorted to.

Treatment

Most of the patients were given a diaphoretic mixture. In a few cases septanilam was tried without beneficial result. Some patients were given oil of cinnamon only and it was noticed

that abdominal discomfort was very much less. To prevent cracked lips vaseline or boroglycerine was applied frequently. To prevent oral sepsis the mouth is cleaned with bicarbonate of soda and a slice of lemon fruit and the patients are encouraged to suck lemon fruits thrice daily and are given acid lemon drop sweets to suck. This keeps the salivary glands in working order. It has been found during the last three years that this line of treatment is very beneficial, very few cases of parotitis occurring. For meteorism oil of cinnamon by mouth and turpentine stupes were found very satisfactory. For constipation liquid paraffin and/or soap and water enema are given as required. For diarrhoea only when it is excessive, the patient is given kaolin and/or bismuth and salol and diet is reduced. When intestinal hæmorrhage occurs, the patient is given straight away morphia injection, the foot of the bed is raised, and ice is kept over the abdomen. Fluid and food are withheld for 24 hours. Calcium chloride or calcium gluconate is given intravenously. 500 mgm. of vitamin C is given intravenously daily for four days after the hæmorrhage has stopped and thereafter by mouth, since deficiency of this substance is believed to increase the fragility of the capillaries and to delay the healing of ulcers. Portnoy and Wilkinson found severe degrees of deficiency of vitamin C in hæmorrhage from peptic ulcer. Transfusion of blood is given when a donor is available.

For pneumonic cases M.&B. 693 is given. Retention of urine is treated first with hot fomentation over the bladder, and an enema. If this fails doryl is given by mouth. Catheterization is done only as a last resort. In toxic cases where there are signs of peripheral circulatory failure, 50 per cent glucose is given intravenously as required. Cardiazol, coramine or camphor in oil and strychnine injections are given as needed. Cortin (supra-renal cortical extract) was given in two cases and the result was encouraging. Saline by drip method per rectum was tried for toxic cases and the result was not encouraging.

Complications

There was an unusually large number of cases with lung affections in this series and many cases with distension of the abdomen. There were 23 cases of intestinal hæmorrhage of whom 12 were cured and 11 died. There was one case of perforation and as the patient was in *extremis* operative treatment was refused by the relatives. One man aged 24 years, a month after his discharge from the hospital, while working in his office suddenly became unconscious and fell down with a hemiplegia of the left side. Speech was also affected. Blood pressure 120/80; Wassermann reaction was weak positive; urine was normal. He regained consciousness, power of speech and use of the affected limbs within a

FIVE-YEAR SALVAGE OF CARCINOMA CERVIX CASES TREATED BY RADICAL VAGINAL OPERATION

By SUBODH MITRA, M.B. (Cal.), M.D. (Berlin), F.R.C.S. (Edin.), F.R.C.O.G.

Associate Professor of Obstetrics and Gynecology, Carmichael Medical College; Surgeon to Sir Kedarnath Maternity Hospital; Surgeon, Chittaranjan Seva Sadan (Women's Hospital), Calcutta

THE rationale of the treatment of carcinoma cervix is still a controversial subject. While the general trend of opinion is going towards radiation therapy, the surgical treatment still occupies

(Continued from previous column)

week—perhaps a case of cerebral embolism (see table II).

TABLE II
Complications

Bronchitis ..	53	Otitis ..	6
Pneumonia and broncho - pneumonia ..	70	Epistaxis ..	1
Pleurisy ..	5	Hæmaturia ..	1
Diarrhoea ..	41	Neuritis ..	8
Distension ..	Many cases	Macular rash ..	4
Hæmorrhage ..	23	Abortion ..	2
Perforation ..	1	B. coli infection ..	1
Parotitis ..	10	Multiple abscesses ..	4
		Periosteal abscess ..	1
		Cerebral embolism ..	1
		Relapse ..	31

Thirty-one cases relapsed. The relapse occurred on an average on the 11th day of normal temperature. The earliest was on the 5th day and latest on the 17th day. Secondary fever lasted on an average for 13 days. Five days was the shortest duration and 28 days was the longest. Two cases relapsed twice.

Mortality

Three-hundred and fifty-six patients were admitted and 72 died giving a mortality rate of 20.22 per cent. If 19 patients who were admitted moribund and died within 24 hours are excluded, the mortality rate is 14.87 per cent only (see table III).

TABLE III
Causes of death

1. Broncho-pneumonia ..	8	5. Cardio-vascular failure ..	16
2. Pneumonia and hypostatic pneumonia ..	7	6. Perforation ..	1
3. Toxæmia ..	10	7. Admitted moribund. (Died within 24 hours after admission.)	19
4. Hæmorrhage ..	11		72

Six cases died within 72 hours of admission. These are included in cardio-vascular failure and toxæmia.

I am grateful to my chief, Colonel J. C. Pyper, O.B.E., I.M.S., for encouraging me to send this article for publication.

a great and well-established place in its management. Moreover, some workers who were previously converts of radiation therapy are coming back again to surgery supplemented by radiation therapy. So far as surgical procedure is concerned, the difficulty lies in proper and efficient technique of the operations, which are either Wertheim's radical abdominal operation, or Schauta's radical vaginal operation. Wertheim's operation is attended with enormous primary mortality, although satisfactory end-results have been found by Victor Bonny. Schauta's operation has been popularized and greatly improved by Adler by supplementing it with radiation therapy; but it is a difficult operation if conscientiously done. According to Stoeckel, most of the surgeons, while professing to perform the radical operation, are satisfied with a simple hysterectomy, thus bringing discredit to this particular method of treatment.

Before evaluating the end-results, I would like to give a few practical hints as regards the technique of the operation. The first point worth mentioning is that this operation is not a plain and simple vaginal hysterectomy; secondly, the uterus should be well dissected out to facilitate the removal of the greatest amount of parametrial tissue; thirdly, treatment of a carcinoma cervix case should not be considered complete unless and until the operation is supplemented by a thorough and intensive course of post-operative radiation. Here the difficulty is experienced by most gynaecologists, as they are either not quite conversant with the proper technique of the radiation therapy, or radium and deep x-ray apparatus are not available to them. It will be as bad as giving no treatment if only a partial or an incomplete radiation therapy is administered or if this treatment be deferred to an uncertain period by the x-ray department.

In a previous communique (Mitra, 1939) I gave a detailed technique of this operation with the immediate post-operative results and complications. It is now time to give a 5-year salvage of such cases. I shall try to put my results in tabular form. Table I shows the total number of carcinoma cervix cases operated on, with the incidence of primary mortality. The primary mortality rate in my series is 5.4 per cent. Out of 6 fatal cases, 3 died of shock, 1 of sepsis, 1 of pulmonary embolism and 1 of staphylococcus septicæmia. This is in conformity with the average primary mortality rate in radical vaginal operations, i.e., 7.7 per cent (Mickuliez Radecki), whereas the average primary mortality rate in radical abdominal operations (the so-called Wertheim's operation) is 18 per cent (Pankow). Table II shows the distribution of cases according to different grades as classified by the League of Nations. An incidence of primary mortality has also been given against different grades. This table shows that 2 patients of the first grade died, of two rare complications, namely, pulmonary embolism and staphylococcus septicæmia. Three patients

TABLE I

Total number of carcinoma cervix cases operated on, with the incidence of primary mortality

TABLE II

Distribution of cases according to the grades of the League of Nations with incidence of primary mortality

Grade	Total number	Primary mortality	
I	17	2	1 died of pulmonary embolism. 1 died of staphylococcus septicæmia.
II	58	2	1 died of shock. 1 died of sepsis.
III	35	2	Shock.
IV	nil	..	

died of shock, which could be accounted for by their devitalized and anæmic condition when they come for treatment.

Although much work has been done to find out the optimum dose of radium treatment, the ideal one has not yet been found. Generally 6,000 'milligramme hours' is unsatisfactory as a method of dosage in that it neglects the important factors of distribution and radium-tumour distance and so cannot be accurately and satisfactorily utilized by others.

Recent investigations recommend 10,000 r radium as the lethal dose*; similarly 5,000 r x-ray with 2.5 cu. H.V.L. and average 1.09 A.U. has been found to be the lethal x-ray dose in about a month's time. Figure 1 shows the isodosis chart for the radium tubes pointing out how the intensity of radium r-unit decreases according as the distance increases. This figure shows that within 3 cm. from the site of radium application, the intensity is reduced to half and within 6 cm. it is reduced to about one-sixth the original intensity. This shows that unless the

*7.6 r/hour is the radiation measured at 1 cm. from a point source of 1 mg. of radium filtered by 1 mm. platinum.

distant parametrial tissues are further exposed by x-ray, the effective lethal dose will not be available there. Figure 2 shows the isodosis chart of x-ray in the pelvis where the most lateral part of the pelvis will receive an effective dose. Table III shows the deep x-ray dosage given by the writer in his cancer cervix cases.

Fig. 1.—Isodosis chart for radium tubes: within 3 cm. from the site of application, the intensity is reduced to half and within 6 cm. to about one-sixth the original intensity.

Fig. 2.—Isodosis chart for x-ray in the pelvis where the most lateral part receives an effective dose.

Table IV shows the results of operation given year by year up to 5 years. Twenty-eight cases have already been lost sight of and, not being able to trace them, we have taken them as dead to evaluate our 5-year end-results.

Table V shows 5-year end-results of carcinoma cervix cases treated only by radiation (1926 to 1932).

Table VI shows 5-year salvage of carcinoma cervix cases treated by operation and radiation

TABLE III

Deep x-ray technique for carcinoma-cervix cases—5 fields: 2 abdominal, 2 gluteal, 1 vulval, 220 K.V., 15 mA, 1.5 m.Cu., 50 cm. F. S. D. 25 exposures—at 300 r daily.

Day	Skin dose in air	Effective dose 10 cm. deep (33%) including back scatter (15%)*	Daily loss at 8%	Total effective dose
1st	300	$300 + \frac{45}{3} = 145$..	145
2nd	300	$115 + 115 = 230$	9	221

TABLE IV

Evaluation of results of operative cases

Year	Total cases	Living years					L.S.O.	REMARKS
		1	2	3	4	5		
1932	4	4	1	1	1	1	1	(1 fr. 1st year)
1933	4	4	2	1	1	1	2	(2 fr. 1st year)
1934	17	17	10	7	7	4	6	(3, 1 and 1 fr. 1st, 2nd, 4th and 5th year)
1935	12	12	11	9	7	4	3	(3 fr. 4th year)
1936	16	16	10	6	5	..	7	(4, 2 and 1 fr. 1st, 2nd and 3rd year)
1937	19	19	10	9	5	(5 fr. 1st year)
1938	9	9	4	3	(3 fr. 1st year)
1939	4	4	1	(1 fr. 1st year)

during the years 1932 to 1935. A comparative review of the two foregoing tables will clearly show that on an average the operative cases give better end-results. Taking the first three grades together the operative cases yield 27 per cent 5-year salvage whereas cases treated only by radiation yield 14.4 per cent.

Table VII gives a comparative statement of the world literature drawn up by Adler with the author's result appended below. This table shows that, in spite of manifold difficulties, our

results are comparable with the results obtained in other parts of the world.

TABLE V

5-year results of carcinoma cervix cases treated only by radiation (1926 to 1932)

Stages	Total number of cases	LIVING AFTER 5 YEARS	
		Number	Percentage
I	13	7	53.4
II	56	21	37.5
III	361	34	9.4
IV	60	1	1.7
All stages together.	490	63	12.9
I, II and III combined.	430	62	14.41

PNEUMONITIS

By L. EVERARD NAPIER, C.I.E., F.R.C.P. (Lond.)
R. N. CHAUDHURI, M.B. (Cal.), M.R.C.P. (Edin.),
T.D.D. (Wales)

and

M. N. RAI CHAUDHURI, M.B. (Cal.)

(From the School of Tropical Medicine, Calcutta)

APART from the classical examples of lobar and broncho-pneumonia, the differences between the lung diseases of adults and of children are considerable, and the so-called atypical forms, including central pneumonia, are common in the latter. Recently, cases with a low-grade inflammatory pulmonary change of a benign nature have been described by both American and English workers. The symptoms include a cough, low pyrexia, and lassitude. The physical examination does not reveal any evidence of pneumonia. Weak breath sounds and a few râles are perhaps the only auscultatory findings. The respiration rate is not increased, and there is no toxæmia. The x-ray film reveals some opacity suggesting a localized inflammatory process in the lung. There is nothing in the history to suggest that the condition is the end of a pneumonia, or an unresolved pneumonia. The disease runs a benign course and usually clears up rapidly.

The term 'pneumonitis' has been applied to this clinical entity; it has the same meaning as pneumonia, namely, an inflammatory condition of the lung, a different word being used to indicate the non-specific nature of the reaction, as well as a different ætiology.

In this connexion the following case seems worth reporting :—

A Jewish female child, aged 1½ years, was admitted into the Carmichael Hospital for Tropical Diseases on the 24th April, 1939, with a complaint of cough and low

(Continued from previous column)

3. A few hints on the technique of the operation have been given.

4. The principles of post-operative radiation technique have been explained.

5. A comparative statement of evaluation of 5-year end-results of both surgically treated and irradiated cases has been given. Taking I, II and III grades together, 5-year cure of surgically treated cases (supplemented by radiation) is 27 per cent against 14.4 per cent in only irradiated cases.

6. It is possible to improve further the end-results if the cases can be detected at earlier stages, if proper pre-operative treatment can be given, if the technique of the operation be followed efficiently, and if radium and deep x-ray apparatus be at the disposal of the surgeon, and finally the number of 'lost sight of' cases can be minimized.

REFERENCE

MITRA, S. (1939) .. J. Obstet. and Gyn. Brit. Empire, 45, 1003.

intermittent fever for one week. There was no history of any previous illness, and the parents stated that there was no tuberculosis in the family.

The child showed some evidence of retarded growth; she had a rectal temperature of 100.4°F ., pulse 140, and a respiration of 28 per minute. There was no dullness over the chest; the air entry was weaker on the right side; and scattered râles and ronchi were audible in both lungs. The spleen and liver were palpably enlarged. A few cervical glands were palpable. No abnormality was detected in the ear, nose or throat.

The blood count showed hæmoglobin 56 per cent (7.7 gm.) and total leucocytes 13,500 per c.mm. The differential count showed polymorphonuclears 74 per cent, lymphocytes 23 per cent, monocytes 2.5 per cent and eosinophils 0.5 per cent. The stool examination revealed a mild hookworm infection. The urine was clear.

The Mantoux test was negative with 10000 mgm. and 1000 mgm.

No sputum was obtainable; tubercle bacilli were not found in the gastric juice.

X-ray examination.—Skiagram of the chest was taken at intervals during the child's stay in the hospital (plate XIII).

Discussion

This is a case with radiological opacity in the lung, suggestive of pneumonia but with a remarkable paucity of symptoms and signs. The low intermittent fever, the milder leucocytosis, the absence of any toxæmia or increase in respiration and the physical signs do not offer any clinical support to a diagnosis of pneumonia. Besides, the *x-ray* density is neither lobar nor of typical broncho-pneumonic distribution. It is difficult to consider it to be due to unresolved pneumonia in the absence of any history of a recent attack of pneumonia.

Tuberculous enlargement of the hilar glands and an allergic reaction in the lungs would be a reasonable interpretation of any of the skiagrams in this case, but the negative Mantoux reactions and the subsequent progress seem to negative this diagnosis.

In the past, more-or-less similar cases have been described as sub-acute or chronic pneumonia, atypical pneumonia or 'symptom-poor' pneumonia. In recent years, it has been recognized that such inflammatory changes in the lungs running a benign course are relatively common, and it is to this type of case that the term 'pneumonitis' has been applied.

Blake and Cecil (1920), as a result of experimental pneumococcal infections in monkeys, showed that the pneumococci enter through the mucous membrane of the main bronchus and then pass through the lymphatics of the lung giving rise to an interstitial inflammation. With the progress of the inflammatory process the blood becomes infected and exudate fills the alveoli, resulting in consolidation of lung tissue.

Maxwell (1938) is of the opinion that the course in the human subject depends upon the resistance of the patient and the virulence of the organism. In the presence of good, general and local, resistance with an infection of low virulence the organisms give rise to interstitial pneumonitis, but the process stops short at this stage and there is only a little exudation into the alveoli. The temperature and pulse may be

raised, but the respiration is not hurried; there is no toxæmia. The diagnosis depends upon *x-ray* examination. On the other hand, if the general immunity mechanism breaks down, the inflammatory process will progress to consolidation of the lung, and the patient will exhibit evidence of toxæmia that is characteristic of pneumonia. 'A patient with pneumonitis will develop pneumonia if the resistance fails, or lung abscess may result from local tissue damage. The clinical picture varies considerably in different cases'.

This view of regarding the condition as a mild or abortive pneumonia of acute specific type has, however, been disputed. There are many instances in which bacteriological studies of the sputum and blood have failed to reveal pneumococci. Sulphonamide derivatives are usually ineffective in this disease; the case under review also bears out this fact. It has been suggested that the condition is due to virus rather than bacterial infection, hence the condition has also been called 'virus pneumonia'. Some workers consider it to be more infectious than pneumonia and have reported epidemic outbreaks. Different opinions have been expressed as to the nature of virus in different outbreaks, e.g., the virus of Q fever, psittacosis. There is, however, no evidence to show that it is due to the influenza virus.

Smiley *et al.* (1939) applied the term acute interstitial pneumonitis to this condition and considered it to be a new disease entity. They studied eighty-six cases. They observed that the radiological opacity appears about the second day of illness, and that the infection spreads from the hilus outward. According to the *x-ray* appearance, they divided the cases into three groups. In the first group the onset was marked by increased hilar density, 'with a fan-shaped localized accentuation and a numerical increase in the linear pulmonary markings extending from the hilus into the adjacent lung field'. They usually clear up in one to two weeks' time. In the second group the fan extended to the periphery of the lung, and it took a longer time to clear up. In the third group, there was more severe and extensive involvement. Almost an entire lung is affected as well as partial or complete involvement of the other lung. This may be associated with a higher rise in temperature and some toxæmia. The resolution is slow and may take a few weeks or months. Mild leucocytosis often occurs. The condition usually terminates with little or no complication.

The more severe forms of the disease occasionally prove fatal, and a few autopsies have been performed. The pathological lesions were found distinct from those of pneumonia.

Conclusion

This case illustrates an acute benign infection of the respiratory tract in which a skiagram of the chest revealed fan-shaped

(Concluded on opposite page)

PLATE XIII
SKIAGRAMS WITH REPORTS

Fig. 1. 5th June

Fig. 2 (oblique view). 29th June

Fig. 3. 13th July

Fig. 4. 7th August

5th June.—There is a homogeneous opacity in the right lung field extending outwards from the hilum and shading off towards the periphery. This occupies the greater part of the upper zone and the inner two-thirds of the middle zone.

On the left side there is an opacity similar in distribution but of the type of a dense mottling.

The extreme apices on both sides are comparatively free.

The appearances suggest a lobar pneumonia starting in the left upper lobe which is now resolving, and a more recent involvement of the right upper and middle lobes.

29th June.—The opacity on both sides is less extensive though perhaps more dense mesially. The apices and clear peripheral lung are now more evident.

13th July.—The film shows a further contraction of the opaque areas.

7th August.—The clear areas have further extended. The consolidation on the left side has almost completely cleared up while that on the right side has become less dense.

Conclusions.—According to our present knowledge of these conditions in children this series of skiagrams would seem to portray the gradual resolution of a pneumonic process. It is difficult to differentiate here between a pure pneumococcal infection and tuberculous disease.

There are two shadows which might be due to enlarged glands—skiagrams of 5th June and 29th June. Such an appearance would support the diagnosis of tuberculous disease. Time, however, alone will tell. A pneumococcal or allied pneumonia should clear up completely.

Clinical progress

While she was in the hospital, the child had irregular intermittent fever. Sulphonamide derivatives and quinine were given empirically but without effect; otherwise the treatment was palliative. The general condition gradually improved very considerably; the child put on 3½ lb in weight during her stay in the hospital. The radiological opacity, however, persisted, but it was definitely reduced (*vide* skiagram, 7th August).

HEPATOMA (PRIMARY LIVER-CELLED CARCINOMA)*

By A. C. BOSE, M.B.

Pathologist, Mayo Hospital, Calcutta

HEPATOMA is uncommon; it usually occurs in the second half of life and is accompanied with cirrhosis of the liver. This is more frequent in males than females.

This has been estimated by Forsyth (1922) to constitute 4 per cent of liver cancers and of these a good proportion accompanies a cirrhotic process. At St. Mary's hospital out of 2,083 autopsies in 10 years (1919-1928) there were 372 examples of malignant growths, out of these three were liver-celled carcinoma and seven bile-duct carcinoma, as noted by Langmead (1938). Gharpure (1927) has mentioned 14 cases of primary carcinoma of liver from 6,000 odd *post-mortem* cases in the course of 50 years from 1877-1926 from the Grant Medical College, Bombay, but he remarked two cases only being primary liver-celled carcinoma. This is more common in many tropical countries (about 1 per cent of necropsies) than Europe and North America (about 0.2 per cent of necropsies).

Chatterjee (1926) in his paper on cancer in India mentioned that this is very often preceded by cirrhotic changes in the liver induced by parasitic infections and chronic amoebiasis; and that this is due to the toxin of parasitic infections which cause chronic irritation of the liver tissue and cell proliferation resulting in cirrhosis and hyperplasia—the precursor of cancer. While discussing the aetiological aspect, some other factors (*e.g.*, climate, diet, influence of heat and light, influences due to peculiarities in habits and customs of the indigenous population and their effect on metabolism through the endocrine system) have also been considered. So far I have gathered that there is no record of a case of hepatoma in a child in any of the Indian journals with micro-photographs of the morbid histological changes.

*This specimen of hepatoma was exhibited at the All-India Surgeon's conference, held in Calcutta, 1941, and was presented to the Pathological Museum, Medical College, Calcutta.

(Continued from previous page)

areas of increased density that are apparently not due to true consolidation, or pneumonia, nor is there any evidence to suggest a diagnosis of tuberculous disease. This appears to be a case of acute interstitial pneumonitis, a condition that is now being generally recognized.

The incidence of primary liver-celled carcinoma has also been noted in animals. Winer and Schroeder (1940) reported hepatocellular carcinoma in a roe-deer; this is not usually preceded by cirrhosis but starts from benign adenoma and is ascribed to strongyloides infestation of the small intestine as being the aetiological factor.

Fieldman and Jackson recorded it in dogs, sheep, cattle and Norries in a fowl (rooster), among the domestic animals.

Morbid anatomy.—On naked-eye examination the whole liver may present one single tumour or may be a collection of nodules of different sizes projecting from the surface, or there may be a diffuse infiltration.

The irregularly shaped bossed organ may become of enormous size and may be nearly all replaced by growth, the remaining liver tissue showing a coarser or finer cirrhosis. The right lobe is usually affected; the colour of the tumour varies from light yellow to light grey, but occasionally it is bile-stained.

The nodules are hard and perhaps stony in resistance, in the less rapidly growing forms, but usually the bosses become soft and even fluctuant, sometimes from necrosis with or without hæmorrhage and from suppuration. The bosses are sometimes marked by depression at their summits; matting of the liver is the result of perihepatitis.

Microscopically primary carcinomas of the liver are divided into (1) liver-celled carcinoma (hepatoma), or (2) bile-duct carcinoma (cholangioma), originating in the walls of the finest bile ducts. In hepatoma the masses of cells look like liver cells but are larger and more variable in size and shape (including giant cells), the nuclei are irregular, darkly staining, and show numerous mitosis. The cells are sometimes bile stained and there is characteristic vascular stroma between them. The origin of the tumour (hepatoma) either in ordinary liver cells or in benign adenomas is not decided but when accompanied by cirrhosis it arises in the actively growing cells of regeneration nodules. The tumour invades blood vessels, fills their lumen with tumour 'thrombus', spreads along them throughout the liver by intra-hepatic metastasis, and may reach the right heart by direct extension. Extra-hepatic metastasis is rather rare; lungs and lymphatic glands are first involved.

Clinical features

1. *Cirrhosis* marked by general ill-health and digestive disturbance is the usual accompaniment in hepatoma in adults, this is either manifested early or remains latent, but in infants may be absent altogether.

2. *Pain* is usually of a dragging character felt over the liver, or in the epigastrium (unrelated to food) or in the right shoulder and may be reflected to the right arm, or pain may be altogether absent.

3. *Jaundice* appears in about half of the cases as a result of intra-hepatic obstruction of the bile channels, or by compression of the larger ducts in the portal fissure by secondary glands, or by cholangitis. Pipe-clay coloured stools are not a constant finding.

4. *Ascites* is almost always present and is caused by invasion of the portal vein by the growth or by secondary glands in the portal fissure or by obliteration of the branches of the portal vein in the liver. The character of the ascitic fluid varies; it may be serous or chyliform due to necrosis of the nodules, or purulent from secondary infection but is usually blood stained due to hæmorrhage.

5. *Edema* of the legs is caused by the malnutrition and circulatory failure in the later stages.

6. The *general condition* of the patient is characterized by increasing anæmia, weakness and emaciation; finally, the extreme shallow lustreless look of the patient with prominent abdomen in a markedly wasted frame becomes a striking picture. Fever almost always accompanies the illness. With the rapid enlargement of liver there may be produced pressure symptoms, e.g., vomiting from pressure on the stomach and dyspnœa from that on the diaphragm. In the terminal stages the patient is carried away either by broncho-pneumonia, internal hæmorrhage or pleurisy with effusion resulting in extreme exhaustion and sleeplessness, usually ending in delirium and coma.

Diagnosis and differential diagnosis

Hepatoma is characterized by hard and irregular liver with multiple bosses, rapid enlargement, rapid development of wasting and anæmia, and the presence of pain and tenderness.

It is to be distinguished from other enlarged, hard, or irregular livers due to syphilis and hydatid disease of the liver.

In syphilis there is absence of pain, slow enlargement specially of the left lobe of the liver, visible signs of collateral circulation, absence of extreme cachexia, signs of congenital syphilis in infants, and a positive Wassermann reaction.

Hydatid disease of the liver usually provides a smooth, resilient, soft and non-adherent swelling; and is characterized by the presence of a thrill, absence of cachexia and pressure-symptoms and presence of eosinophilia and positive precipitin tests.

Case report

Hindu male child, aged 6, was admitted on 27th April, 1940, with a history of fever of 2 months' duration and protuberant abdomen. At the time of admission he was found to be very weak and extremely emaciated. Conjunctiva was pale and anæmic. The pulse was regular but of low tension and volume.

On examination.—There was marked ascites and œdema of the lower extremities, liver was found to be

nodular, hard and enlarged 3 inches below the costal margin, the dullness also increased upwards to the 4th interspace. Spleen was just palpable. There were no palpable glands. Heart and respiratory system were normal and nothing else abnormal was found.

Blood count—red cells 2,520,000 per c.mm., some anisocytosis; hæmoglobin 50 per cent; colour-index, 0.98; white cells 14,800 (polymorphonuclears 71 per cent, lymphocytes 25 per cent, monocytes 4 per cent, eosinophils 0 per cent), aldehyde and antimony tests negative.

The patient died on 3rd May, 1940.

Post-mortem findings.—Heart weighing 2½ ounces was normal and so also was the pericardium.

Abdomen.—There were 5 pints of hæmorrhagic fluid inside the peritoneal cavity; the mesentery was not involved. Spleen weighing 5 ounces was normal. Kidney—right one weighing 2 oz. and left one weighing 2½ oz. were found normal. Supra-renal—normal. Liver was found to be fairly enlarged, with an irregular surface. Its weight was 2 lbs. and 4 oz. The whole of the right lobe was occupied by a growth with round irregular masses of different sizes projecting from the surface. The mass showed an area of necrosis and softening leading to bursting and throwing out of its contents leaving a cavity with ragged walls. A few small dark-coloured (hæmorrhagic) cysts were seen. A few secondary nodules of irregular sizes were detected in the left lobe. The quadrate lobe was enlarged and tongue-shaped while the cut surface showed a cirrhotic appearance. The gall-bladder was thin-walled and very small in size, while the cystic duct was seen to be pressed by the enlarged quadrate lobe. Cut section of the tumour showed whitish rounded soft masses in the liver tissue (plate XIV, figure 1).

Microscopical appearance showed rounded masses of enlarged liver cells of different sizes and having deeply stained nuclei undergoing mitoses. These are interspersed with healthy liver cells in different degrees of degeneration and showing spaces filled with degenerated cell debris. There is distinct proliferation of fibrous tissue round the groups of malignant cells (figures 2 and 3).

Summary

1. Hepatoma is a rare disease.
2. It is more uncommon in a child of 6 years.
3. The detailed description of the case has been presented with the photograph of the liver and microphotographs of the morbid histological changes.

Acknowledgments

The writer acknowledges his indebtedness to Dr. F. H. B. Norrie, Surgeon Superintendent, Mayo Hospital, for his kind interest and permission to publish this case. Thanks are also due to Dr. B. P. Tribedi, professor of pathology, Medical College, for the microphotographs.

TUBERCULOSIS OF THE HEART

(SIMULATING A NEOPLASM)

By A. C. BOSE, M.B.

Pathologist, Mayo Hospital

TUBERCULOUS infection of the pericardium occurs as a part of general infection and is usually caused by the rupture or extension of caseous lymph nodes laden with *Mycobacterium tuberculosis* into the serous cavity. The miliary tubercles may also appear in the myocardium and also on the endocardial surface, but this is not of common occurrence. The tuberculous heart becomes enlarged due to thickening of the pericardium and sometimes presents the appearance of a neoplasm and can hardly be diagnosed prior to death. The following case illustrates this fact :—

Case report

A Hindu male, aged 25 years, was admitted into the hospital on 19th March, 1941.

History.—The patient gave a history of cough, fever, and palpitation on exertion for more than a month; he also noticed gradual swelling of legs and feet for about 2 months.

On examination.—Patient was emaciated, with puffy appearance of the face, œdema of the lower extremities having red flush (pitting on pressure), and slight bulging of the abdomen.

On admission: temperature—102°F., pulse—118, and respiration—44 per minute, temperature was ranging from 98°F. to 100°F. usually, but sometimes went up to 102°F.

Lungs.—Slight expectoration; right side—dullness at the base; left side—dullness at the back; both lungs were full of râles and ronchi. After a month the dullness seemed to have increased on the left base, and there was dyspnoea; two months after there was a swelling on the third sterno-costal articulation, attended with tenderness and fluctuation. (This was not reduced by iodide.) Six months after, left axillary glands were enlarged and there was another fluctuant swelling on the right second sterno-costal joint. Glands at the left supra-clavicular fossa were also enlarged and hard.

Abdomen.—There was shifting dullness and ventral hernia. Liver and spleen were enlarged and tender.

Heart was enlarged, apex beat was displaced and faintly audible; after about 2 months clubbing of fingers was noticed; the swelling of legs and feet was diminished for some time but later went on increasing and involved the genital organs. There was marked ascites.

Laboratory findings

On admission.—Blood: hæmoglobin—50 per cent (Sahli), white cells—7,100 per c.mm., red cells—2,550,000 per c.mm., neutrophils—75 per cent, lymphocytes—15 per cent, mononuclears—7 per cent, eosinophils—3 per cent. Aldehyde test—negative; antimony test—negative; Kahn's test—negative; Wassermann reaction—strongly positive. Stool: no ova nor any parasite or any cyst found. Urine: albumin—trace, sugar—nil, reaction—acid. Microscopically triple phosphates and epithelial cells present. Sputum: streptococci, staphylococci and diplococci were found, but no *Mycobacterium tuberculosis* was detected.

On 23rd July.—Blood: hæmoglobin—40 per cent, white cells—5,800 per c.mm., neutrophils—81 per cent, lymphocytes—17 per cent, monocytes—2 per cent, eosinophils—0 per cent. Kahn's test—doubtful. Wassermann reaction—strongly positive. Sputum: presence of streptococci, staphylococci, diplococci.

Mycobacterium tuberculosis was absent. Urine: albumin present (not estimated), sugar—nil. Microscopically amorphous phosphates, ammonium urates and triple phosphates were present. Blood on culture—there was no growth after 48 hours on three successive examinations.

X-ray report

The x-ray examination of the chest on 18th April showed enlargement of cardiac shadows; both the arches of the diaphragm appeared hazy, possibly due to pleuritic condition and chronic bronchial catarrh of the bases.

On the 24th July, in another x-ray examination, dense appearance over the mediastinum masking the cardiac shadow suggesting a new growth was noticed.

Post-mortem findings

Lungs.—miliary tubercles were found to be scattered over the lungs with inter-lobar adhesions. There was bilateral pleurisy with some effusion and adhesion in places. Bronchial glands were matted together and caseous.

Liver and spleen were enlarged and studded with small tubercles on their surface. They weighed 3 pounds, 12 ounces and 1 pound, 4 ounces, respectively.

Chest.—fluctuant swelling; on excision cheesy purulent material was found.

Abdomen.—mesenteric glands were also involved; the intestine was very slightly affected, only very few scattered small tubercles were detected at the ileo-cæcal region. There were about 9 pints of fluid in the peritoneal cavity.

Heart.—to the naked eye the heart appeared as a neoplasm (figure 1). It was pale, enlarged and weighed

Fig. 1.*—Photograph of the heart—simulating a neoplasm. It has been cut open to show greatly thickened pericardium, pale myocardium but normal endocardium.

1 pound and 3 ounces. The pericardium was greatly thickened (varying from 2 cm. to 2.5 cm. in depth), the parietal and visceral layers could hardly be separated. The pathological process of the pericardium also involved the myocardium, but the endocardium was not affected. No definite tubercles were visible either on the surface of the pericardium or in the substance of the heart muscle.

(Concluded on next page)

*This specimen was presented to the pathological museum, Medical College, and exhibited at the All-India Surgeon's Conference (1941).

OSTEOPOIKILOSI WITH DISSEMINATED LENTICULAR DERMATOFIBROSIS

WITH THE REPORT OF A CASE

By MADAN LAL AGGARWAL, M.B., B.S.
Lahore

Case report

PATIENT, Hindu female, aged 20, was admitted to the Sh. Gulab Devi Tuberculosis Hospital for Women with fever, cough, dyspnoea on exertion, loss of weight, poor appetite and night sweats. Duration of illness before admission was six months. There was no history of previous illness. A brother died of pulmonary tuberculosis. Examination of circulatory, digestive and urogenital systems did not reveal any pathology. Chemical and microscopic examination of urine did not reveal any abnormality. Stools were negative for ova and cysts. Her sputum contained tubercle bacillus. On radiological and clinical examination she showed active tuberculosis of the right lung. She is getting artificial pneumothorax.

During her stay in the hospital she developed swelling on her thenar (right) and interscapular regions. X-ray picture of the dorsal spine did not reveal any disease but the shoulder joints in this picture showed dense white spots. Diagnosis of osteopoikilosis was made and x-ray pictures of all the joints of the body, spine and skull were taken (plate XV).

The skin of thighs and arms was covered with tiny lentil-sized nodules. This condition is known as lenticular dermatofibrosis.

The bone condition

Roentgen description.—White dense spots which were multiple, round or somewhat oblong, circumscribed but sometimes confluent were seen in the spongiosa of the epiphysis and metaphysis of long bones. Their size varied from a diameter

(Continued from previous page)

Lymph glands—showed marked caseous changes.

Other organs were found to be normal.

Histological examinations of the different organs, e.g., liver, spleen, lungs, heart, etc., all showed typical tuberculous infection with caseation-necrosis and conspicuous giant-cell systems.

The section from the heart shows wide areas of necrosis in the pericardium and many giant cells and lymphoid cells in the myocardium (plate XIV, figures 2 and 3).

Summary

A case of tuberculosis of heart is described. This is of interest because clinical symptoms and repeated x-ray findings suggested this case to be a neoplasm of the heart and even the naked-eye appearance after *post-mortem* examination gave the same impression. This was finally diagnosed to be tuberculous from the microscopical study.

Acknowledgments

My sincere thanks are due to Dr. F. H. B. Norrie, Surgeon Superintendent, Mayo Hospital, for the interest and kind permission to report this case, to Dr. B. P. Tribedi, professor of pathology, Medical College, for the photo-micrographs, and to Dr. P. K. Ghosh, physician, Mayo Hospital, for the clinical materials.

of 1 mm. to an area of 4×15 mm. In this case all the bones were involved except the ribs and the clavicles. The greatest number of the spots were seen in the bones of the pelvic girdle. The central portions of the iliac wings were free from these spots. The elbow joint was least involved. The spots were smallest near the joints but increased in size further away from the joints. The spots arranged themselves along the general direction of the principal trabeculae. In the shafts of the long bones the spots were elongated. They were observed with regard to their number roughly in the following order: pelvic girdle, shoulder joint, carpal bones, tarsal bones, knee bones, metacarpals, metatarsals, skull and spine. Other observers have recorded the condition in the clavicles also. Thus, the condition affects all the bones except the ribs. Even the sesamoid bones have been involved.

Prognosis is very good. A wrong diagnosis can put a patient to a good deal of worry, expense and wrong treatment. The condition is usually found by accident as was the case in this patient. Neweomet (1929) noted no roentgenographic changes in the lesions exhibited by his patient during four years of observation and the case reported by Nichols and Shiflett (1934) showed no changes during a period of seven years.

Albers-Schönberg is generally credited with having reported the first case in 1915, but according to Koenig the disease reported by Albers-Schönberg was an entirely different clinical entity. According to Bloom (1933) the first authentic report of osteopoikilosis was that by Stieda, in 1905, who reported 'eases of circumscribed condensing of the bone in the region of the substantia spongiosa, based on roentgen examination of macerated bone and anatomical specimens.'

Pathology

Schmorl performed the first reported autopsy of a case in 1931. Nichols and Shiflett (1934) have abstracted from the pathological report of Schmorl as follows:—

'Pathological examination showed that the areas which had shown as increased bone density on the roentgenograms varied from needle-head to pepper-grain size and were seldom larger. These were irregular and had somewhat jagged borders, and on the saw plane surface had homogeneous, greyish white areas, appearing as small osteomas. They were partly round and partly oval. The areas of osteopoikilosis were compact and entered the spongiosa plates and trabeculae as small nodular formations. Almost never did these areas lie immediately in the bony terminal lamina of the epiphysis on which the joint cartilage is fastened, but were of a greater or lesser distance from it. Only in the surface of the intermediary cartilage were they at times situated on the latter. Those which lay on the spongiosa section of the diaphysis were almost never in the axial plane of the spongiosa, but rather in the periphery where the spongiosa trabeculae attached to the bone rims, which at this point were not very thick.

The microscopic examination showed that the areas of increased density were formed by numerous juxtaposed trabeculae resembling those of the spongiosa more than of the cortex. This close arrangement gave the appearance of compact bone which was observed

while studying the gross specimens. The merging of the trabeculae into the spongiosa was gradual and sharply defined borders were absent. The trabeculae were thin at times, at other times they formed tufts in which the thickness of the trabeculae varied. The thickened ones consisted of lamellous bone arranged mostly parallel to the long axis of the bone but a few were obliquely arranged, while some were grouped chiefly in the periphery, concentrically around blood vessels, without a typical osteomatous formation.

The histologic study did not permit definite conclusions as to the genesis of the trabeculae. The author thought that they probably arose from the fibrous portion of the bone marrow. It was not possible to determine whether the areas of osteopoikilosis increased in size after they were once formed. Schmorl stated that this would have to be determined by repeated roentgen examination at regular intervals. He did not consider an enchondral origin probable as the areas of increased density were not connected with the enchondral zone of growth and areas of cartilage were not observed in any of the numerous areas described above.

Etiology

Windholz, Wilcox (1933), Svab (1932) and Voorhoeve believe the condition to be hereditary. The bones of the hand of a paternal uncle of our case did not reveal the condition. Typhoid, tuberculosis and diabetes have been variously described as factors contributing to the appearance of this condition, but many of the reported cases do not give any such histories and the condition has been found accidentally in healthy individuals, although our case is also suffering from pulmonary tuberculosis. Blood calcium and phosphorus were normal in the cases in which these were estimated, only Windholz has recorded a slight deviation in the calcium and phosphorus metabolism in the blood of two of his three cases.

In the cases reported by Pokorny and Pokorny, Windholz, Svab (1932), Curth (1934) and Buschke and Ollendorf a disseminated lenticular dermatofibrosis was noted. Our case also shows this skin condition and we are of the opinion that there is some definite relationship between these two conditions. If this condition is looked for in cases of osteopoikilosis more such associations will be recorded. We would have missed this condition had we not read an abstract of the paper by Windholz. According to Windholz comparative histological investigation revealed that the foci of osteopoikilosis were the result of islands of compact bone, showing normal osseous structure, whereas the skin changes were the result of fibrotic changes of the cutis, such as described by Buschke and Ollendorf. Voorhoeve thinks that this condition is due to a disturbance of enchondral ossification and should be grouped under dyschondroplasias. Wilcox (1933) thinks it is due to a congenital cartilage anlage. Schmorl's findings do not favour Voorhoeve's theory, and Wilcox's idea does not explain the association of disseminated lenticular dermatofibrosis. The best conclusion seems to be that of Schmorl who thinks the condition to have developed from a congenital anlage without committing the type of the anlage. It is also interesting to note that

Schmorl thought it probable that this condition rose from the fibrous portion of the bone marrow. Perhaps we will be nearest the truth if we say that the condition develops from a mesodermal anlage. This will explain the association of the two conditions. A further investigation of these conditions may throw more light on the process of ossification. Schmorl stated that he found no evidence of inflammation or infection. Bacterial embolism has also been advanced as a possible cause, but without sufficient supporting evidence.

Skin condition

The skin of the thighs and arms was covered with tiny lentil-sized nodules. The colour of the nodules was the same as that of the surrounding skin which was wheat coloured. The patient had these prominences since her birth; they never altered in size.

Pathology

This condition of disseminated lenticular dermatofibrosis was first described by Buschke and Ollendorf in 1928. Their case was a woman of forty-one years of age who was of an infantile build. The skin of shoulders, lower abdomen, gluteal regions and both thighs of this woman showed a net-like arrangement of lentil-sized rather regular prominences. Microscopically, there was evidence of a fibrous thickening of the cutis without the characteristics of tumour formation and with maintenance of the elastic fibres.

The relationship between the two conditions has been discussed above.

Comment

Osteopoikilosis is a very uncommon condition. One can hardly quote fifty cases from the world literature. On looking up the Indian medical literature we did not come across any previous report of this condition. We, however, do not believe that the condition is so rare as that, but it must be admitted that it is quite uncommon. In cases showing the bone condition the skin should be examined for disseminated lenticular dermatofibrosis. We are sure that if this is done their co-existence will be reported more frequently. We believe that the scantiness of the number of cases reported is due to incorrect diagnosis. We hope that more case reports will follow from this country. A wrong diagnosis can put a patient to lot of expense, worry and inconvenience of wrong treatment. A correct diagnosis, on the other hand, will mean a very good prognosis and no treatment will be needed for this condition.

Summary

1. A case of osteopoikilosis of bones with disseminated lenticular dermatofibrosis is reported.

PECULIAR SEROLOGICAL BEHAVIOUR OF A STRAIN OF *LEPTOSPIRA* *CANICOLA*

By B. M. DAS GUPTA

(From the School of Tropical Medicine, Calcutta)

THIS strain was received on 9th July, 1941, from the Lister Institute, London. Since then it has been maintained by subculture on Vervoort's medium.

On 14th October, 1941, a specimen of serum from a case of febrile jaundice was sent to the department for agglutination reaction for leptospiral infection. The serum was put up against all the strains of leptospira then available in the laboratory, viz, strain Chopra (classical *L. icterohæmorrhagiæ*), Mg. Tin Tin (= Java bat strain), Andaman CH 31, Andaman CH 11, and *L. canicola*. It failed to agglutinate all these strains except *L. canicola*. In the latter a few definite clumps were seen and there was also some evidence of lysis in dilutions up to 1 : 80. A week later another specimen from the

before and with identical results. This persistent quality of the serum to agglutinate and lyse in low dilutions the dog strain of leptospira could not be explained. This strain was therefore treated with the serum of a person who had never had jaundice in his life. In this case also the serum in low dilutions tended definitely but not markedly to agglutinate and lyse the leptospiræ up to 1 : 40. But the same serum used 15 days later gave an entirely negative reaction with the strain, thus showing that the agglutinating and lytic properties exhibited by the serum in the fresh state were lost by keeping. It was further noticed that fresh sera heated at 56°C. for 30 minutes also lost these properties.

An anti-serum was prepared by intravenous injection of a rich culture of this organism into a rabbit at intervals of 4 days. After 10 injections the rabbit was bled and the serum was found to react to a titre 1 in 1,000,000. The titre of the anti-serum was not, however, affected by heating. Finally, in order to ascertain if this leptospira will also agglutinate with the normal sera of other animals we procured

Table showing titre of agglutination of various animal sera with the *L. canicola* and some other strains of leptospira

	TITRE WITH				
	<i>L. canicola</i>	<i>L. icter</i>	Andaman CH 31	Andaman CH 11	Mg. Tin Tin
Serum, dog ..	1 : 80	0	0	0	0

same individual was received and agglutination tests were carried out with the same strains as

(Continued from previous page)

2. There is a close relationship between these two conditions and the importance of examination of the skin in cases of osteopoikilosis is emphasized.

3. It is hoped that more case reports of these conditions will follow from this country.

I have to thank the medical superintendent and the staff of the Sh. Gulab Devi Tuberculosis Hospital for Women for their sympathetic co-operation, and Dr. K. L. Wig, M.R.C.P. (Lond.), for constructive criticism.

absolutely fresh samples of sera from a dog, two different species of monkeys, a rabbit, a horse, a hen, an ass and a goat, and tests were carried out with the dog strain and some other strains of leptospira isolated in Calcutta and elsewhere.

The results are shown in the table above.

Summary and conclusion

It will be seen from the foregoing results that many fresh human and animal sera agglutinate a dog strain of leptospira in low dilutions up to 1 : 40 and 1 : 80 and that this property is lost when the serum is kept or heated. As such agglutinating reactions are apt to lead to errors in the diagnosis of leptospiral infection it is important to remember that some strains of leptospira may exhibit the property. The points to remember about such agglutinations are (i) that they are seen only in low dilution; (ii) that only fresh sera exhibit the property; (iii) that the property is lost when the serum is kept or heated to 56°C. for 30 minutes. Although none of the 4 strains available in this laboratory for diagnosis of human leptospiral

A COMPARATIVE STUDY OF THE CAPSULAR REACTION AND THE AGGLUTINATION TEST IN THE TYPING OF PNEUMOCOCCUS

By N. G. PANDALAI

From the Department of Bacteriology, Andhra Medical College, Vizagapatam

As early as 1902, Neufeld observed that the capsulated pneumococcus showed a peculiar change when it was treated with its specific anti-serum, but for a number of years the important practical value of this reaction had not been realized and until our knowledge that there are several serological types of pneumococcus was fully established this reaction had not been utilized in the typing of the organism. Later on, Neufeld and Etinger-Tuleynska (Topley and Wilson, 1936; Armstrong, 1932; Logan and Smeall, 1932; Sabin, 1933) and a number of other workers demonstrated the value of this reaction for the immediate typing of pneumococci. To-day, the capsular reaction, or Neufeld reaction as it is sometimes called, is done in many laboratories as a routine measure for the detection of the type causing lobar pneumonia. However, in view of the accumulating evidence for the efficacy of chemotherapeutic preparations in the treatment of lobar pneumonia, it would appear that the motive for immediate typing of the organism may cease to operate and only the purely scientific value of it will remain.

The capsular reaction is done either immediately with the sputum or any exudate containing the organism, or with the mouse's peritoneal exudate aspirated five to six hours after inoculating the animal intraperitoneally with the infective material. Mouse inoculation is resorted to to concentrate the coccal content in the test material. A well-developed capsular coating is essential to bring out this reaction effectively. Even in the best of cultural conditions capsule formation does not take place so satisfactorily as to produce reliable response. Hence concentration of the organism by cultural methods is useless for the performance of this reaction. Besides, it is time consuming. Mouse

(Continued from previous page)

infection behaved in a similar manner yet the possibility of other strains exhibiting this property when mixed with normal serum or with sera of persons suffering from diseases other than leptospirosis should be borne in mind. As specific agglutinins are not destroyed by heating to 56°C. for half an hour, this procedure may be adopted in cases of doubt.

[After the report was sent to the press, Sir John Taylor, who very kindly studied the strain at my request, informed me that after sub-culture on Fletcher's medium the spirochæte did not agglutinate with the sera of guinea-pigs and horses, and showed doubtful reaction with rabbit's serum in 1 in 20. The difference in the results might be due to the use of different media.—B. M. DAS GUPTA.]

inoculation obviates these difficulties and sufficient peritoneal fluid can be aspirated for typing by either the Neufeld reaction or the agglutination test.

Two other serological methods are available for typing. They are the agglutination and the precipitation reactions. Obviously both are unsuitable for immediate typing. The capsular reaction, though time saving, is not regarded by all authorities as equally reliable as the agglutination test. As specificity is a factor of the capsular substance, the agglutination test should be carried out only with the smooth cultures.

In this article, the writer has endeavoured to show that a simple method of capsular reaction done with adequate care about details is equally as reliable as the agglutination test. Both capsular reaction with sputum and agglutination test with cultures were done individually on 60 different strains of pneumococcus contained in such materials as sputum, pus and cerebrospinal fluid obtained from various sources and the results are studied.

On receipt of each specimen a smear was made and examined for the presence of pneumococcus after staining by Gram's method. Next it was seeded in duplicate on 6 per cent rabbits' blood agar plates for isolation of the organism and inoculated at 37°C. The positive material was then emulsified with four times its volume of sterile normal saline. This process has undoubted advantages as otherwise practical difficulties will be encountered in titrating the tenacious sputum with the serum and longer time would be required for the serum to soak into the fleck of sputum. Besides, with an emulsion a rough quantitative adjustment of the reagents is possible. It would also obviate any error due to unequal distribution of the organism in the gelatinous sputum. For reliability it is essential that the test should be conducted on fresh specimens; otherwise sharp differentiation may not be possible. Having made the emulsion the capsular reaction is done on it immediately. Save for some slight modification, the technique followed is the one that was kindly demonstrated to me by Dr. W. R. Logan in his laboratory at Edinburgh. The specific serum employed throughout this work was the Wellcome brand of anti-pneumococcal rabbit serum and as this firm could not supply all the type sera, it was found necessary to confine this work to the two dominant types—I and II. Three slides were used for each specimen. On slide labelled I and marked off into two halves by a grease pencil line, two loopfuls of the emulsion were placed on each of the two halves. A loopful of Loeffler's methylene blue was placed near one of these and two loopfuls of type I serum near each. They were then mixed separately, covered with coverslips, and rimmed with vaseline. A similar preparation was made with the second slide but substituting type II serum in the place of type I while the third with no serum formed the control. The preparations

were examined after ten minutes by the 1/12 immersion lens under slightly restricted illumination. In positive cases the unstained greenish-white capsule both in the stained and unstained specimen appears very much swollen and in the former stands out in strong relief to the blue surroundings and to the blue-black lanceolate central dots constituting the organism apparently reduced in size. Such reacting pneumococci arrest the attention immediately.

A comparative study of the stained and unstained preparations revealed that the former has more advantages than the latter. Methylene blue has not been found to interfere with the potency of the serum in this particular. Not uncommonly specimens of sputum are encountered in which, while the majority of pneumococci react to the specific serum, a fair number of the typical capsulated diplococci remain apparently unaffected. Probably this may be due to the inevitable admixture of the sputum with mucus containing other types from the throat and the mouth. Mixed infection with more than one type may also explain this inertness. The only difficulty encountered was

that an occasional strain of *M. tetragena* also showed a capsular swelling, particularly with type I serum, but with a little experience this difficulty would vanish. It was also noticed that when a specimen is taken late in the course of the disease, either a higher dilution of the emulsion or a greater proportion of the serum was found necessary to bring out the capsular swelling prominently. Type II pneumococcus presented a wider capsular zone than type I. Whether it is due to any larger amount of specific substance present in the capsule of this type is not evident. As stressed by workers in this field capsular reaction is independent of the agglutinating action.

After twenty-four hours of incubation of the plates a number of green colonies appearing to possess the characteristic features of pneumococcal colonies was subcultured from each plate into tubes of serum broth of pH 7.6 and these were again incubated. These were tested the following day by Gram's method for identification. What appeared to be pneumococcal cultures were inoculated separately into inulin serum water tubes and put into the incubator.

								98	"	1	1	+	+		

All the morphologically pneumococcal cultures from the same plate were mixed, about 5 c.cm. were removed to a sterile test tube and the rest was killed in the water-bath at 56°C. for 30 minutes. The 5 c.cm. quantity was then tested for bile solubility. In the beginning the reagent employed was 10 per cent sodium taurocholate adding 5 drops of it to 5 c.cm. of culture, but it was unsatisfactory often producing only a slight turbidity, even in some of those cases where the organism was subsequently proved to be pneumococcus by the serological methods. Later, a 10 per cent sodium desoxycholate was substituted with entirely satisfactory results. Use of Hartley's broth is preferable to serum broth in the execution of this test.

Next, the agglutination test following Dreyer's method was done with the killed culture, incubating the stands for two hours at 56°C. and reading the results on the following morning, although in most of the cases rapid agglutination took place as in the case of flagellar agglutination. The results were entered parallel with those of capsular reaction, inulin fermentation, and bile solubility (*see table*).

In the above series only those cases where clumping took place in a dilution of 1 in 80 or more have been included. The blank in the 'remarks' column represents cases of lobar pneumonia.

It was noted that the method of dissolving the organism with bile salt does not interfere with its antigenic property; for when the homologous serum was added to the clear solution a thick precipitate was formed while the control remained unaffected. In the case of empyema fluid, or cerebro-spinal fluid, the supernatant fluid from a centrifugalized specimen also produced in low dilutions the precipitation phenomenon on the addition of the specific serum.

The table brings out the fact that there was agreement between the capsular reaction and the agglutination reaction in 58 out of 60 cases. In specimen 61 the smear did not show the presence of pneumococcus while the culture was positive, and in specimen 70 there was disagreement between these two reactions. About 75 per cent of cases are due to the first and the second types. The table also reveals a close correlation between the capsular and the agglutination reactions. Therefore, it would appear that the method of direct typing is adequate, at any rate, in those positive cases of capsular reaction and to proceed further to mouse inoculation or culture for confirming the type for therapeutic purposes would seem to be unnecessary. Only when the organism is very scanty in the specimen does enrichment by mouse inoculation become necessary.

Conclusion

Direct typing of pneumococcus from the sputum or other material is, with rare excep-

IN VIVO ACTION OF SOME SUBSTANCES ON THE PROTEOLYTIC SYSTEM IN BLOOD

By N. K. IYENGER

N. K. DUTT

and

B. MUKERJI

(Biochemical Standardization Laboratory, Government of India, Calcutta)

THE possibility of the changes in the proteolytic system that may be brought about by certain therapeutic substances has been studied in the present paper. The changes in the trypsin content of blood in certain pathological conditions have been reported by Iyengar *et al.* (1942). From these experiments it was considered likely that changes in the trypsin content may be reliable index of changes in nitrogen metabolism. The accumulation of the proteolytic enzymes in blood in certain diseases like nephritis, and its significant reduction in other diseases like cancer and anæmia, etc., were particularly observed. If such abnormal changes in an important constituent of blood take place as a result of the specific pathological condition, it should be the endeavour of the biochemist to investigate the action of drugs that may be able to counteract this tendency. It is, however, not suggested that the rectification of this particular abnormality will cure the specific disease. A study of this kind may help the clinician to give a fair therapeutic trial to those drugs which may be found to have an effect on the proteolytic system opposite to the one brought about by the specific pathological condition. The present study has, therefore, been undertaken with this object, as well as to throw light on the complex proteolytic system reported to be present in blood.

The use of cobra venom in the therapy of cancer has been recommended by Calmette *et al.* (1933) and largely extended by Chopra and Chowhan (1935) and his collaborators. They

(Continued from previous column)

tions, as reliable as the agglutination reaction. The addition of Löffler's methylene blue to the reagents in the slide method does not interfere with the capsular reaction and is advantageous.

Acknowledgment

My thanks are due to the members of the medical staff of the King George's Hospital for the supply of specimens.

report that in most cases the patient is considerably relieved of the pain and this they ascribe to the neurotoxin that is reported to be present in cobra venom. The other explanation is that the venom contains a proteolytic enzyme which acts on the tumour tissue, thus bringing about an improvement in the condition of the patient. This is rather untenable on account of the fact that the amount of trypsin present in the cobra venom is too small to exert any lytic effect, when injected in the doses recommended by the above authors.

The protease in cobra venom has been investigated by Iyengar *et al.* (1938) and found to be a trypsin which is not highly active at a pH near neutrality. The *in vivo* action of the venom on the proteolytic system of blood has not been reported. In view of the significant decrease of the trypsin content of blood in cancer, the rationale of the treatment of this malignant disease by cobra venom may be explained in the light of the results of such a study. Further, Chopra and his collaborators (1937) have reported that the clotting time of blood from a monkey is accelerated by the injection of small doses of cobra venom and is inhibited when the dose of the venom exceeds a particular limit. No satisfactory explanation based on any experimental evidence is offered by them for this rather interesting observation. They merely visualize the possibility of digestion of fibrinogen by the large dose of cobra venom. In view of the rôle played by trypsin in the process of coagulation, it occurred to us that *in vivo* changes in plasma trypsin might be brought about by the injection of the venom.

Current evidence indicates that the oxidation-reduction state of the medium probably plays a determining rôle with respect to the direction in which proteolytic enzymes (particularly cathepsin) act. Bersin and Logemann (1933) investigated enzymic proteolysis as influenced by oxidizing and reducing agents. They observed that mild reducing agents activate proteolysis; whereas oxidants, such as hydrogen peroxide and benzo-quinone, inhibit the reaction. Excessive oxidation or reduction destroys the enzyme itself. Reiss (1938, 1939), who studied this problem in its physico-chemical relation, finds that at a pH near 7.4 the proteolytic activity decreases sharply in a medium where the potential is more positive than + 50 millivolts or more negative than - 100 millivolts. With lower pH value (4.9) there is a shift to a more positive range between + 500 millivolts and + 50 millivolts.

In the light of this interesting phenomena, it was considered exceedingly interesting to study the *in vivo* action of substances like vitamin K. The study of the action of vitamin K in this respect is of particular interest, since it plays an important rôle in the synthesis of prothrombin which is a globulin protein. One of the suggested mechanisms of prothrombin formation is that vitamin K activates protein synthesis, by tending to inhibit proteolysis. There is, however, no

suggestion that vitamin K promotes the synthesis of any other protein except prothrombin. Its action in synthesizing prothrombin should be regarded as remarkably specific.

The *in vivo* action of various doses of 2-methyl-1 : 4 naphthaquinone (synthetic vitamin K) is reported in the present communication.

Material and methods

Cobra venom.—This was obtained from the School of Tropical Medicine through Capt. J. S. Chowhan.

2-methyl-1 : 4 naphthaquinone.—This was prepared by us in the laboratory by the oxidation of 2-methyl naphthalene. The crystals were dissolved in olive oil under sterile conditions before using for injections.

Determinations of free plasma trypsin and total plasma trypsin were made according to the method described in our previous communications (Iyengar *et al.*, 1942).

Determination of trypsin content in red blood corpuscles.—The blood corpuscles are first washed with normal saline and centrifuged twice. Two c.cm. of the washed corpuscles are laked with distilled water and the solution is then precipitated with 4 volumes of acetone. The precipitate obtained after centrifuging is washed well with acetone. The tryptic activity of this precipitate is determined as above.

Determination of catheptic activity of serum.—Two c.cm. serum are precipitated with acetone, centrifuged, and the residue washed twice with acetone. After ordinary drying this precipitate is made into a fine suspension with 10 c.cm. of 1 per cent casein in phosphate buffer of pH 7.0 and the increase in NPN determined after incubation as usual.

Experimental

The experiments were carried out on two dogs kept under controlled conditions in the laboratory animal house. Before we study the action of drugs on the trypsin content of plasma, it is necessary to ascertain the limits within which the trypsin content of the same dog may vary from day to day.

TABLE I

Days	Dog No. 1		Dog No. 2	
	Free	Total	Plasma trypsin expressed as increase in NPN for 100 c.cm. plasma	
			Free	Total
1	18.5 mg.	61.8	22.8	69.4
2	23.2 mg.	58.8	28.4	76.5
3	20.9 mg.	65.6	20.5	62.6
4	24.8 mg.	69.8	26.6	65.8

The free trypsin and the total trypsin in plasma appear to remain fairly constant in each dog.

The effect of injecting various doses of cobra venom intramuscularly on the free trypsin content of plasma was next studied, and the results are given below:—

Weight of the dog = 7 kilograms. Blood was taken for each determination 2 hours after injection of the venom. The injections were given once in 72 hours.

TABLE II

Dose of venom	Trypsin in 100 c.cm. plasma	Dose of venom	Trypsin in 100 c.cm. plasma
<i>nil</i>	25.5 mg.	0.10 mg./kilo	90.9 mg.
0.03 mg./kilo	65.3 "	0.12 "	107.2 "
0.05 "	72.2 "	0.15 "	46.6 "
0.07 "	79.2 "	0.19 "	17.3 "

There is a significant rise in the free trypsin content of plasma after the injection of cobra venom. This increase is, however, not maintained. At the end of 24 hours the trypsin content tends to decrease and within 48 hours it comes to its original level. The cause of this increase in trypsin can be explained in different ways. The venom itself has tryptic activity (Ghosh, 1936; Ghosh and De, 1936; Iyengar, Sehra and Mukherji, 1938) and the increase brought about may simply be an additive effect. This is extremely unlikely, since the actual amount of trypsin that is present in the quantities of the venom injected is extremely small and is further diluted by the circulating blood. The dilution of the venom in the blood after injecting the dose of 0.12 mg./kilo, which brings about a maximum increase in trypsin, is found by calculation to be 1 in 700,000. In such a microscopic quantity of the venom, the trypsin present is practically negligible. Since the blood plasma contains, in addition to free trypsin, a compound of trypsin-inhibitor which is normally inactive, but which can be activated by a kinase, the possibility that the venom might contain the trypsin-kinase has to be considered. In order to test this possibility the following experiments were undertaken:—

Plasma was precipitated directly with acetone and the precipitate was dried after washing with acetone twice. This contains the trypsin-inhibitor compound as well as the small quantity of free trypsin. If this compound could be split up by the addition of cobra venom in a concentration of 1 in 20,000 (which is very much higher than the maximum concentration of the venom in blood after the injection), and consequently increased trypsin activity demonstrated, it could then be regarded as sufficient evidence of the presence of trypsin-kinase.

The above results clearly disprove the possibility of the presence of trypsin-kinase in cobra venom, since there is practically no increase in the tryptic activity of plasma trypsin on the *in vitro* addition of the venom.

TABLE III

In vitro action of cobra venom on plasma proteins

	Increase in NPN after 48 hours
1. (a) 100 mg. acetone precipitated plasma proteins incubated in 10 c.cm. buffer of pH 8.4.	0.25
2. (a) + 0.5 mg. cobra venom in 10 c.cm. buffer of pH 8.4.	0.27
3. 100 mg. casein + 0.5 mg. cobra venom in 10 c.cm. buffer of pH 8.4.	<i>nil</i>

The next possibility of the mechanism of this *in vivo* increase of plasma trypsin is the increased capacity of the red blood corpuscles, leucocytes or platelets which are the chief sources of trypsin in blood, to synthesize the enzyme. Determination of the trypsin content of red corpuscles and the mixture of leucocytes and platelets made before and after the injection do not show any significant difference.

In the light of the above results, the only reasonable explanation that can be offered for the observed increase is that the proteolytic enzyme is released into the blood from the tissues under the influence of the venom. This tentative hypothesis could not be put to test.

By an examination of table II, it can be seen that the plasma trypsin content which has a progressive tendency to rise until a dose of 0.12 mg./kilo of cobra venom is reached, falls down suddenly when the amount of venom is increased to 0.15 mg./kilo. If the dose is further increased, the fall in the plasma trypsin content is much more significant. The presence of trypsin-inhibitor in the cobra venom (Ghosh, 1936, and Iyengar *et al.*, 1938) might be responsible for this strange finding. This inhibitor is present in such small quantity that it cannot effectively exert its action until sufficient concentration of the venom is obtained. When a dose of 0.15 mg./kilo is reached, the inhibitor probably begins to exert its effect and inactivates the trypsin that is released from the tissues. The inactivation of the normal plasma trypsin is also noticed when the amount of the venom injected is further increased to 0.19 mg./kilo. In this case the plasma trypsin content (17.3 mg.) is lower than the normal value (25.3 mg.).

The *in vivo* action of an analogue of vitamin K (2-methyl-1:4 naphthaquinone) was next investigated and the results are given below. Since the substance was injected in an oil medium, the time allowed for complete absorption was six hours. In some cases, the blood was taken even after 24 hours for trypsin determination. It is reported that prothrombin increase can be noticed 6 hours after the injection of vitamin K, although a significant rise can be observed only at the end of 12 to 24 hours.

There does not seem to be any change in the plasma trypsin activity, either free or combined, on the administration of 2-methyl-1:4 naphthaquinone, a synthetic analogue of vitamin K.

TABLE IV

Dog weighing 7 kilos.

Amount injected	ACTION OF 2-METHYL-1:4 NAPHTHAQUINONE ON PLASMA TRYPSIN	
	Free plasma trypsin 6 hours after injection	Total trypsin 6 hours after injection
<i>nil</i>	23.5 mg.	62.6
1 mg.	22.8 "	68.5
2 "	18.5 "	64.2
3 "	24.6 "	61.9
4 "	17.9 "	67.2
5 "	14.8 "	68.4
	18 hours after injection	18 hours after injection
3 mg.	14.5 mg.	65.6
4 "	18.2 "	62.8
5 "	16.8 "	67.9

Trypsin, however, is not known to be influenced by mild oxidizing or reducing agents while cathepsin is known to be definitely affected by the oxidation-reduction state of the medium. It is, therefore, reasonable to expect changes in the catheptic activity of serum under the influence of this drug.

TABLE V

Action of 2-methyl-1:4 naphthaquinone on serum cathepsin

Amount injected	Serum cathepsin (6 hours after injection)	Amount injected	Serum cathepsin (6 hours after injection)
<i>nil</i>	42.6 mg.	3 mg.	28.2 mg.
1 mg.	41.2 "	4 "	29.5 "
2 "	36.5 "	5 "	30.8 "

There is a significant reduction in the catheptic activity of the serum after the injection of the drug. This inhibitory effect must be due to change in the oxidation-reduction state of the medium brought about by the anti-hæmorrhagic substance. This substance is a reversible oxidation-reduction catalyst, the hydroquinone form of which is readily oxidized by molecular oxygen. This action of inhibiting the catheptic proteolysis by 2-methyl-1:4 naphthaquinone may be regarded as favouring protein synthesis since normal anabolism and catabolism of proteins tend towards equilibrium. The net

effect of inhibiting proteolysis must be to favour protein synthesis in the system. This action of vitamin K will therefore serve as a link to explain the mechanism of its action of increasing prothrombin protein as visualized by McCawley and Gurchot (1940).

Summary

The action of cobra venom on the tryptic activity of plasma has been studied. It has been found that up to a dose of 0.12 mg./kilo, there is a remarkable increase in the trypsin content of plasma and it begins to go down if the dose is increased beyond this limit. The various possibilities regarding this increase have been investigated and it is suggested that the venom may be releasing into the blood stream trypsin from the tissues. It is interesting to recall that Iyengar *et al.* (1942) have reported that plasma trypsin is reduced considerably in cases of malignant growth and that Chopra and Chowhan (1935) have recommended the administration of cobra venom solutions in the therapy of cancer. The finding in the present investigation that the plasma trypsin is increased by the administration of the cobra venom may therefore be useful partially to explain the rationale of the treatment of cancer by cobra venom. The decrease in plasma trypsin brought about by larger doses of the venom is explained as due to the trypsin inhibitor reported to be present in the venom. This inhibitor effectively comes into action only when the venom is administered in larger doses not encountered in clinical practice. 2-methyl-1:4 naphthaquinone does not exert any action on the plasma trypsin, but appears to inhibit the catheptic activity of serum. It is suggested that this action of the drug may serve to explain the mechanism of the action of vitamin K in synthesizing prothrombin.

Acknowledgments

Our thanks are due to Sir R. N. Chopra for his keen interest in this investigation, and for the help rendered in certain parts of the experimental work to Mr. K. B. Selra.

A SHORT NOTE ON THE METHODS OF WATER-PROOFING CALICO OR OTHER COTTON FABRICS

By S. N. CHAKRAVARTI, D.Sc. (Oxon.), F.I.C., F.N.I.

and

S. N. ROY, M.Sc.

Chemical Examiner's Laboratory, Agra

As a result of the shortage of rubber owing to war conditions, great difficulty is being experienced in obtaining water-proof fabrics, *e.g.*, coverings for first-aid dressings, military dressings, etc. These coverings are generally made of water-proof sheeting largely of a rubber basis but this is now difficult, if not impossible, to obtain and hence it was thought desirable to discover some simple and cheap methods of water-proofing calico or other cloth fabrics from materials readily available in India.

The following are the more important methods of rendering cloths water-proof :—

General methods

(1) By imbibition of fatty, oily or tarry substances (oiled or tarred fabrics), or the like.

(2) By immersion in a suitable bath leading, after special treatment, to the formation of insoluble compounds of the elements composing the material, the latter being thus rendered water-proof or impermeable.

(3) By coating one or both sides of the material with a layer of rubber or by uniting two fabrics by means of a layer of rubber—the most commonly used method for preparing water-proof material.

(4) By covering one or both sides with a layer of pasty material which is capable of drying rapidly and is based on waxy or paraffin materials or drying oils; the most diverse mixtures of these substances with rubber, resin, castor oil, gypsum, barium sulphate, koalin, talc, ferric oxide, lamp black, etc., are also used.

(5) By covering one or both sides of a material with a more-or-less thick uniform layer of nitrocellulose and camphor mixed sometimes with castor oil and with coal tar colouring matters or substances which give it an opaque appearance, such as zinc oxide, mineral white, etc.

Special methods

(6) *Lowry's process*.—Two ounces soap, 4 ounces glue, 1 gallon water. Soften the glue in cold water, and dissolve it together with the soap in the water by aid of heat and agitation. The cloth is filled with this solution by boiling it in the liquid for several hours, the time required depending upon the kind of fibre and the thickness of the cloth. When properly saturated, the excess of liquid is wrung out, the cloth is exposed to the air until nearly dry, then digest for 5 to 12 hours in the following solution: 13 ounces alum, 15 ounces salt, 1 gallon water. It is finally wrung out, rinsed in clean

water, and dried at a temperature of about 80°F. (27°C.).

(7) *Berlin water-proof cloth* is prepared by saturating the cloth in a solution of aluminium and copper acetate, then dipping it successively in water glass and resin soap.

(8) *Belgian war method*.—The materials to be water-proofed are soaked in a solution of aluminium acetate and then withdrawn without being wrung, and dried in the air.

(9) Apply boiled linseed oil with a little litharge in it (5 per cent) on the calico or other fabric and allow to dry. Give 3 or 4 coats. Each coat should be allowed to dry before the next is put on.

(9a) Dissolve some good resin or lac over the fire in drying linseed oil, till the resin is dissolved and the oil brought to a thickness of a balsam. Spread this upon the cloth so as fully to drench and entirely to glaze it over and then allow to dry thoroughly.

(10) *Wax-cloth or paraffin cloth*.—The superiority of paraffin over most other materials for some kinds of water-proofing consists in its comparative cheapness, in being easily applied and in not materially altering the colour of fabrics. The method of water-proofing with wax or paraffin is too well known to merit description. The chief drawback of the method is that fabrics water-proofed by this method do not stand autoclaving.

Methods (3), (4) and (5) are most widely used but as the essential raw materials for these methods (rubber, nitrocellulose, etc.) are not now available, they may be ruled out. Methods (2), (6), (7), (8), (9) and (9a) were specially investigated by us as we were particularly interested in products that would not only be water-proof but would also stand sterilization in an autoclave. Method (6) was found to be unsatisfactory. Calico or other cotton fabrics can be conveniently water-proofed by the following simple methods :—

(1) Boil for about ten minutes (with stirring) double-boiled linseed oil (available in the market), 100 parts, with 5 parts of shellac and filter through cloth. Apply the filtrate carefully with a brush on the calico or other cloth to be water-proofed and allow the treated fabric to dry in the sun. When dry, give a second coating with the treated linseed oil and again allow to dry in the sun.

(2) Dip the fabric in a saturated solution of aluminium acetate (which for practical purposes can be conveniently prepared by mixing a 30 per cent alum solution and 30 per cent lead acetate solution and filtering) and allow the fabric to remain in the solution (completely immersed) for about 24 hours. Heat the treated fabric in a steam chamber for about 3 hours or allow it to remain in the aluminium acetate bath for a further period of 2 hours and keep the aluminium acetate solution boiling during these two hours. Allow the fabric to dry in the air and then keep it immersed in a hot solution

(80° to 90°C.) of soap (8 per cent) and glue or gum (2 per cent) for about one hour. Take out the fabric, rinse it with a little water (to remove excess of soap and glue) and dry in a drying chamber and finally calender it.

Calico or other cotton fabrics rendered water-proof by any of the above two methods can be sterilized without any detriment to their water-proofing properties. Cloth treated by method (1) is completely water-proof, while water-proof cloth prepared by method (2) has an *excellent appearance* although this method requires careful scientific supervision (e.g., of the pH value of the aluminium acetate solution, etc.).

In European countries it is not now considered necessary that coverings for military dressings

should be impervious to both air and water. The modern methods aim at producing cloth which is water repellent and yet allows comparatively free passage of air. The modern tendency in water-proofing is to treat fabrics with organic compounds which decompose on heating and leave an insoluble, water-proofing film on the fabrics. Among such compounds, velan and quaternary ammonium salts containing a long paraffin chain attached to a polar group which is unsaturated, or which becomes unsaturated by ionization on heating, have been receiving much attention recently. But for the present, these newer methods have to be ruled out for practical purposes as the starting substances are not readily available in India.

A Mirror of Hospital Practice

TETRACHLORETHYLENE AS AN ANTHELMINTIC FOR TAPEWORM

By P. C. DUTT, L.M.F.

Assistant Medical Officer, Tinkong Tea Estate, Assam

MALE fern has been commonly used for many years as an anthelmintic against cestodes, though its administration is very troublesome and even risky to the host.

Maplestone and Mukerji (1931) mention trying of tetrachlorethylene in three cases of *Tænia saginata* infection with apparently no effect. But their further experience with tetrachlorethylene (Maplestone and Mukerji, 1937) claim the drug as an effective remedy in treating *tænia* infections.

Considering the advantages of tetrachlorethylene over *Filix mas* in respect to its simplicity of administration and very little toxicity we also tried it in three cases of tapeworms with encouraging results, which are briefly summarized as follows :—

Conclusion

(i) The treatment in three cases of tapeworm infection with tetrachlorethylene has been noted.

(ii) It is very cheap, easy to administer, fairly efficient and safe, and seems worthy of trial in preference to male fern.

My thanks are due to my chief Dr. J. A. Lewis, medical officer, for his encouragement and kind permission to publish the report.

A CARBUNCLE TREATED WITH HEAT AND CHEMOTHERAPY

By M. L. DIDI, L.S.M.F.

Chief Medical Officer, Kumarsain State, Simla Hills

ONE, Balia, aged 47 years, resident of a village in this State attended the out-patient department of the hospital for the treatment of an abscess on the back

Case	Treatment	Toxicity	Result
(1) Female, 34 years	(i) Tetrachlorethylene .. dr. 1 Saturated solution of magnesium sulphate .. oz. 1 Mixed well after shaking in a phial and given on empty stomach in the morning. (ii) Followed two hours later by saturated solution of magnesium sulphate .. oz. 1	Nil	Successful. (Report after eight months shows no recurrence of the worm. Stool—no tapeworm ova.)
(2) Male, 35 years	Do.	Nausea, warmth in the epigastrium. Slight nausea.	Do.
(3) Male child, 7 years	(i) Tetrachlorethylene .. m. 25 Saturated solution of magnesium sulphate .. dr. 4 Mixed well after shaking in a phial and given on empty stomach in the morning. (ii) Followed two hours later by saturated solution of magnesium sulphate .. dr. 6		Successful. (Treated recently.)

of neck early this month, i.e., May 1942. On examination a big carbuncle was noticed on the back of his neck with several openings discharging pus. The patient was experiencing agonizing pain with no relief in any position. Duration one month. The patient was admitted to the ward. His urine was examined and found sugar-free.

Treatment.—Operation was considered necessary, but as these hill-men are of very hasty nature and do not like to stay in the hospital very long it was avoided and palliative measures were tried. Finely powdered sulphonamide tablet (Boots) was introduced in the interior of the carbuncle through its various openings and hot kaoline plaster was applied over it. Solu-septasine (M.&B.) 10 c.cm. was injected intramuscularly and proseptasine (M.&B.) four tablets a day was prescribed; this is less than the ordinary recommended dose owing to shortage of stock. The effect of all this was that the patient passed a relatively restful night, but next day again he complained of severe pain as before and insisted on going home back in despair. He was dissuaded from leaving the hospital with great difficulty and was given another soluseptasine injection, only 5 c.cm. being given this time plus oral and local treatment as before except that the local treatment was repeated twice a day. Next day, i.e., on the third day of treatment, there was noticed much improvement in his condition and by following up the treatment, except injections, for another two days the whole thing was reduced to discharge as he was feeling cured. However, he was detained for three days more and the same treatment was continued, and at the end of this period (total of one week) he was almost cured, his carbuncle having been reduced to what appeared only a big weal. He was discharged from the hospital in this condition and after a week of his discharge he was quite all right.

MENINGITIS—SIX CASE REPORTS

By N. A. AIENGAR, L.R.C.P., M.R.C.S.
S. T. PARTHASARATHY, M.B., B.S.
S. GUNDU RAO

and
K. RAMSHASTRY

(From the Sri Chamarajendra Hospital, Hassan)

THE ætiology of six cases of meningitis has been investigated in this hospital and the observations are being continued. For lack of facilities, cultural examinations have not been done. All the same, the diagnosis has been arrived at and the ætiology has been decisive in almost all the cases.

Case 1.—Female, aged 22 years, previous history of malaria and cachexia—had been treated in this hospital.

The patient came with a history of fever for 15 days. Admitted in a semi-comatose state with delirium. Fever continuous, ranging between 100°F. and 102°F. Pupils equal on both sides, reacting to light. Facial paresis on the left side. Kernig's sign doubtful; no exaggeration of reflexes; superficial reflexes preserved; response to pain present; incontinence of urine and motion. There were no lung signs. Heart—weakness of the myocardium. Urine—nothing abnormal. Blood smear—malaria parasite not found on repeated examination; differential leucocyte count; polymorphonuclears—60 per cent; lymphocytes—35 per cent; eosinophils—4 per cent; large mononuclears—1 per cent. Total leucocyte count—15,000 per c.mm. of blood. Lumbar puncture—cerebro-spinal fluid under moderate pressure (pressure not measured). Cell count—20 per c.mm. of fluid. Cells—lymphocytes predominating in the fields; polymorphonuclears also present conspicuously.

Organisms—non-motile, Gram-negative bacilli definitely present.

Diagnosis of meningo-encephalitis was made. **Treatment.**—M.&B. 693 soluble 3 c.cm. was given intramuscularly every day, as also prontosil rubrum soluble 5 c.cm. M.&B. 693, 2 tablets twice a day, was given as long as the patient was able to take it, i.e., till the sixth day. The temperature continued unabated.

On the fourth day the patient was more conscious. On the sixth day the patient developed progressive bulbar paralysis and died on the seventh day after admission.

Case 2.—Boy, aged 10 years. Fever for three days. Unconscious and delirious. Kernig's sign positive. Retraction of the head positive. Blood—malaria parasites not found. Polymorphonuclear leucocytes—90 per cent; lymphocytes—10 per cent. Total leucocyte count—25,000 per c.mm. Lumbar puncture—fluid under pressure; highly turbid, almost milky white in appearance. Cell count—500 per c.mm. Organisms—non-motile; Gram-positive diplococci (pneumococci) found in plenty. Cells mostly polymorphonuclear leucocytes.

The patient was put on M.&B. 693 by mouth, 2 tablets once in 4 hours. Fever continued unabated and the patient died on the second day after admission.

Case 3.—Male, aged 25 years, was an in-patient in the ward with influenza broncho-pneumonia. On the 12th day of fever patient had a higher temperature (103°F.) and became delirious. Mild retraction of the head and positive Kernig's sign. Blood—malaria parasites not found. Polymorphonuclears—80 per cent; lymphocytes—20 per cent. Sputum—pneumococci not present. Lumbar puncture—cerebro-spinal fluid under high pressure; almost purulent in appearance. Cell count—500 per c.mm. Organisms—non-motile, Gram-negative bacilli found. Cells—polymorphonuclears predominant.

The patient died 3 days later; he had been put on sulphonamide 2 tablets thrice daily and urea sulphazide, 5 c.cm. intramuscularly daily.

Case 4.—Boy, aged 12 years, was being treated in the ward for influenza broncho-pneumonia. On the 10th day of fever, the patient developed signs of mild meningitis. Blood—malaria parasites not found. Polymorphonuclears—80 per cent; lymphocytes—20 per cent. Total leucocyte count—20,000 per c.mm. Lumbar puncture—cerebro-spinal fluid under high pressure. Cell count—30 per c.mm.; polymorphonuclear cells. Organisms—non-motile, Gram-negative bacilli found.

The patient improved after two lumbar punctures and he made an uneventful recovery. Sulphonamide tablets, 2 thrice daily and urea sulphazide, 5 c.cm. a day intramuscularly were given for 5 days.

Case 5.—Male, aged 40 years. Diagnosis—lobar pneumonia. Admitted on the fifth day of fever, delirious. Blood—total leucocyte count—25,000 per c.mm.

On the sixth day of fever he showed definite signs of meningitis. Lumbar puncture—fluid under pressure, deep straw-coloured and markedly hazy. Cell count—300 per c.mm. Organisms—pneumococci found in plenty. Cells—polymorphonuclears only.

The case ended fatally on the seventh day of fever, in spite of M.&B. 693, which was given orally 2 tablets once in 4 hours.

Case 6.—Female, aged 22 years. Admitted to the hospital with a history of fever for three days and was sent as a case of cerebral malaria. Patient delirious, semi-comatose with 102°F. temperature. Blood—malaria parasites not found. Leucocytes: cent. Total leucocyte count—20,000 per c.mm. There were mild signs of meningitis. Lumbar puncture—fluid under high pressure, hazy. Cell count—50 per c.mm. Organisms—pneumococci found. Cells—polymorphonuclears.

Patient recovered completely after treatment with M.&B. 693 orally and by injection; in all three injections of M.&B. 693 soluble were given and 2 tablets three times a day were given for four days.

Discussion.—Cases of meningitis were reported in the *Lancet* of December 1941, in which the causative organism was shown to be Pfeiffer's bacillus (influenza). With a view to find out the exact cause of meningitis or meningitic signs and symptoms occurring as a complication in cases of pneumonia of all types, a series of lumbar punctures were done. The first series of six cases have been reported here and the observations are still continuing. The first case did not show any lung signs till the sixth day when mild bronchitis was noticed on the right base. This case showed all the signs of meningo-encephalitis. The causative organism in this case and also in cases 3 and 4 was, as far as could be seen, Pfeiffer's bacillus. The other three were cases of lobar pneumonia and developed pneumococcal meningitis as has been reported here. These six cases occurred fairly concurrently and we have had two more cases after them. These two were also lobar pneumonia cases. They developed mild signs of meningitis, or probably meningism on the seventh day of fever and responded well to lumbar punctures and large doses of M.&B. 693. Though the cerebro-spinal fluid in these two cases was under moderate pressure, yet, there was no increase in cellular content and no organisms were found.

URTICARIA DUE TO MALARIAL INFECTION

By P. C. SEN GUPTA, M.B. (Cal.)

(From the School of Tropical Medicine, Calcutta).

ALLERGIC reaction in man as a result of malarial attacks is an exceedingly rare occurrence and available literature shows very few references to such an event. Zallocco (1928) reported a case of a child in whom asthmatic paroxysm accompanied malarial attacks and Thonnard-Neumann (1928) described cases in Haiti where treatment of malaria cured co-existent asthma. Castellani and Chalmers (1919) regard urticaria as a manifestation of hypersensitiveness to the malarial parasite as extremely rare. In recent years, cases showing urticaria as a result of hypersensitiveness to malarial parasites have been reported by Eyermann and Strauss (1930), Davies (1936), Gouriou (1938) and Agrama (1940) in Africa and Europe and by Chatterjee (1939) in India, who reported three cases.

The case reported below was encountered at the Kaorapukur treatment centre, of the Calcutta School of Tropical Medicine. The Kaorapukur centre is situated in the heart of a highly-endemic malarial area about 5 miles from the outskirts of Calcutta. Here about 60 per cent of the total cases treated are malarial subjects and during the malaria season, i.e., end of

September to the first half of January; about 80 to 90 per cent of the total attendance is formed by malaria cases.

Case note

J. B. D., Bengalee female, aged 18 years, attended the out-patient clinic on the 29th April, 1942, for recurring attacks of fever. This year the patient had the first attack of fever a month previously. The fever came on with chill and rigor and with it there were severe urticarial eruptions all over the body and the patient had fits of unconsciousness. The temperature came down somewhat next morning, but it went up again on the following days with chill and rigor and the urticaria persisted. The patient was treated with cinchona alkaloids and she became afebrile after about a week's illness. The next attack of fever (about a fortnight previous to the date of attendance) was similar to the previous one, and lasted about a week, finally coming down with treatment.

The patient was at the clinic at the onset of fever on the 29th April. She had chill and rigor and vomiting, started scratching her body, and soon developed an urticarial rash all over her body. She had a fainting attack too, this however was very short-lived. Her spleen was palpable. Blood was taken immediately and examined for the presence of malarial parasites. *Plasmodium falciparum* ring forms, *Plasmodium vivax* ring forms, growing trophozoites and schizonts were found and the infection was quite heavy. The patient was given an injection of adrenaline hydrochloride m.v. hypodermically to relieve her urticaria for the time being and was given quinine sulphate gr. x in a mixture immediately and advised to continue the mixture twice daily for a week. The fever and the urticaria subsided next day. The attacks of fever were stopped completely in the course of the next three or four days, and she was afebrile and free from urticaria when seen a week later. Quinine was continued for one week more and then the patient was put on a tonic mixture containing iron and arsenic.

In this case each malarial paroxysm was associated with an attack of urticaria and with the subsidence of malaria urticaria disappeared. It seems that in this case, the patient was hypersensitive to the malarial parasites and the liberation of numerous merozoites at the onset of malarial paroxysm gave rise to this manifestation of allergy, viz, urticaria. It was apparently not due to quinine, which really cured the urticaria along with malaria.

Summary

A case where every paroxysm of malarial fever was accompanied by urticaria is reported. This is probably an instance of a very rare condition—hypersensitiveness to malarial parasites, producing urticaria.

JULY

SHOCK

A POPULAR criticism of the medical profession is that we are often so interested in obscure diseases that we are inclined to ignore economically important conditions such as the common cold. There is not so much justification for this criticism to-day as there was, say, before the 1914-18 war when the profession as a whole was less public-health minded than it is to-day. Further this weakness is a natural one; there are two interdependent qualifications that will raise the maximum medical interest in any disease, namely, that it should be (i) a serious and often fatal condition and (ii) preventible and/or curable. It is very difficult to sustain any interest in a disease that is invariably fatal, until some ray of hope appears on the horizon; similarly, we are a little inclined to be bored by other diseases, individually benign, with none the less a high nuisance value and equally incurable, as is the common cold, especially as the practitioner is always expected to produce some infallible cure which must be quite different from that of any other doctor whom the patient has consulted before (because their specifics so often successful at first, as the common cold is a self-limiting disease, have in the long run of course always failed).

Now shock possesses both these qualifications; untreated it is a very serious and often fatal condition, and adequately counteracted it is, one can almost say, a hundred per cent preventible and even when well established almost as certainly curable. It has therefore attracted a very great deal of medical attention during the last few years, especially since circumstances have made it a very common incident, and a distinct advance in our knowledge of the subject has been achieved.

What exactly is shock? Though this is a question that cannot be answered with absolute certainty, there is to-day a fair degree of unanimity of opinion that shock is brought about simply by *loss of plasma from the circulation*, with the other elements of the blood in hæmorrhage, from the surface in the case of a burn, and into the damaged tissues in the case of other forms of injury.

By way of experimental proof of this fact, it has been shown that if an animal is bled repeatedly, the red cells separated from the plasma, and the former returned into the animal's circulation that animal will die even more rapidly than will a similarly-bled animal in which the red cells are not returned. Next, it has been shown that if an animal is subjected to trauma of one limb to the extent of causing shock and then the animal is killed and its two limbs weighed, the increase in weight of the

traumatized limb corresponds to the loss of plasma from the circulation, and that this increase in weight of the limb is due to exudation of plasma into the tissues. Finally, it has been shown that if plasma is given to an experimentally burnt or traumatized animal, in sufficient amount and quickly enough, shock can be obviated.

Shock is thus reduced to very simple terms. Is its treatment as simple? One can say that given suitable facilities it is. The first step is of course to remove the cause, to stop the hæmorrhage or the surface exudation if this is possible; the second is to replace the loss from the circulation. How should this loss be replaced? This will depend on the nature of the loss, namely, whether it was plasma or whole blood. If the loss was whole blood it is usually advantageous, but not necessarily so, to replace it by blood; if the loss was plasma it will certainly be better to replace it by plasma or a plasma substitute rather than by whole blood, but again in most circumstances whole blood will be better than nothing. In neither case will replacement by isotonic saline, glucose, or any other crystalloid solution be of the slightest use for shock proper, as they only remain in the circulation for a very short time and produce only a very temporary rise of blood pressure, though they may be of value to combat dehydration, a very common accompaniment of shock.

The only satisfactory substitute for plasma is serum, and for practical purposes, in the matter of ease of preparation and storage, this has certain distinct advantages over plasma. Another, though infinitely less satisfactory substitute, is gum-saline solution. Experiments are being carried out in different parts of the world to find some really satisfactory transfusate that is not human in origin, whole animal blood, plasma or serum cannot be used on account of the anaphylactic effects that it produces, but as most of the specific substances are associated with the globulin fraction it is believed that it may be possible to prepare an albumin fraction from bovine or sheep's blood that it will be possible to use in the place of human plasma. However this substitute has not yet been perfected and meanwhile we must rely on human sources alone.

The plasma loss in a case of severe shock is very considerable and may amount to half the total plasma volume, that is $2\frac{1}{2}$ pints in an average man, and when it is associated with blood loss the total fluid loss from the circulation may amount to 4 or even 5 pints. It may not be necessary, and it will usually not be advisable, to replace this whole loss, but in a severe case of shock it is seldom worth while giving less than 2 pints, but one is naturally influenced in the individual case by the patient's reaction to the transfusion, and the blood pressure is the best guide. An average good blood donation is a pint; from this very little more

than one-third the amount of plasma or serum is obtainable, so that for a good transfusion at least six blood donations are necessary. This gives some idea of the difficulty of providing sufficient material for blood transfusions that are necessary in the battlefield and in towns during air raids, and emphasizes the urgent necessity for the establishment of proper organizations for obtaining blood from volunteers and the necessity for all healthy persons volunteering when such organizations are established.

Shock is a very fatal condition but it is also curable; the material with which it can be cured is plentiful—every healthy man or woman can easily spare one-tenth of his or her blood per month without detriment to health. It only needs an organization and a very little personal sacrifice to ensure that sufficient of this life-saving material is ready for any emergency. Save, therefore, in exceptional circumstances it is a very grave reflexion on the community when anyone is allowed to die of shock for lack of a blood or plasma transfusion.

NEW EMERGENCY COMMISSIONS FOR SERVICE IN INDIA ONLY

ATTENTION is drawn to this new scheme, further details of which will be found on page 424.

There has been a somewhat surprising hesitancy on the part of the younger members of the medical profession in India to volunteer for service in the present emergency. Political opinions have been used rather as an excuse than a reason to this hesitancy, for no one will deny India's danger or the necessity to defend her shores and frontiers, and if these facts are accepted it is sheer inhumanity to deny her

soldiers proper medical care. The claim that India was being defended in Lybia and at Singapore—which was in some quarters stigmatized as a recruiting trick—is we now know only too true, as the failure to defend our eastern outpost adequately has brought the enemy to our very gates.

There are however many young Indians who have a genuine deep-rooted, not to say a religious, prejudice against leaving their native soil, and the terms of these new emergency commissions will meet this objection; those who take up these commissions will not be asked to leave India. Otherwise, the terms of service are almost identical with those of the temporary and short-service commissions; the basic pay is from Rs. 300 per month to Rs. 550 at the end of six years, there are extra allowances for specialists, liberal charge pay, and generous terms for antedating so that experienced medical men may start well up or even at the top of the grade.

We are sure that there are a very large number of medical men who would genuinely like to be serving their country, and who themselves do not entertain any prejudices but are deterred from volunteering by family opinion. It is not unnatural that parents and wives should be anxious for the safety of their children and husbands but, they are often ashamed to voice these personal fears in the face of the national danger which they cannot deny, and they consequently translate their objections into terms of politics and religion. The young medical man now has an answer to these objections. We believe that very large numbers will apply for these commissions and we strongly recommend those who are proposing to apply to put in their applications immediately.

Special Article

A NOTE ON THE WORK OF DR. P. L. SIMOND ON THE TRANSMISSION AND EPIDEMIOLOGY OF PLAGUE

By J. LOWE, M.D.

School of Tropical Medicine, Calcutta

RECENTLY the author had occasion to prepare a post-graduate lecture on plague, and in doing so read the chapters on plague in several standard textbooks of medicine. In these chapters the portions relating to the early researches on plague at the end of the 19th century and the beginning of the 20th century appeared rather unsatisfactory, and therefore a study was made of the original publications. This study made more clear the unsatisfactory nature of the published account of the work of the period. In particular there was little or no appreciation of the work of a Dr. Simond in

Bombay in 1898 and of a very able article published by him in the *Annales de l'Institut Pasteur* (1898, pp. 625-687) in which many of the now-accepted facts and theories about the epidemiology and transmission of plague were enunciated apparently for the first time.

For a few years after their publication the views of Simond were strongly criticized and even ridiculed, and, later, when the truth of most of Simond's views became apparent, his work appears to have been forgotten, and other people generally credited with the enunciation of the now-generally-accepted theories concerning the epidemiology, spread and transmission of plague. It therefore seems desirable that in the country in which Simond worked and wrote and in the journal which ridiculed his ideas, there should be some acknowledgment of the fact that his contribution to the study of the epidemiology and transmission of plague was

probably greater than that of any other single worker.

The present author does not even know who Dr. Simond was. From his name and from the fact that he wrote in French and published in French journals one surmises that he was of French nationality. In 1894 Simond had made a report to the sanitary authority in French Indo-China (where he was apparently on a mission) of the occurrence of plague in Tonkin. In 1895 this report was published in the *Archives de Médecine Navale*. In what circumstances he came to work and write in Bombay in 1898 is unknown. He apparently published only two articles on plague, but the second of these was of such outstanding merit as to establish him as one of the great workers in tropical medicine.

In order to assess the value of the work of Simond, it is necessary to remind ourselves of what was the state of knowledge of plague at the time that Simond worked and wrote, and shortly afterwards.

As Greenwood has well said, plague is perhaps the best example of the beliefs of unlearned people containing more essential truth and practical wisdom than the opinions of wise and learned men. In all countries of the world where plague was common in ancient times, the fact had been noted that rats began to die before an epidemic of plague occurred amongst human beings. References to this fact are contained in ancient literature of many countries, and the idea is expressed that dying rats had an important connection with human plague. When the last great pandemic started in 1894 and the causative organism was discovered by Yersin, the danger of the spread of plague to many countries was soon realized, and various countries appointed commissions to study the spread and prevention of plague. There was an English Commission in India in 1898-99, a German Commission, an Austrian Commission, a Russian Commission and an Egyptian Commission, and possibly others. These commissions failed to realize the true connection between rat plague and human plague, and they regarded the disease as being conveyed chiefly from person to person. The Indian Plague Commission in 1899 even stated 'there is absolutely no evidence that the disease has ever been carried from one country to another by plague-infected rats in ships'. Even several years later than 1899 the idea was being expressed that rats were commonly infected from human beings and that other rats got the disease by eating dead plague-rats. The idea was also commonly expressed that the disease was a soil infection which could be acquired by man and rats. The main anti-plague measures recommended by the various commissions at that time were the early detection and isolation of plague cases and the disinfection of houses, of articles and clothing by spraying with anti-septics. Both these measures are of very

doubtful or limited utility and it is not surprising that plague continued to flourish.

The idea of plague being primarily a disease of rats was first expressed by Yersin and Roux in 1897 (*Acad. Med.*, 1897, p. 93) and the idea that the disease might be conveyed from rats to human beings by fleas was apparently first expressed very tentatively by Ogata in 1897 (*Centralbl. f. Bakt.*, Vol. XXI, p. 774). Ogata noticed that rats handled immediately after death were dangerous and also flea-infested, but that rats handled some time after death were not flea-infested and were not dangerous. He transmitted plague to healthy rats by the injection of emulsion of fleas from a plague-rat.

This was the state of knowledge in 1898 when Simond wrote his article. It is doubtful whether Simond had any knowledge of Ogata's suggestion regarding the fleas. He makes no reference to it in his article which was published very shortly afterwards, and it appears probable that Simond's ideas were entirely original.

As already stated the article by Simond was published in the October 1898 number of the *Annales de l'Institut Pasteur*, Paris, and was signed by him in Bombay in August. The work was, therefore, probably done at least several months before this date. In this article, which runs to 62 pages, Simond gives an exhaustive and well-documented account of the history and epidemiology of plague in the world as a whole and in India in particular up to that date, with particular reference to the pandemic of plague which he describes as beginning in 1893 in China, the arrival of which in French Indo-China he had reported in 1894. He interprets this history as pointing to the rat as the main reservoir of the disease and the main source of infection to man.

He then goes on to describe his own personal observations and experimentation on the epidemiology and transmission of plague and he advances many views about plague which were completely new at that time, but which have been amply confirmed by later experience.

He stated for instance that the introduction of plague-rats into a healthy area was generally followed by an epidemic of plague in man, but that the introduction of an infected man into a healthy area was often not followed by an epidemic. He found that the epizootic preceded the epidemic, that it was usually localized in one area of a town to begin with, and that human plague later started in that area. He considered that the rat was a much more important agent of transmission of plague than man. He recorded the incidence of plague, month by month, in Bombay and elsewhere and noted that plague epidemics were at the height in the cold season and attributed this to factors connected with the rat. He carried out extensive feeding experiments in rats, and proved that rats were not usually infected by eating the infected tissues of other dead rats, by showing that in order to transmit the disease in this

way, enormous numbers of bacilli had to be ingested and that the disease so produced varied markedly from that seen in nature.

He noticed that in about 5 per cent of human cases a primary lesion in the form of a blister containing plague bacilli was seen, and recorded the site in the body of many of these blisters and found that they were most common on the foot and leg. He considered that the blister was probably at the site of the bite of the transmitting insect.

He then went on to study the parasites of the rat. He found that a plague-rat free from parasites could not transmit the disease to healthy rats kept in the same cage but that a plague-rat infested with parasites could and usually did transmit the disease to healthy rats. He studied the parasites of the rat, the flea and the louse, and he found that these, particularly the flea, contained numerous ingested plague bacilli in their intestinal tract. He crushed infected fleas and injected the material into rats and produced the disease. He therefore considered that the mode of transmission of plague was from rat to rat and rat to man by an infected parasite, most probably the flea. He studied the behaviour of fleas on rats dying of plague. He reported that on death of the rat the fleas detach themselves from the rat's body but remain for a time in the fur, and quickly attach themselves to any animal or man coming in contact with the dead rat. If no such contact occurred they left the dead rat in search of another host. He studied the actual mechanism of transmission. He found that infected fleas while feeding passed plague bacilli in their excreta and considered that the infection might be introduced at the time of the bite and into the proventricular valve with regurgitation of infected blood in attempts to feed, which was actually not recorded until sixteen years later by Bacot and Martin (*Journal of Hygiene*, January 1914, *Plague Supplement*, p. 423).

He noted many other points about plague. He found that fleas may remain infected for a considerable period and suggested that this fact might help to explain the carrying of plague from one season to another. He found that in cities where plague had been present, rats showed a relatively high degree of immunity to plague. He also suggested that variations in the rat population and in their susceptibility to plague played an important part in causing the periodicity of plague. He ascribed the decline and disappearance of the infection in an area to the death of a large part of the rat population, immunity of the remaining rats, and thought that re-population of the area by new strains of susceptible rats might cause recrudescence. He also believed that plague might continue to linger among rats in a benign form in the period

following an epidemic and that sporadic cases in man might thus be explained.

Simond attributed the immunity of laboratory workers to plague to the fact that while wild rats usually had numerous fleas, laboratory rats usually had not. He noted the rarity of plague among the staff of plague hospitals and attributed this to the absence of rats and fleas in the hospitals.

Perhaps the most surprising thing is the fact that he used the mouse-protection test as a measure of the efficacy of anti-plague serum and in his article he gives the result of his work on this subject. He also recorded that the bacilli in cultures gradually lost their pathogenicity, and that for certain experimental transmission, best material. He showed that anti-plague serum (which he obtained from Paris) could usually protect a mouse against infection with bacilli from a culture, but usually did not protect a mouse against infection with fresh virulent material.

He stated that the prophylaxis of plague must be based on the destruction of rats and also of their parasites and on the prevention of the access of rats to human habitations by proper construction or reconstruction. He stated that the conveyance of plague from one country to another on ships could be prevented by the destruction of not merely the rats but of the rats' parasites in ships and advocated the use of poison gas for this purpose. (He suggested sulphurous acid fumes.) He advocated also the immunization of the population exposed to plague infection by the use of anti-plague serum as produced in Paris. (The use of the Haffkine type of vaccine in human beings had only just begun and the vaccine was used chiefly for inoculating animals to produce anti-plague serum.)

Simond stated that his work was very incomplete and had been carried on under great difficulties (he mentions for instance the difficulties for working in a tent in the Indian monsoon), but he considered that it justified the conclusions which he enunciated.

These then were the contributions of Simond to the knowledge of plague all made in 1898. It is extremely doubtful if in the history of medicine any single article has ever advanced so many new and original views which have later been confirmed. A proof of the originality of Simond's views is seen in the fact that in the same number of the same journal in which Simond's article appeared, is another sixty-page article on the same subject by Hanken of Bombay, but it contains not even a mention of the flea.

The reception of Simond's views in the medical world was, on the whole, a very cold one. The various plague commissions and most individual writers either ignored or found little or nothing in the theory of flea-transmission.

A few writers later supported the idea of flea-transmission of plague, including Ashburton Thompson and Tidswell in Sydney, Australia in 1900, Gauthier and Raybaud in Marseilles in 1902 and 1903, and Verjbitzki in 1904, but most workers on the subject scoffed at the idea. A scornful editorial comment in the *Indian Medical Gazette* in 1902 spoke of the 'worthlessness' of Simond's flea hypothesis, and quoted Nuttall of Cambridge and Galli-Valerio as having 'pretty completely demolished' it.

In 1905, however, Captain W. G. Liston published a paper in the *Indian Medical Gazette* on the flea-transmission of plague, in which he reported work very similar to that of Simond with very similar conclusions, but he gave no true account of Simond's work and publication, and quoted Simond's article in relation to one small matter, namely, the occurrence of blisters at the site of the insect bite.

In 1905 and 1906 the Indian (Research) Plague Commission of which Liston was a member carried on its work and issued its report which was published in 1906 and 1907 in the *Journal of Hygiene*. This report quotes freely from Simond's paper and entirely supports Simond's views although it does not make clear how much of the work of the Commission was a repetition and an extension of Simond's work.

It is amazing to note that in 1906 the *Indian Medical Gazette* (still under the same editor who published the scornful editorial of 1902) speaks of the flea-transmission theory as having

been enunciated by Liston, actually calls it 'Captain Liston's rat-flea theory', stated that evidence to support the theory is daily accumulating, and in general hails it as new and epoch-making discovery.

As far as is known the *Indian Medical Gazette* never made any apology for the scorn that it had poured on Simond's work and theories. Perhaps now, forty years later, it may do so and help to establish the name of Simond as a great pioneer of plague research. It should be noted, however, that Browning Smith writing in the *Indian Medical Gazette* in 1906 quoted Simond's work and supports Simond's views and that Bacot and Martin (1914) in their article describing the 'blockage' of fleas, acknowledge Simond's work on the flea-transmission of plague. Since then, however, the work of Simond seems to have been largely, if not entirely, forgotten. In one standard history of medicine which the present writer has just consulted, the name of Simond is not even mentioned. Casual references are made in chapters and articles on plague to certain, often minor, aspects of Simond's work by such writers as H. H. Scott in his *History of Tropical Medicine*, but few modern writers can have studied the original article of Simond as a whole, for, if they had done so, they would have been astounded, as was the present writer, that such an outstanding piece of work viewing plague from so many aspects and recorded at such an early date should not be more widely known, and that Simond should not be recognized as the great early worker on plague.

Medical News

THE TUBERCULOSIS ASSOCIATION OF INDIA

(Proceedings of the Third Annual General Meeting held on the 26th March, 1942, at the Viceroy's House, New Delhi)

HER EXCELLENCY THE PRESIDENT confirmed the proceedings of the second annual general meeting held on the 25th March, 1941.

Lieutenant-General Sir Gordon Jolly, chairman of the central committee of the Association, presented the report of the Association for the year ending 31st December, 1941, and in doing so he said:—

Your Excellency, Ladies and Gentlemen,

Before I present the report for the year 1941, I should like to express to Your Excellency, on behalf of us all, our pleasure and satisfaction that Your Excellency's stay in India has been extended, and that the campaign against tuberculosis in this country will have the benefit of Your Excellency's knowledge, enthusiasm and driving power for a further period.

A full account of the work of the Association and connected organizations is given in the report which is in your hands, and it is not necessary for me to do more than refer to the more important features of the year.

Three new tuberculosis associations were affiliated to the Tuberculosis Association of India during 1941, and there are now 27 affiliated tuberculosis associations of which 14 are provincial and 13 are State. Seven new

tuberculosis clinics have been opened in different parts of India, 12 are in process of construction, and schemes for three more have been approved. Tuberculosis hospitals have been opened in Travancore State and in Bombay Presidency, and the tuberculosis hospital in Baroda State is nearing completion. A scheme for such a hospital in Udaipur has been approved. Sanatoria have been opened in the Punjab and in Sind, and a project for a sanatorium in Assam has received sanction. Increased accommodation for tuberculous patients and improved arrangements for the diagnosis and treatment of tuberculosis have been provided in many general hospitals throughout India. It is apparent, therefore, that the campaign initiated by Your Excellency is progressing favourably and is indeed gathering impetus.

The New Delhi tuberculosis clinic has during 1941 more than justified the expectations of success which were expressed when it was opened, and I think we can claim that it is rapidly approaching the standard to which we desire a central institution to attain. There have been over 20,000 attendances of patients at the clinic during the short period of its existence, and a particularly satisfactory feature was that, of the patients treated, half were referred to the new clinic from hospitals, maternity and child welfare centres and by general medical practitioners. I interpret this as evidence that the clinic has already secured the confidence both of tuberculous patients and

[JULY, 1942]

of the medical profession. Collaboration with the general practitioner is one of the aims of the institution, and there is now a team of local doctors who co-operate with the clinic staff in the organized home treatment of patients which is advocated by the Tuberculosis Association of India. Sir Shri Ram and his committee and Dr. Sikand and his staff are to be congratulated on the excellent beginning they have made.

While the opening of the New Delhi tuberculosis clinic was the important feature of 1940, the year under report will always be notable in the history of the Tuberculosis Association of India for the institution of the Lady Linlithgow Sanatorium in Kasauli. This sanatorium was, as you know, opened by Her Excellency in May last, and the institution, which by her kind permission bears her name, fittingly commemorates Her Excellency's connection as Founder committée with the Tuberculosis Association of India and the great campaign which owes so much to her inspiration. At the opening of the sanatorium Her Excellency announced a magnificent donation of Rs. 20,000 from herself and another of Rs. 10,000 from His Excellency the Patron. As a result of the construction of the sanatorium, for the occupation of which by patients will provide a source of revenue to the sanatorium. Her Excellency has also secured a handsome donation of Rs. 25,000 from a generous donor who prefers to remain anonymous, for a recreation hall and other gifts for equipment such as a cinema outfit and telephone system.

Following upon negotiations carried out with the defence department, wards for the accommodation of forty military patients will be built, the original cost of which is almost completely met from defence services estimates, and the maintenance of which will be paid for by the State for the next ten years. These military wards and twenty of the cottages are under active construction. The number of patients in the sanatorium at present is 88, and further increase is limited only by the uncertainty of the water supply for 1942. Arrangements for an increased supply to the sanatorium have been made and it is hoped that in spite of difficulties occasioned by the war, the additional supply will be forthcoming. It is intended that the sanatorium besides providing modern methods of treatment for patients, will also act as a central teaching centre for doctors and health visitors. This also is dependent upon improved water supply which, it has to be realized, is our limiting factor.

Our most sincere thanks are due to Her Excellency for all she has done to establish and develop this important central institution. We are also indebted to the Pasteur Association of India for their transfer of land and buildings, to the Government of India for their most generous grants, and to all the donors who have made such magnificent contributions of either to the initial cost or to the maintenance of the sanatorium. The medical superintendent, Dr. Joseph, and the medical and nursing staff have worked wonders in the short time that the sanatorium has been open, and provided the water supply difficulty is overcome, the institution can look forward to a successful future. The tuberculosis clinic in New Delhi and the sanatorium at Kasauli will always remain associated with the name of Dr. Frimodt-Möller, the medical commissioner of the Association since its inception until now. What these institutions owe to Dr. Frimodt-Möller's enthusiasm and organizing capacity can never be sufficiently acknowledged. It was a great blow to the Association when Dr. Frimodt-Möller fell seriously ill last August, and the satisfaction at the progress of the work of the Association was clouded by this catastrophe. Apart from Dr. Frimodt-Möller's special interest in the clinic and the sanatorium, his services to the campaign against tuberculosis in the provinces and States of India during his tenure of the post of medical commissioner have been invaluable. His knowledge and experience of tuberculosis in India were

unrivalled, and this gave him an unchallengeable authority as our chief executive officer. You will, I am sure, wish me to make this public appreciation of the services of Dr. Frimodt-Möller as the first medical commissioner of the Tuberculosis Association of India, and of our deep regret that his failing health has made it necessary for him to terminate his connection with the Association.

Dr. Frimodt-Möller's work has, since the end of October, been done by Dr. Benjamin, and I must express the thanks of the Association to Dr. Benjamin for coming to our aid at considerable inconvenience to himself, and also to the Union Mission Committee for generously allowing us the benefit of Dr. Benjamin's services during these months.

The details of the work done by the medical commissioner and his 'locum tenens' during the year are given in the report. An unfortunate result of Dr. Frimodt-Möller's illness has been somewhat to hold up the various training schemes and post-graduate courses based on the New Delhi tuberculosis clinic and the Kasauli sanatorium, but it is hoped that in due course these schemes will be completed and put into execution. Two short post-graduate courses were conducted by the Association during 1941, one in Bombay and one in Calcutta. These courses are being continued during 1942 in Patna and in Lahore. During the year, an important report on the standardization and classification of pulmonary tuberculosis has been prepared by a sub-committee appointed by the Tuberculosis Association of India, and has been published in booklet form. As in the previous years, a special tuberculosis number of the *Indian Medical Gazette* was published, while another publication of the Association was the proceedings of the second tuberculosis workers' conference held towards the end of the year 1940.

This, Your Excellency, closes my brief survey of the most important features of the work of the Association during 1941. The year has been a busy one and I would like to record my own and my committee's grateful thanks to our honorary treasurer, Sir Cameron Badenoch upon whom a particularly heavy burden has fallen and whose wise counsel has at all times been placed unreservedly at our disposal. To the committee I am particularly indebted for their executive support and guidance in the affairs of the Association. Our secretary, Rai Bahadur Dutt, and the office staff have worked to my entire satisfaction.

Sir Cameron Badenoch, honorary treasurer of the Association, presented the audited accounts for 1941. The meeting proceeded to the election of two women members on the central committee under rule 3 (viii) and after voting had taken place Her Excellency the President declared the following persons as elected to the central committee:—

1. Rani Phul Kaurwari of Sherkote.
 2. Dr. G. Stapleton, C.M.O., W.M.S.
- The meeting proceeded to the election of 5 members on the central committee under rule 3 (ix) and after voting had taken place Her Excellency the President declared the following persons as elected to the central committee:—
1. S. B. Teja Singh Malik, C.I.E., I.S.E.
 2. R. B. Captain K. S. Nigam, M.D., F.R.C.S.
 3. Major-General W. C. Paton, M.C., I.M.S.
 4. Dewan Bahadur Balasundaram Naidu, C.I.E.
 5. Mr. G. Kaula, C.I.E.

Her Excellency the President addressed the meeting as follows:—
Once more I have the pleasure of welcoming you and I think you will agree that the Tuberculosis Association of India and its affiliated associations have not allowed the grass to grow under their feet during this last year. Progress goes steadily forward and interest is increasing. I have the opportunity during my tours through India of not only seeing sanatoria and clinics but of talking to those who are engaged in tuberculosis work in those areas and I have been

very much struck by the enthusiasm displayed by those who had taken up the work and who before had hardly realized the existence of this menace in their midst.

Since our annual general meeting last year I have had the pleasure of opening the sanatorium at Kasauli of which Sir Gordon Jolly has given you details. Some of you may have seen the photographs published in the *Illustrated Weekly* of this most lovely spot. When I visit it I always feel that the mere fact of sitting on the verandah absorbing the beauty of the mountains and inhaling the clear sweet air which comes straight from the summits must rehabilitate one in body and in mind. We are fortunate in our superintendent, Dr. Joseph, and the reports which he sends me from time to time show that the patients are happy and are doing well. Some of you may know the difficulty experienced in persuading patients to stay in the hills during the cold weather, but in the last report which I have had Dr. Joseph tells me that he had been able to keep them all.

I have also visited the clinic in Nagpur which is certainly one of the best in India and is doing admirable work. I saw the site for the clinic which is being built in one of the most crowded areas of Calcutta by the Servants of Humanity Society, but at the moment work is held up owing to difficulty of getting materials. In Sind I opened a sanatorium 8 miles from Karachi which will provide an interesting experiment as provision is made for both allopathic and ayurvedic treatment. The patient will be given the choice as to which he prefers, and if the two doctors work in together and compare notes, I feel that each may derive benefit from the other's experience.

I am always rather apprehensive for the future of buildings on scale of this one which have no endowment and I wish that people would take as great an interest in the endowments of buildings as they do in their erection. I fear the custom is too prevalent of putting up a building and expecting Government to keep it going. Recently in Patiala I laid the foundation stone of a first-rate sanatorium and was delighted to find that the State had accepted Dr. Frimodt-Möller's scheme of organized home treatment in full. Two days ago I went to the Model Clinic in Delhi and was able to see the important place which it has made for itself in the scheme for Delhi Province and I am satisfied that the name 'Model Clinic' is being lived up to in the fullest sense of the word.

I feel I cannot close my remarks without paying a personal tribute to Dr. Frimodt-Möller, the first medical commissioner of the Tuberculosis Association of India. His knowledge of the disease, his energy, his organizing ability, his missionary spirit, have been of invaluable help in the start of this Association and of the many associations affiliated to it. His advice was sought in every part of India and his tours must have covered many hundreds of miles. He never spared himself and he inspired all those with whom he came in contact with his own enthusiasm. We as an Association will miss his guiding hand sorely and I will miss him also as a friend and as a collaborator in the work which we both have so much at heart. I know that I carry you all with me when I express to him our profound gratitude for the work he has done for India and our heart-felt wishes go with him for the recovery of his health.

As Sir Gordon Jolly told you, Dr. Benjamin has carried on and we are grateful to him and the Mission which has spared him. I hope Dr. Benjamin will stay on.

The time has now come to appoint another medical commissioner and I feel that the Association would like to have the chance of putting up nominations. This will now be circulated to all the associations. Meanwhile, we propose to ask the United Missions Committee to spare Dr. Benjamin's services to us for a bit longer until arrangements for his successor can be made. I do not think there is anything more to

say, except that all the associations will be circulated for their nominations.

Sir V. T. Krishnamachari proposed a hearty vote of thanks to Her Excellency the President.

MINUTES OF THE MEETING OF THE UNITED PROVINCES MEDICAL COUNCIL HELD IN ITS OFFICE AT LUCKNOW ON FRIDAY THE 27TH MARCH, 1942, AT 11 A.M.

The two following items were included in the minutes:—

The following resolution was considered: 'This Council thinks that the strike by the house staff of the King George's Hospital was a serious offence against the professional conduct of registered medical practitioners and those who took part in it should be dealt with under section 26 of the United Provinces Medical Act'.

A point of order was raised.

It was decided that the resolution as it stands is not according to the procedure in that names are not mentioned. There should be a specific complaint against a specific individual or individuals and anybody may bring forward a proper complaint as required by rule 2 of the rules for the conduct of inquiries under section 26 of the Act.

The following resolution was passed:—

'The United Provinces Medical Council recommends to the Government of India through the United Provinces Government to be pleased to recognize the medical qualifications recognized by the Council as registrable by Indian Medical Council during the present emergency following the precedent adopted by the British Government under Defence Regulation 32-B, by which medical qualifications, hitherto unrecognized have been declared temporarily registrable by the General Medical Council.'

The resolution be forwarded to the Government of India through the Provincial Government for favourable consideration.

MEDICAL SUPPLIES TO CHINA

'I SPENT a busy week exploring their difficulties, learning much of what can be done with courage and capacity in the face of gravely curtailed resources and appreciating the spirit of dogged determination that lies behind the Chinese war effort', said Lieut.-General Sir Gordon Jolly, Director-General, Indian Medical Service, giving an account of his recent visit to Chungking in a broadcast from the All-India Radio. 'My immediate contacts in Chungking', he said, 'were to be with the medical authorities and there on the ... greet me were General Loo Chih Teh, ... of the Chinese Army Medical Services, a man on whom has been laid the heavy burden of organizing and equipping the military and medical services of his country in the face of great difficulties in regard to both personnel and supplies; Dr. P. Z. King, Head of the National Health administration, whose task of providing medical relief for the civil population and preventing the spread of epidemics after many years of war would break the heart of anyone less patient and less resourceful; and Dr. Robert Lim, Director of the Chinese Red Cross, a graduate and former member of the physiology staff of Edinburgh University who speaks English with the homely accent of that town. He controls the Red Cross Medical Relief Corps and the highly efficient Medical Service Training School at Kwei-Yang.'

'With these ... I spent a busy week. We examined ... whole range of medical supplies including those manufactured in China, those which India may be able to supply and those which need to be imported from elsewhere. We also formulated plans for better liaison with one another and discussed the prevention and control of epidemic disease, particularly bubonic plague.'

'Interviews with Dr. Foo, the Vice-Minister for Foreign Affairs and later with the War Minister,

JULY, 1942

General Ho Ying Chin, helped to give me an insight into the problems that have confronted the Chinese in their determined resistance against Japanese aggression and into the methods that have kept them unbeaten. At a special exhibition organized by the War Minister to demonstrate to military officers war production in Free China, which General Ho invited me to view, I was greatly impressed by the range and quality of the munitions and other supplies displayed. In this section dealing with medical stores I noted that many of the drugs we make in India are also manufactured in Free China, while I saw and examined some excellent surgical instruments and a particularly fine exhibit of artificial limbs.

'General Denny's' death made it necessary for me to make certain medical contacts in Burma, which meant my leaving at once, but before doing so Generalissimo Chiang Kai-shek was good enough to give me an interview at very short notice. It took place in His Excellency's house at 9 p.m. The objects and results of my visit were discussed and various proposals for co-operation in regard to medical personnel and stores received the Generalissimo's approval. As a first instalment of these it has already been arranged to give Chinese medical officers special training facilities in India and to release to China from Indian stocks five million tablets of quinine.

TERMS AND CONDITIONS OF RECRUITMENT OF EMERGENCY INDIAN COMMISSIONED OFFICERS TO THE MILITARY SERVICE CADRE OF THE INDIAN MEDICAL SERVICE DURING WAR FOR SERVICE WITHIN INDIAN LIMITS

Type of commission and method of appointment.—The additional temporary medical officers required by the military authorities for service within Indian limits will be appointed by the Government of India on the recommendation of the Indian Medical Service Selection Board from candidates who have applied to the Director-General, Indian Medical Service, for commissions in His Majesty's Indian Land Forces for the duration of the War and for so long thereafter as their services may be required. They will be on probation for a period of 6 months in the first instance and those found unsuitable will be gazetted out of the Service. Candidates will normally be required to appear for an interview before the nearest provincial administrative medical officer, and will have to undergo a medical examination which will ordinarily take place at the time of the interview. Unless the Selection Board decides otherwise they will also be required to appear for an interview before the board or the Director-General, Indian Medical Service. For journeys in India in connection with the interviews and medical examination candidates will be allowed travelling and daily allowances.

Qualifications for appointment.—In order to be eligible for consideration an applicant must—

- (i) be either—
 - (a) a male British subject of Indian domicile whose father (if alive) is a British subject or a subject of a State in India, or a British protected person of the tribal areas; or (if dead) was at the time of his death either a British subject or a subject of a State in India, or a British protected person of the tribal areas, or a person in permanent service of the Crown, or a person who had retired from that service; or
 - (b) a Ruler or a subject of a State in India, provided that the requirements of parts (a) and (b) of this rule may be waived at the discretion of the Government of India;
 - (ii) possess a medical qualification registered in Great Britain and Northern Ireland under the Medical Acts in force at the time of his appointment or an Indian medical qualification recognized under section II(2) of the Indian

Medical Council Act, 1933, or any other medical qualification considered adequate by the Selection Board and registered in British India under one of the Provincial Medical Acts; and be, in the opinion of the Government of India, in all respects suitable to hold a commission in the Indian Medical Service.

Age limit.—A candidate should normally not have attained his 40th birthday at the date of appointment. The Selection Board may, however, waive the age limit at its discretion in individual cases.

Antedate of commission.—(a) An officer will be eligible for an antedate in consideration of professional experience, equal to half the period from the date of his medical qualification to the period of his appointment to an emergency commission in the Indian Medical Service, subject to a maximum of 5 years.

(b) An officer who has held an approved whole-time appointment in a recognized civil hospital may be granted an antedate equivalent to the period of his appointment but not exceeding one year. The period spent in hospital and appointments will not count twice in reckoning the total antedate admissible under clause (a) and this clause.

(c) An antedate not exceeding 6 months may be granted to a candidate who, at the time of selection, is in possession of a Diploma of Public Health registered by the General Medical Council or of a qualification recognized by the General Medical Council as in all respects equivalent to the Diploma of Public Health and as involving a similar period of post-graduate study.

In the case of a candidate who is eligible for an antedate under clauses (b) and (c) above the total period of antedate under those clauses will be limited to one year.

(d) The Government of India may also grant to an officer at the time of his appointment an antedate not exceeding 12 months, in respect of higher qualifications obtained just prior to appointment, which in their opinion justify such grant. Such an antedate may be granted in addition to antedate under clauses (b) and (c) but the total period of antedate in all cases will in no case exceed 18 months.

The maximum period of antedate admissible under this paragraph is 6 years and 6 months. The period of antedate will count as commissioned service for increments of pay and promotion but not for gratuity. In no case will an antedate carry back pay.

Rank and promotion in rank.—An officer will be appointed to the rank of Lieutenant, and if in all respects qualified and recommended, he will be promoted to the rank of Captain on completing one year's full pay service.

Pay and allowances.—The issue of pay and allowances is subject to the general conditions prescribed in the Pay and Allowance Regulations for the Army in India. The following are the monthly rates of basic pay payable from the date of joining for duty:—

Rank and service in rank	Basic pay in rupees per mensem
Lieutenant	
Captain, during 1st year as such	300
" " 2nd and 3rd year as such	350
" " 4th and 5th year as such	400
" " 6th and subsequent years as such	450
	550

In addition to pay, officers who are appointed to hold certain posts will be granted additional pay as shown below:—

Specialist pay at Rs. 100 per mensem will be admissible to an officer who is appointed as a specialist.

Command pay from Rs. 60 to Rs. 240 will be admissible to an officer appointed as officer commanding, or in the case of larger hospitals, as second in command of an Indian Military Hospital.

Charge pay varying from Rs. 80 to Rs. 240 per mensem will be admissible for the medical charge of staffs of certain stations, depots, factories, etc., and at Rs. 60 per mensem for an officer in charge of a brigade laboratory.

For holding charge of a Cantonment Hospital or Cantonment Dispensary an officer will be eligible for such allowance as may be approved by the Cantonment authorities concerned and sanctioned by the General Officer Commanding-in-Chief, the Command.

Note.—The above rates are liable to change from time to time.

Outfit allowance.—Subject to the provision of paragraph 14(c) an officer will be granted on appointment an allowance of Rs. 533.

Uniform, etc.—The uniform will be the same as for regular officers of the Indian Medical Service. Instructions regarding the articles of uniform to be maintained will be issued on appointment by the military medical authorities.

Leave.—Will be governed by the rules applicable to regular officers as authorized from time to time.

Gratuity.—An officer on release from army service will receive a gratuity computed as follows:—

- (a) For the first completed year of army service.
- (a) If he obtained the basic registrable qualification before the 1st January, 1940—Rs. 2,000.
- (b) If he obtained the basic registrable qualification on or after the 1st January, 1940—Rs. 1,000.
- (ii) For each subsequent completed year of army service, one month's pay.

Pensionary concessions on account of disabilities, etc.—An officer who has been pronounced permanently unfit for service within Indian limits owing to a 100 per cent disability attributable to military service, may, on relinquishment of his commission at the rate of Rs. 2,000 per annum. Proportionate rates may be granted for less disability down to 20 per cent. No addition for service shall be made. The amount and continuance of the award will depend on the degree and duration of the disability.

Pensions and compassionate allowances to widows, children and dependents of officers whose deaths are due to wounds, injuries or disease directly attributable to conditions of military service will be admissible under the same conditions and to the same extent as authorized for permanent Indian Commissioned Officer the Service, e.g.—

(a) Widow—		
Rank of officer		Rupees per annum
Lieutenant	..	1,200
Captain	..	1,340
(b) Legitimate children—		
(i) Children's allowance for each child irrespective of the rank of the officer.	..	320 (535, if motherless).
(ii) Educational allowance which may be granted in special cases in addition for each legitimate child in case of pecuniary needs, etc.	..	Not exceeding 310.

The gratuity admissible to the widow of an officer killed in action shall be:—

Rank of officer		Amount of gratuity, rupees
Lieutenant	..	2,000
Captain	..	2,670

Termination of service.—The services of an officer will be terminated normally at any time after the war

is over, but his services shall, at any time, be liable to be dispensed with in the event of any misconduct on his part, of which misconduct the Government of India will be the sole judge, and if his services are so dispensed with he shall automatically forfeit the gratuity specified in paragraph above.

Applicability to ex-temporary and short service commissioned I.M.S. officers.—The preceding terms and conditions will apply to ex-temporary and ex-short service commissioned officers of the Indian Medical Service recruited to emergency commissions in the following modifications:—

- (a) They will count all previous commissioned service in the Indian Medical Service towards pay, promotion and seniority;
- (b) they will be junior to Army in India Reserve of Officers Category 8 (Medical) with the same length of service;
- (c) they will receive the outfit allowance of Rs. 533 only if their previous service in the Indian Medical Service terminated 3 years before the dates of appointment to emergency commissions.

Provided that an ex-short service commissioned officer who is appointed to an emergency commission without a break in service shall be senior to an officer of the Army in India Reserve of Officers Category 8 (Medical) with the same length of service. Officers recruited under these terms and conditions will not be considered for permanent commissions in the Indian Medical Service unless they have transferred to General Service Cadre.

APPENDIX 1

Form of declaration

I, the undersigned, hereby promise and declare that if I am granted an emergency commission I will serve His Majesty the King-Emperor of India, his heirs and successors, as an officer of His Majesty the King-Emperor's Indian Land Forces (Indian Medical Service), so long as my services may be required or until my resignation is accepted and that I will serve in any place to which I may be sent within Indian limits.

Signed this

Witness. day of 19 .
Signature and date. Signature of applicant.

THE INDIAN HONOURS LIST

11TH JUNE, 1942

The following are the names of medical men, and others associated with medical institutions, in the Indian Honours List of date 11th June, 1942. We offer them our congratulations.

Knighthood
Major-General J. Taylor, C.I.E., D.S.O., I.M.S., Director, Central Research Institute, Kasauli.

C.I.E.
Lieutenant-Colonel A. H. Shaikh, I.M.S., Inspector-General of Prisons, United Provinces.
Lieutenant-Colonel G. R. McRobert, I.M.S., Professor of Medicine, Medical College, Superintendent and Physician, General Hospital, Madras.
L. Everard Napier, Professor of Tropical Medicine and Director, School of Tropical Medicine, Calcutta.

O.B.E. (Civil Division)

Major F. D. Dentker, I.M.D. (retired), District Superintendent, No. 3 District, St. John Ambulance Brigade Overseas, Bombay.

M.B.E. (Civil Division)

Miss Jerusha Jhirad, Medical Officer-in-Charge, Cama and Abless Hospitals, Bombay.

Lieutenant-Colonel K. K. Chatterjee, District Superintendent, St. John Ambulance Brigade, Bengal.

Lieutenant J. E. Howard, I.M.D., Assistant Port Health Officer, Karachi.

Rai Bahadur S. H. Pandit, Lecturer in Surgery, King Edward Hospital Medical School, and Medical Officer-in-Charge, Ophthalmic Department, K. E. M. Hospital, Indore.

S. M. Sarwar, Esq., Superintendent, Civil Veterinary Department, North-West Frontier Province.

Kaisar-i-Hind Gold Medal

Miss Hilda Mary Lazarus, W.M.S., Principal, Lady Hardinge Medical College, Delhi.

Miss Ida Mary Roberts, Medical Officer-in-Charge of the American Hospital for Women and Children, Madura, Madras.

A. C. Ukil, Esq., Senior Honorary Visiting Physician, Chest Department, Medical College Hospitals, Calcutta.

Bar to the Kaisar-i-Hind Gold Medal

C. F. Frimodt-Möller, Esq., C.B.E., Medical Commissioner, Tuberculosis Association of India.

Kaisar-i-Hind Silver Medal

Mrs. Alice Helen Duncan, retired Lady District Superintendent, St. John Ambulance Brigade Nursing Division, Calcutta.

Miss Florence Ruth Hart, Doctor-in-Charge of the Church Missionary Society Hospital, Multan Cantonment, Punjab.

Miss Eva Marks, Hospital Matron, Peshawar Indian Troops Zenana Hospital, North-West Frontier Province.

N. J. Everard, Esq., In-charge, Mission Hospital, Kachwa, Mirajpur District, United Provinces.

G. Henderson, Esq., Medical Officer-in-Charge, Mission Dispensary and Leper Asylum, Sankeshwar, Belgaum District, Bombay.

Captain V. K. Mehendale, Medical Practitioner, Sholapur, Bombay.

Bar to the Kaisar-i-Hind Silver Medal

Miss Janet Alexander, In-charge, Mission Hospital, Montgomery, Punjab.

Kaisar-i-Hind Bronze Medal

Miss Mona Ishwardei Das, Lady Doctor-in-Charge, Indian Troops Welfare Centre, Meerut, United Provinces.

Lala H. C. Khosla, Senior Sub-Assistant Surgeon-in-Charge, Civil Dispensary, Beri, Rohtak District, Punjab.

Lala B. L. Malhotra, District Leprosy Officer, Kangra District, Punjab.

Khan Bahadur

Dr. M. Yacob, Assistant Director of Public Health, Epidemiology, and Personal Assistant to the Director of Public Health, Punjab.

Rai Bahadur

Rai Sahib S. C. Sarkar, Police Surgeon, Calcutta.

Rai Sahib R. P. Ghosh, Medical Practitioner, Samastipur, Bihar.

M. Chatterjee, Esq., Civil Surgeon, Bilaspur, Central Provinces and Berar.

Rai Sahib D. N. Ahluwalia, Chief Medical Officer and General Minister, State Council, Bundi State, Rajputana.

Rai Sahib K. Chand, Assistant to the Director, Malaria Institute of India, Kasauli.

Rgo Bahadur

Major T. V. P. R. Pillai, A.I.R.O., Superintendent, Government Royapettah Hospital, and Surgeon, IV District, Madras.

T. Satakopan, Esq., Honorary Physician, Government General Hospital, Madras.

B. Badami, Esq., Director, Veterinary Department, His. Exalted Highness the Nizam's Government, Hyderabad, Deccan.

Shifa-ul-Mulk

Hakim Nizamuddin, Proprietor of the Nizami Dawa Khana, Ajmer.

Rai Sahib

R. R. Mukherjee, Esq., Editor, *Bankura Darpan* and Medical Practitioner, Bankura, Bengal.

K. N. Bhattacharjee, Esq., Medical Practitioner and Honorary Magistrate, Rangpur, Bengal.

B. D. Wadhwa, Esq., Municipal Medical Officer of Health, Moradabad, United Provinces.

H. R. Aggarwal, Esq., V.H.S., Vice-Principal and Lecturer in Pathology, Medical School, Amritsar, Punjab.

B. N. Banerjee, Esq., Assistant Surgeon, Dhanbad Hospital, Dhanbad, Bihar.

S. K. Ghosh Dastidar, Esq., Lecturer in Medicine, Medical College, Patna, Bihar.

J. S. Dutta, Esq., Medical Practitioner, Muzaffarpur, Bihar.

A. P. Sinha, Esq., Civil Surgeon, Koraput, Orissa.

R. L. Badhwar, Esq., lately Chief Botanist, Medicinal Plants and Food Poisons Inquiry, School of Tropical Medicine, Calcutta.

Rao Sahib

K. N. Nair, Esq., Stanley Medical College, Madras.

N. S. N. Ayyar, Esq., Lecturer in Orthopaedics, Medical College and Surgical Registrar, General Hospital, Madras.

M. N. R. Nayudu, Esq., Medical Practitioner, Ellore, West Godavari District, Madras.

C. H. Rao, Esq., Medical Practitioner, Guntur, Madras.

M. Ponnayya, Esq., District Veterinary Officer, Coimbatore Circle, Madras.

C. H. Karnik, Esq., Medical Officer, Sawantwadi State.

O.B.I.

To the First Class with the title of 'Sardar Bahadur'

Indian Medical Department

Sub-Maj. and Hony. Lieut. Bachint Singh, Bahadur.

Sub-Maj. and Hony. Lieut. Rai Sahib Karam Chand Kapur, Bahadur.

Sub-Maj. and Hony. Lieut. Rai Sahib Bishnu Das Sawhney, Bahadur.

Subdr. Khan Sahib Fazal Ilahi, Bahadur.

RURAL SANITATION—A KEY TO SUCCESS

By GAURCHANDRA GHOSH, B.E., M.R.SAN.I.

THERE is a growing demand for the improvement of rural sanitation in India, and many voluntary organizations such as health leagues, co-operative anti-malaria societies, etc., are coming into existence in rural centres. Such organizations always start with a great deal of initial enthusiasm, specially when inaugurated under official influence, but soon die a natural death for lack of co-ordination and want of a definite workable programme.

Any programme of rural sanitation should be drawn up on the basis of the following major considerations :—

- (i) Existing field conditions.
- (ii) Type of executive agents available for the guidance of the workers.

An ideal programme dealing simultaneously with all the problems, big and small, is never workable. It should always be built around one main marketing project which depends on local conditions. Whereas ventilation might be an important problem in the United Provinces, it is of secondary importance in Bengal where the huts have always sufficient ridge ventilation. On the other hand, malaria would be problem no. 1 for Bengal, but may not be so in other parts.

Small isolated and backward villages should always form the nucleus for working out any new methodology for improvement of rural sanitation based on mutual co-operation and self-help. The writer was associated with the work of a health centre situated in a semi-rural area, not far from a big city. Most of the male adult population in the area are daily passengers to city offices, going out early in the morning and coming back tired in the evening. These 'daily-passengers' (as they are popularly called), owing to their constant contact with a big city, consider themselves to be the cleverest of all people, and think that they know everything of all things. Moreover, they could spare very little time to think of public health work. An anti-malaria scheme was introduced in such an area. The scheme was drawn up with the hope that the villagers themselves would co-operate and no expenditure would be incurred on such items as clean weeding of tanks and *dobas*, digging of village drains, minor drainage, etc. All the prominent and influential men of the area were invited to a meeting in which the scheme was discussed. A committee was elected, which was to organize volunteers and submit their recommendations in a subsequent meeting. This second meeting was attended by a single gentleman who happened to be the father of a local clerk of the health centre. So

much for co-operation. Then when the scheme was introduced and a surveyor was preparing a map of the area, he was seriously maltreated and threatened to be handed over to the police, by the owner of a particular tank (open and away from houses) for going round it and fixing flags.

In contrast with this, the writer had experience of working in a village—very backward and far remote from cities. With a view to preparing a malaria control scheme for this area (consisting of five villages) a malaria engineering survey was undertaken in which the villagers co-operated to the extent of providing voluntarily three to six labourers to work as survey coolies every day for a period of about one and a half months. Unfortunately however the control scheme for this area was ultimately dropped.

The second major consideration in drawing up a programme of rural sanitation is the type of technical personnel available for working out the programme. The key man for this kind of work is the sanitary inspector. Under the existing conditions in India the term sanitary inspector is a misnomer. Their major duties consist of vaccination and collection of vital statistics and they can devote very little time to think of environmental sanitation. Nor are they properly trained or qualified enough to carry out the right type of sanitary measures. They are more or less semi-medical officers of health, who not only carry out vaccination and inoculation but are also supposed to diagnose and record diseases (for purposes of statistics) which even trained and qualified medical men are unable to do without the use of proper instruments and laboratory facilities. About the efficiency of such a system the less said the better.

The following describes the duties of a sanitary inspector, in an advanced community:—

'It will be his duty to investigate nuisances and complaints, make sanitary surveys, inspect dairy farms, mosquito breeding grounds, and the drainage area of the watershed upon which the town supply is collected, and to undertake the various miscellaneous outside duties such as the collection of milk samples for laboratory examination, the inspection of markets, etc.' He should also report on any obnoxious or offensive trades, waste or fouling of water, inspect shops relating to ventilation, temperature and sanitary conditions, report on occurrences of infectious or epidemic diseases and arrange for isolation of cases and disinfection, report on overcrowding and supervise scavenging services. 'The position of sanitary inspector calls for a man who is first of all diligent and responsible. He should have a well-developed detective instinct and an abundant supply of tact.'

Pending a reorganization on the above lines little real work on rural sanitation can be successfully carried out. Environmental sanitation must gradually replace the medical functions of the sanitary inspectors. This will also need a reorientation of the course of training for the sanitary inspectors. More stress must be laid on the practical side of things and they must

learn to use their own hands. They should, for example, be able to drill bored-hole latrines, sink tube-wells, and carry out simple repairs. Hundreds of tube-wells in rural areas are remaining out of use for want of simple repairs. Here a bolt is missing, there a piston rod is broken or the valves are worn out—defects which the sanitary inspectors can easily learn to remedy. If again, they are to help in malaria control projects, they must not only learn all the technique such as use of sprayers, larvicides, etc., but must also know how to collect larvae and identify them, and most important of all must have an exact idea as to what is being aimed at as regards the malaria vector for the particular area. Insufficient knowledge in this direction is very dangerous. For example, in some places, indiscriminate opening up and clearing of jungles (which is a very popular item of work for many lay organizations) may actually do more harm.

There is no end to the types of constructive works the rural health organizations could carry out under the directions of properly qualified and trained sanitary inspectors. A number of such items are indicated in the programme given below. This was drawn up as a special detailed programme that might be undertaken for a health week by the Village Health Leagues in Bengal.

Programme for health week

The programme indicated below is a general one and may need modification for particular areas depending on local conditions.

Water supply.—Tanks as sources of drinking water supply are very rapidly becoming obsolete, being replaced by tube-wells in many places. There is a general consciousness even in the remotest villages, regarding desirability of using pure water for drinking purposes, and people would even take the trouble of walking a good distance to collect water from a distant tube-well. Excavation, re-excavation, or protection of tanks for purposes of safe drinking water sources is therefore not recommended except under rare conditions where tube-wells or open wells are not in existence.

1. **Protection of tube-wells.**—Most tube-wells are however unprotected and give a false sense of security. A tube-well must be protected from surface pollution. To ensure this it is necessary that waste water from the tube-well is led away to a sufficient distance from the well. There should be a water tight platform surrounding the tube-well. The following is a typical specification :—

Three-inch beaten terrace floor [lime concrete in the proportions : lime 1 part + sand $1\frac{1}{2}$ parts + *sirkhi* $1\frac{1}{2}$ parts + brick chips ($\frac{1}{2}$ inch) 5 parts], 5 feet \times 5 feet over a brick flat, $\frac{1}{2}$ inch cement plaster over the floor (proportion 1 part cement + 2 parts sand). Three-inch wide brick band round the floor in cement mortar and cement plastered. A 6-inch wide concrete drain at least 20 feet long to lead the waste water away from the tube-well. The floor should have a slope of 1 inch from the centre towards the drain. Brickwork in cement round the pipe, 3 feet 6 inches height \times 10 inches, of which at least 2 feet should be below the ground level.

2. **Repairs to tube-wells.**—Many tube-wells get out of order due to want of minor repairs. Such simple repairs can be very easily carried out by ordinary people, once they are shown how to do it. The following are the usual defects :—

(i) **Leather bucket.**—This gets worn out in about 6 months to 1 year, when it has to be changed.

(ii) **Washers and valves.**—These also get worn out and may be easily replaced.

(iii) **Piston rod.**—This lasts for at least two years and costs about a rupee; it can be easily changed.

(iv) Bolts and nuts often get worn out or broken.

Tools required for opening the pump are two pipe wrenches and a screw wrench. When refitting the pump to the pipe base all the nuts should be tightened simultaneously bit by bit, as otherwise the casting is liable to break. Bolts, nuts and washers should be occasionally oiled with mustard oil as otherwise they get rusted and it becomes difficult to open them.

Even where tube-wells are all in working order it would be a good plan, for purposes of demonstration to the villagers, to dismantle the pumps (by sanitary inspectors or mistries) and show how to change the different parts and assemble them.

3. **Chlorination of open wells.**—Bleaching powder is widely used for disinfection of water. It contains, when fresh, about 33 per cent of available chlorine, but being very unstable it is considered not to possess more than 25 per cent of available chlorine, under working conditions.

Before chlorinating a well its volume of water must first be determined. The diameter and depth of water are measured (in feet) by means of a tape. The volume (in cubic feet) will be

$$\frac{22}{7} \times \frac{\text{diameter} \times \text{diameter}}{4} \times \text{depth of water.}$$

To convert this into gallons the figure has to be multiplied by $6\frac{1}{4}$.

The chlorine dose will vary according to the amount of organic impurity present in the water. The usual dose is 1 part per million (p.p.m.). This works out to 7 grains of available chlorine for 100 gallons of water. Assuming bleaching powder to contain 25 per cent available chlorine we would require 28 grains of bleaching powder for 100 gallons of water. If a stock solution is made such that 100 c.cm. of it contains 28 grains of bleaching powder then for every gallon of water to be disinfected we would require 1 c.cm. of this stock solution, for a dose of 1 p.p.m. The required amount of stock solution is poured into the well and then the water is thoroughly agitated by means of a bucket tied to a rope.

It will however be found that bleaching powder, if not properly kept, will have lost much of its strength. For this reason a sample of 1 gallon of the water to be treated is first collected in a bucket. To this sample is added, say, 1 c.cm. of the stock solution.

For proper disinfection it is necessary that there should be some residual chlorine in the water, after treatment (this can be tested 30 minutes after application by adding 0.5 c.cm. of orthotolidine solution to 10 c.cm. of sample of water). If orthotolidine solution is added to water containing chlorine, the water turns yellow.

The sample of chlorinated water is tested for residual chlorine. The procedure should be repeated with different doses till the correct dose which just indicates some residual chlorine is determined. Once the dose per gallon of water

is determined the required amount of stock solution for the volume of water in the well can be easily calculated.

Open wells should be kept covered. There should be a common rope and a bucket for drawing water. A simple arrangement of pulleys is desirable.

4. *Reserved tanks.*—In villages where there are no tube-wells or masonry wells, one or more tanks should be kept reserved for supply of drinking water. These tanks should be cleared of vegetation which should be removed away from the banks. All jungles and trees on the banks are to be cut off. Trees and shrubs on the banks of tanks provide privacy for the people defecating on the banks. The banks should be raised with earth so that no surface water can get into it.

Chlorination of tanks.—A stock solution of bleaching powder in water is prepared. This is carried to the middle of the tank in a small boat or fisherman's raft. The solution is to be poured into the tank working radially from the centre outwards in all directions and the water is to be thoroughly agitated.

The old method of tying a bag of bleaching powder on to the middle of a bamboo pole and working it backwards and forwards by two men holding the pole at two ends does not work satisfactorily and is not recommended.

5. *Digging of village drains.*—In digging a drain the first point to consider is the point at which the sullage water is to be finally disposed of, i.e., the outlet. This outlet must be at a lower level than the drain, otherwise there will be stagnation of water.

The drains should be straight as far as possible and change in direction is to be provided by means of smooth or circular curves.

6. *Kitchen garden.*—Sullage water in villages may be very well disposed of by watering kitchen gardens. Where this is not possible, bored-holes or soakage pits may be provided.

7. *Soakage pits.*—These may be used as urinals or for disposal of sullage water. A circular pit 4 feet diameter is dug to a depth of about six feet. This is filled with broken *jhama* (overburnt brick) chips starting from 2-inch size at the bottom to $\frac{1}{2}$ inch on the top. The pit, when used as a public urinal for men, is divided diametrically into four sections by means of vertical screens 3 feet high. Ordinary bamboo matting or *hogla* may be used as screens. Two bricks are placed in each section for use as foot rests. For women, another rectangular enclosure for the sides is required in addition.

When used for disposal of sullage water no screens are necessary and one pit may serve four houses.

8. *Bored-hole latrines.*—Bored-hole latrines in many places are more or less in an experimental stage, and where most of the tube-wells are either shallow or unprotected, mass production of bored-hole latrines is not recommended.

This should only be undertaken where the site is carefully selected by the sanitary inspector or other health personnel, and the necessary equipments are available.

A bored-hole latrine is a round hole bored into the earth with an auger 16 inches in diameter. The depth to which it is bored depends on the sub-soil water level. There should be a minimum of about 3 feet of water during the dry season.

A hole about 6 inches deep and 16 inches in diameter is first dug and the auger is placed in this hole and rotated in a clockwise direction. When the auger is filled it is lifted up and the earth is emptied. It is again put back into the hole and the process is repeated till the desired depth is reached.

If the soil is very loose and the hole tends to cave in, it can be protected by putting in a bamboo lining. (figure 1).

Fig. 1.

Squatting plates.—This should be of reinforced concrete. Squatting plates 3 feet by 2 feet 6 inches are made of cement concrete in the following proportions : Cement 1 part, sand 2 parts, stone or brick chips ($\frac{1}{4}$ inch to $\frac{1}{2}$ inch) 4 parts.

The thickness of the plate throughout is 2 inches. The plate is sloped $1\frac{1}{2}$ inches from edges to centre. The concrete is reinforced with $\frac{1}{4}$ -inch diameter rods (figure 2).

The bare squatting plate with the hole is first cast in a mould. After 24 hours it is removed from the mould and the top surface is smoothed and the foot rests are added.

It should be noted that the face of the hole in the squatting plate is splayed outwards and downwards so as to have the larger area of the hole on the bottom surface of the plate.

Completed slabs should be kept in a cool place immersed under water for a period of ten days when they can be removed and fixed over the latrine.

Superstructure.—Any type of superstructure can be constructed. An inexpensive one would consist of side screens of bamboo matting fixed

on to bamboo poles. A type design for a permanent superstructure is shown in figure 3.

9. *Cleaning of tanks and dobas.*—It is necessary to clear weeds in all tanks and dobas and to remove the weeds to a distance. The solid liquid edges have to be cleared of grass.

is almost always inimical to anopheline breeding.

10. *Improvement of cowsheds.*—Living conditions in many places are such that very little can be done in this direction on a general scale. They are very often adjacent to living rooms and

in most cases they form a part of the kitchen with a small bamboo matting partition. There is no ventilation and being very dark provide excellent resting places for mosquitoes.

All that can be done is to provide some simple openings of bamboo framework where this is practicable. Ventilators may also be cheaply constructed by nailing down iron patties (as used in packing boxes) on to a wooden frame. White-washing the walls, where possible, improves matters. The floor is invariably of bare earth and all the urine soaks into it. The remedy is to provide a bedding of dry leaves of banana and other shrubs, waste straw, etc. The urine will soak into it and cowdung can also be easily collected. This bedding is to be removed next morning for composting.

11. *Composting.*—Composting is almost an unexplored field under Bengal conditions. Too much stress therefore must not be laid on this item. The Indore method is too complicated and cannot be advocated for the mass. The Bangalore method seems to be a good one and is undoubtedly simple and may therefore be advocated.

Dry banana leaves, shrubs, water hyacinth, pistia or other vegetation removed from tanks, and straw are provided

as a bedding in the cattleshed for collection of urine and cowdung. An emulsion is made of cowdung in water. A trench is dug 4 feet wide by 4 feet deep by any suitable length. The bedding removed from the cattleshed together

Fig. 2.

Fig. 3.

The banks and edges should be cleared so that they become approachable during the rains for purposes of anti-malaria treatment. Where there is lemna it should not be removed but its growth encouraged. A complete cover of lemna

with other refuse and garbage is to be utilized for composting. First a layer of refuse 2-inch thick is spread on the floor of the pit. This is thoroughly impregnated with cowdung emulsion. Then another layer of refuse is put on it and impregnated with cowdung. In this way the pit is to be filled up within 6 days. On the seventh day the pit is covered up with earth and allowed to decompose anaerobically. No further attention is necessary and the compost would be ready for use as manure after three months.

Summary of programme

1. Protection of existing tube-wells by providing masonry platforms and drains to remove waste water to at least 20 feet away from the tube-well.

2. Simple repairs to tube-wells, like changing of leather buckets, washers, bolts and nuts. This can be arranged as a demonstration by tube-well mistries or sanitary inspectors to educate the villagers so that some of them may themselves be able to carry out such minor repairs in the future.

3. Chlorination of all open wells and provision of covers.

4. Reservation of tanks for community purposes :—

- (a) Water for kitchen.
- (b) Washing and bathing.
- (c) Cattle washing.

5. Where tanks are the sources of drinking water supply, provision of reserved tanks for such purpose. Clearing the weeds, clearing the banks of all shrubs and trees, raising the banks so that no surface water can get into it, provision of bamboo fencing all round if possible, and finally chlorinating the water and not allowing it to be used for any other purpose than for supply of drinking water.

6. Digging of village drains.

7. Provision of kitchen gardens to be watered by sullage water.

8. Provision of soakage pits (6 feet deep by 4 feet diameter) filled with broken *jhama* (over-burnt brick) chips (graded size 2 inches at bottom to $\frac{1}{2}$ inch on top) for disposal of sullage water or use as soakage pit urinal. One pit may serve four houses for disposal of sullage water.

9. Bored-hole latrines at selected sites only, and in localities where augers are available from the Health League, Union Board or other local bodies.

10. Clean weeding all tanks and *dobas* and removing the weeds to a distance. The solid liquid edge to be cleared of grass. Cleaning the banks and edges so that they become approachable during the rains for purposes of treatment (for malaria control) if possible. Where there is lemma its growth should be encouraged.

11. Provision of inexpensive openings of bamboo frames in cowsheds and white-washing where possible.

12. Providing a bedding of dry banana leaves, shrubs and straw in the cattle shed for collection of urine and cowdung.

13. Using the bedding removed from cattle shed together with other refuse for purposes of composting. A trench 4 feet wide by 4 feet deep by any length to be filled up in 6 days with layers of composting material impregnated with cowdung solution. The pit to be filled up with earth covering on the seventh day. It will be ready for use as manure in about 3 months.

Conclusion

In conclusion it must be remembered that the main weapon for this kind of work is persuasion, and as such cent per cent results can never be achieved. A constant watch is essential as otherwise the whole thing soon collapses. '*Time rather than money, and continuity rather than perfection*' should be a motto well applicable to public health work in rural areas.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF ASSAM FOR THE YEAR 1940

THE climatic agricultural and economic conditions during the year were on the whole satisfactory. There were deficiency of rain in January and April, and excess during March. The prices of agricultural produce tended to rise. The vital statistics were collected in the same way as in previous years, and their reliability may be taken to be the same. As explained in the report, the ratios for deaths and births have been calculated on the 'estimated population', and the resultant death-rate and birth-rate are 17.20 against 1925 for 1939 and 28.21 against 28.44 for 1939 for the whole province. The death-rate for infants again decreased, being 141.75 against 149.73 for 1939. The mortality among infants is still heavy, and is due largely to ignorance of mothers, improper feeding and exposure of infants to insanitary surroundings. The need for expansion of child-welfare and maternity work is pressing.

The chief death-causing diseases were fevers, diarrhoea and dysentery, respiratory diseases, cholera, and smallpox. The highest mortality for fevers, which include malaria, kala-azar, and other diseases having fever as a predominant symptom, was recorded in Goalpara, and the lowest in Kamrup. As in previous years quinine and cinchona febrifuge were distributed free to indigent malaria patients throughout the province. The method of diagnosis and treatment for kala-azar was the same as in the previous year. The number of deaths was more by 198, and the number of patients treated by 3,393. The incidence of kala-azar, as a result of survey work, was found to be higher than in the previous year. An indoor hospital with 50 beds was built at Golaghat for serious bed-ridden and complicated cases, and two new public health dispensaries were opened during the year under report. Government have noted with interest the suggestions of the Director of Public Health with regard to further preventive measures and it is hoped that experiments for controlling the suspected vector of the disease may be carried out.

The figure for deaths from typhoid fever is shown as 60, including 12 for Barpeta and 8 for Dibrugarh. The disease is difficult to diagnose, and statistics may not be reliable. Contaminated water-supply and insanitary towns must contribute to the prevalence of the disease, and Government would again draw the attention of municipalities that have failed to provide uncontaminated sources of water-supply or have

otherwise paid insufficient attention to sanitary measures, to their responsibility in the matter.

The reported figure for deaths from cholera was 2,809 against 3,020 in 1939. There was no serious epidemic in any district. Intensive preventive inoculation has been carried out since 1938 with the aim of protecting persons in infected or threatened villages. The number of inoculations carried out in 1940 was 335,559 against 113,727 in 1939, but it appears that further investigation is required before judging the success of the preventive measures.

The reported deaths from dysentery and diarrhoea was 8,964 against 11,641 in the previous year, and for deaths from smallpox 1,400 against 2,197.

Lepers treated in leper asylums and other centres under the medical and public health departments numbered 4,227. A special leprosy officer was appointed and trained during the year. He is now engaged in a survey with a view to devising better organization for preventing the spread of leprosy. Propaganda was carried on with magic-lantern demonstrations by public health officers as before.

Tuberculosis.—The chest clinic at Shillong worked with increasing popularity. The number of patients treated was 206 against 132 in 1939. An x-ray plant installed in November, greatly increased the usefulness of the clinic. It is noted that the honorary work of three private medical practitioners has greatly assisted its success, and Government hope that this clinic and the help received will serve as examples in other districts, where the organization of tuberculosis work,

under the Tuberculosis Association of Assam, still proceeds slowly. In the present year, arrangements are being made for considerable improvement in the facilities for treatment in Shillong.

Food adulteration.—The working of the Assam Pure Food Act is still not satisfactory, and Government have urged on the authorities concerned the necessity for taking up the matter energetically and seriously. Government agree with the Director of Public Health that it is not lack of staffs or the amount of the fees charged for examination of samples that stand in the way of improvement, and trust that the local bodies will be more vigilant in checking adulteration.

Maternity and child welfare.—Trained staff is lacking and there is no recognized institution for the training of midwives in the province. Maternity and child-welfare work continued to be carried on mainly under the Red Cross Society. Government note with appreciation that the welfare centres at Shillong, Sylhet and Nowgong continued to do good work, that there was increased interest in the Goalpara District, and that the Cachar centre has earned special praise from the Director of Public Health. The Shillong Municipal Board made liberal grants for the upkeep of the Shillong centre. The Siva-Sundari Narishikhasram provided a course of training for *dhais* in accordance with the regulations of the Victoria Memorial Scholarship Fund, New Delhi. It is hoped that a Bill for the registration of nurses and midwives will be passed in the near future and that Government will be able to extend facilities for training.

Current Topics

Treatment of Haemorrhage from Dental Sockets

By J. D. CAMBROOK, M.R.C.S., L.R.C.P., L.D.S.

(From the *Medical Press and Circular*, Vol. CCVI, 6th August, 1941, p. 120)

THE vast majority of teeth are extracted without mishap, but when hæmorrhage occurs, the importance of correct diagnosis and a definite plan of treatment is essential. It may vary from a slight ooze to a profuse hæmorrhage, and it may be easily controlled or very resistant to treatment. It occurs at all ages and more often in multi-rooted teeth, owing to greater trauma in extraction.

Immediate hæmorrhage is normal, but in cases complicated by factors interfering with coagulation this passes into the intermediate stage. Intermediate hæmorrhage arises within the first 24 hours, and is commonly the result of a local rise in blood pressure due to alcohol, activity, lying down or the diminution of the astringent action of the adrenalin in the local anæsthetic used. Secondary hæmorrhage takes place after 24 hours and is due to sepsis, unless it is a continuation of the intermediate stage.

The history is of importance and the time and difficulty of extraction should be elicited. Enquiry should also be made as to any previous hæmorrhage from tooth sockets and its course and treatment. The extent of bleeding from cuts and abrasions can be verified as a guide to the general condition.

For examination of the mouth, the patient should sit in such a position that a good light can be directed into it. All clot should be removed, including that protruding from the socket. If the escape of blood from the socket can be prevented in any way, clotting normally occurs and may be strong enough to prevent further hæmorrhage. With this end in view, a plain tampon of cotton wool is made and inserted over the socket and bitten upon for five minutes. If the patient is averse to biting, a four-tailed bandage may be used to ensure that there is some pressure. When tying the bandage,

the presence of paper between it and the hair will prevent entanglement. The clots may now be examined to see if they appear fragile, as happens in blood diseases. After the prescribed interval, the cotton-wool is removed and the socket examined. If the flow has been diminished, it is well worth trying the effect of further tampons left in for a longer time. Small degrees of hæmorrhage and lacerations can be stopped in this manner and the temporary arrest of the bleeding by the pressure of the cotton-wool allows clotting to occur. In cases where there is no diminution in the flow, the socket should be inspected to see if the blood is coming from the gum or the depths of the socket. To do this satisfactorily, the clot is removed with curved dressing forceps. When the blood comes from the gum it will be necessary to insert a stitch to bring the edges of the sockets together, and for this a curved non-cutting needle and horse-hair are necessary. It requires some dexterity to insert a needle through the gum without catching on the bone, and as cutting needles cut through the gum, a plain needle is usually used. Horse-hair is much easier to remove subsequently, as the black colour shows up well against blood and decolorized blood clot. After the stitch has been tied, another tampon is inserted and subjected to pressure. Cases in which bleeding continues are due usually to the stitch being ill-placed or not being tied tightly enough. The actual cautery may be of use when there is bleeding from the gum edge, but there are few cases where it can be conveniently used.

When the blood arises from the depths of the socket and pressure upon a pad does not control the flow, then the socket requires to be plugged. Normally, a plug should aim at occluding the socket, never dilating it. To ensure this, a piece of cotton-wool is fashioned into the shape of a mushroom with a short stem, and the head broader than the socket. This is soaked in the chosen medicament and inserted over the dried socket with its stem into it. Pressure from a tampon causes the medicament to ooze from the stem and mix with the blood. A plug should not be pushed down into the depths of the socket unless all attempts at controlling the hæmorrhage fail and in such cases gauze

soaked in a styptic should be used. It should be removed after 24 hours for fear of sepsis. If the socket is plugged deeply with cotton-wool, its entire removal is not easy in view of the clot, and any left behind causes future pain and suppuration. For preference I use Stypven as the medicament, but with one modification. The package of Stypven contains two bottles, one of liquid and the other crystals to be dissolved in the liquid. If the solution of venom is hot, its power is greatly increased although only of short duration, and as its use is greatest in the first few minutes I always use it heated. The bottle of solution is inserted into boiling water for a few minutes, then the contents are added to the crystals. The previously prepared plug is dipped into the solution after the crystals have dissolved and quickly transferred to the dried socket. A tampon is inserted over it, making sure the plug still covers the periphery of the socket, and held in place for 15 minutes. After that time the mouth is inspected to see if blood is soaking the tampon, and if apparently controlled, the tampon is removed, taking great care not to disturb the plug. If bleeding recurs, a fresh plug is inserted combined with pressure. If however it is lessened, it can be assumed that, combined with general treatment, the hæmorrhage will gradually cease. Another hæmostatic which is useful is oil of turpentine, but although antiseptic it has a very unpleasant taste. Other methods that have been of value are the use of hydrogen peroxide, adrenalin, ferric perchloride, but they are not without disadvantages. Whilst the primary object is the control of the hæmorrhage, any method which predisposes to a septic socket will often cause bleeding later. The plug should be gently removed after 24 hours, and if there is further hæmorrhage another should be inserted. It should not be left *in situ* longer, for fear of sepsis, and the most serious cases I have seen have all been from septic sockets.

Where there is a steady ooze that is difficult to control and it is necessary to give the patient some respite, even of a temporary nature, adrenalin may be injected. Up to 5 minims injected very slowly into the gum near the site of bleeding will often cause enough vasoconstriction to arrest the hæmorrhage. It has the great disadvantage that it does cause some local tissue damage and is of a transient nature, but in a few cases the cessation of the flow enables the blood to form a clot sufficiently strong to hold back further bleeding. The promotion of such a clot may also be facilitated by using Stypven in a syringe. It is used warm, the needle being passed gently into the socket at the bleeding point and the venom expressed so as to mix with the blood. A quickly inserted tampon combined with pressure will hold the mixture of blood and venom there. In the laboratory, the addition of Stypven to blood will cause a very strong clot to form and the tooth socket should be able to replace the test-tube.

The general treatment is of great importance in the control of the hæmorrhage. The patient should be in bed, assuming the sitting posture during the day and having several pillows at night, so as to keep the head as high as possible. Stimulants should not be given and all excitement avoided, the patient being kept as quiet as possible. Diet should be liquid and cold and fed through a bent tube. Morphia gr. $\frac{1}{4}$ is of great value, as not only does it soothe the patient but its depressant action retards the hæmorrhage. In cases where there has been considerable hæmorrhage or where the hæmoglobin has fallen below 50 per cent, transfusion should be carried out. Fresh blood of the correct group and matched with the blood of the patient is given. One pint of blood raises the hæmoglobin approximately 12 per cent. When there has been bleeding for several days, the mouth gets very foul and should be cleansed. This is done by holding a tampon over the bleeding site and swabbing around the teeth with hot peroxide, getting all debris away. This is followed by the application of iodine to the necks of the teeth.

In certain diseases there is a predisposition to hæmorrhage and these cases are those which cause most worry.

Amongst them must be mentioned obstructive jaundice, purpura, high blood pressure, leukæmia, hæmophilia, scurvy and septic and toxic states. Extraction of teeth should not be carried out unless strictly necessary and after full pathological investigation of the blood and adequate preparation of the mouth. In view of the fact that some hæmorrhage is likely to occur, as much sepsis as possible should be eradicated by the dental surgeon before extraction. The teeth should be scaled and polished, every care being taken that all subgingival tartar is removed. Local treatment of the dried gums and pockets with 25 per cent silver nitrate or deliquescent zinc chloride will considerably reduce any gingivitis present. All stagnation areas must be dealt with. Cavities in the teeth can be filled with temporary fillings, and deep pockets, which cannot be eradicated, are packed with cotton-wool impregnated with a mixture of zinc oxide and oil of cloves. This sets quite hard and not only does it prevent the stagnation of food but it has a very beneficial effect on the gingivitis present. The use of hydrogen peroxide with an equal quantity of warm water as a mouth wash, forcing it between the teeth to remove any particles of food, is of definite value. In short, any method of improving oral hygiene and curing gingivitis is to be recommended. The adequate preparation of the mouth cannot be stressed too greatly.

The pathological investigations required are blood and platelet counts, group, hæmoglobin and clotting and bleeding times against a normal control. A tourniquet test for capillary fragility is done at the same time. Cases which show a prolonged clotting time should have a prothrombin estimation to see if there is any deficiency present. In all the conditions mentioned, with the exception of raised blood pressure, there is usually some alteration in the blood picture. Obstructive jaundice shows a prolonged coagulation time with a low prothrombin whilst purpura has a prolonged bleeding time with a diminution in the number of platelets and a positive tourniquet test. Leukæmia gives a characteristic blood picture, and it is suggested that in this condition the liability of hæmorrhage is due to the degree of anæmia present causing local damage. Hæmophilia has a marked increase in coagulation time but it must be remembered that in this disease there are negative phases when it is very nearly normal. Therefore, when extraction is contemplated, too great a reliance must not be placed on a short coagulation time but rather it should be done immediately before the proposed time of extraction. Scurvy shows a positive tourniquet test owing to changes in the walls of the capillaries, whilst in septic or toxic states the platelet count is reduced and both the clotting and bleeding times may be increased.

These pathological investigations, combined with the clinical picture, are of the utmost value in prognosis and treatment. They may indicate the very grave risk of tooth extraction unless better conditions prevail. Apart from the general treatment of the patient, there are certain measures which can be taken to improve the deficiencies of the blood. Transfusion of fresh blood when the hæmoglobin is below 50 per cent, has already been mentioned but it has other uses than raising this level. It decreases the clotting and bleeding times and increases the platelet count when these are abnormal and also acts generally as a stimulant to the hæmopoietic system. When used in cases of blood disorder, it should preferably be of the same group as that of the patient. The hæmoglobin may also be raised by other methods of choice when circumstances permit. When the prothrombin is decreased, this may be restored by the injection of vitamin K. The dose should be determined by the level of the prothrombin, and one of the proprietary preparations, five milligrams daily, should be injected until normality is reached. In cases critically ill, the dosage may be increased several times as no untoward effects have been observed. It should be remembered, however, that vitamin K is without effect on blood clotting times that are abnormal owing to causes other than hypoprothrombinæmia. The use of ascorbic acid in scurvy is well known and

in proved cases 1,200 milligrams daily over a period of four days is quite adequate.

In these cases predisposed to hæmorrhage, the extraction of a test tooth is often of value. There are so many factors influencing the prognosis that the removal of one tooth under optimum conditions can be of great value. Usually a front tooth is chosen because of the small diameter of the socket and its accessibility. After all preoperative treatment has been satisfactorily carried out, the tooth is taken out under local anæsthesia. If possible this should be a nerve block to obviate the local trauma of the injection of a fluid into the tissues. Stypven may be mixed with the blood in the socket and a Stypven plug inserted and covered with a tampon. The subsequent course and necessary treatment will give valuable information for the purpose of future extractions.

SUMMARY

(1) Methods of local treatment for the arrest of hæmorrhage are discussed.

(2) The general treatment is described.

(3) Conditions predisposing to hæmorrhage are reviewed with their pathology.

(4) The preoperative local and general treatment is indicated and the method of carrying out a test extraction.

Sulphonamide Therapy of Trachoma

By J. E. SMITH, M.D.

L. A. JULIANELLE, Ph.D.

and

J. H. GAMET, M.D.

(Abstracted from the *American Journal of Ophthalmology*, Vol. XXIV, p. 174)

THE adoption of sulphonamide derivatives for the treatment of various ocular manifestations has aroused considerable interest and enthusiasm in ophthalmology. Among other infections subjected to experimental study with these drugs, trachoma and, to a less extent, the related inclusion-bearing conjunctivitis have been given repeated trials in various countries. While opinion remains divided as to the actual efficacy of sulphonamide compounds in trachoma, it must be admitted that, by popular impression at least, their therapeutic effectiveness in this condition has been largely accepted. In an earlier investigation in which one of the present writers participated, however, trachoma did not respond so favourably to the action of sulphanilamide as had been anticipated at the outset of the study. Since the publication of these observations, an additional number of reports have appeared for the most part stressing the curative value of sulphanilamide and its related products in trachoma. It has consequently become desirable to re-study this form of treatment with the object of establishing, if possible, an explanation for the discrepant results observed by various investigators. With completion of the study, it seemed a timely opportunity to review thoroughly the pertinent literature for the purpose of critical analysis. The present communication, therefore, will serve primarily as a report of the experiments conducted, and secondarily as a critic of the publications appearing up to the time of writing.

METHODS OF STUDY

The bulk of the study was conducted at the Missouri Trachoma Hospital at Rolla, Missouri. The patients, originally 31 in number, were reduced to 26, since the remaining five for one reason or another refused to continue treatment too early in the experiment to be of consequence in the study. They were all native whites, hospitalized during the entire period of observation. Treatment consisted of the oral administration of sulphanilamide, the dosage calculated on the basis of body-weight as recommended by Loe; namely, one-third grain per pound of body-weight for the first 10 days of

treatment, and then one-fourth grain for the following 14 days, the drug being given in three doses, with an equivalent quantity of sodium bicarbonate. No other form of treatment was given, although irrigation with saline and boric acid was carried out each morning. In cases of corneal ulceration, atropine was applied locally as indicated (for example, iritis), a measure which functions not as a curative, but as a palliative.

Detailed clinical examinations were made once a week when visual readings were also determined. Temperatures were taken twice daily, and complete blood counts, including differential and hæmoglobin estimation (by the Sahli method), were made at least once a week and in most patients more frequently. In order to estimate the absorption of sulphanilamide, determinations of the blood concentrations were made once a week or oftener by the method of Marshall and Litchfield. Conjunctival scrapings were examined for the presence of inclusion bodies so that their behaviour during treatment might be ascertained. The frequency of inclusions when present, however, was so low in the patients observed, that the appertaining data appear of little if any value and for that reason they need not be considered in this report.

In addition to the patients treated by oral administration, a group of nine individuals was observed at the Washington University Clinics and a group of three at Rolla under topical applications of 2½ per cent neoprontosil. For the most part, these patients treated themselves and reported for examination at the clinic once a week. The neoprontosil was applied as drops four times a day.

TYPES OF PATIENTS SELECTED FOR STUDY

No particular effort was made to select any of the patients for this study. They were accepted as they were admitted to the hospital unless the disease appeared to be inactive and the predominant condition was obviously complicatory and demanded correction by surgical measures. Nevertheless, analysis after the treatment suggested that presentation of the data might be more readily accomplished by a partition of the patients into four clinical groups: first group consisted of seven patients in whom the infection was essentially limited to the lids, either in the form of follicular or papillary hypertrophy or both, and with little more than a beginning pannus without infiltration of the cornea; the second group, six in number, exemplified varying degrees of activity of both lids and cornea; the third group was composed of nine patients with predominant and massive corneal disease, but exhibiting little or no involvement of the conjunctiva; the lids were more or less scarred and inactive, while the cornea varied in intensity of pannus, degree of infiltration, and scarring, but in every case the infection was distinctly active; and the last contained four individuals in whom the disease was not only corneal as in the preceding, but was in a stage of active ulceration. It was not expected that sulphanilamide would replace cicatricial tissue in the group of corneal patients; they were included for study only to determine whether the drug could terminate the activity of the disease.

Of the patients studied, 16 were males and 10 were females; their ages varied from 7 to 63 years, and their symptoms covered a duration of a few months to over 20 years. Thus, the trachoma was of less than one year's standing in five patients: of 1 to 5 years in three, of 6 to 10 years in four, of 11 to 15 years in four, 16 to 20 years in one, and of 20 years or more in eight. A number of the patients had had several admissions to the hospital in the past and their treatment had been extensive and varied, depending upon the predominant condition at the time. It is seen, therefore, that the total group represents a typical cross-section of both patients and disease.

RESULTS OF THE TREATMENT WITH SULPHANILAMIDE

It may avoid possible misconception to point out in the beginning the degree of adsorption of sulphanilamide in this study. As already stated, the patients received sulphanilamide *per os*, one-third grain of the drug per pound of body-weight for the first ten days

of treatment. During this interval, the blood concentration of the drug ran close to 4 mg., plus or minus, per 100 c.c. of blood. With reduction of the drug to one-quarter grain per pound of body-weight over the next 14 days, the blood level dropped proportionately and the determinations during this period revealed blood concentrations varying between 2.0 and 2.5 mg. per 100 c.c. of blood. It was observed, moreover, that withdrawal of the drug caused a rapid decrease of the blood level, so that, in general, the drug was completely or almost completely eliminated within 24 hours. Irrespective, however, of the type of trachoma, practically all patients undergo a rapid amelioration, as measured by subjective symptoms. Thus, for example, photophobia is minimized, secretion or lachrimation is decreased, and a general feeling of increased comfort is simultaneously noticeable. How much of this improvement, however, is referable to sulphanilamide and how much to the general hospital care instituted is difficult to gauge.

Twenty-six patients with trachoma of different clinical varieties were treated with sulphanilamide *per os*. With termination of the treatment, two were considered asymptomatic or arrested, 11 were regarded as definitely improved but still clinically active, and 13 maintained a more or less stationary clinical condition. In other words, half the patients profited from the administration of sulphanilamide. This proportion is reasonably close to that (60 per cent) observed in the study referred to above.

The patients treated with instillations of neoprontosil, as stated previously, were carried for two to three weeks in this manner. In all there was a definite improvement, not only subjectively but even clinically. The improvement was discernible within a few days and reached a maximum at about the end of the first week. From then on the clinical appearance remained stationary, and it became obvious even after another week or two of continued instillations, that whatever benefit was to be derived from this method had already occurred. Consequently, it became necessary to resort to one or another of the metallic salts, in order to render the patients asymptomatic.

TOXICITY OF SULPHANILAMIDE

The potential toxicity of sulphonamide derivatives has been emphasized frequently by a number of workers, so that there is no necessity for reviewing the different manifestations at this time. As a matter of record in this study, however, it seems desirable to summarize briefly the incidence of toxic reactions observed in the present group of patients. In five patients it was necessary to discontinue sulphanilamide because of its deleterious effects; in one, the red-cell count dropped progressively from 4,210,000 to 3,000,000, with the haemoglobin value decreasing from 78 to 68 per cent during nine days of treatment—bovine was administered and it required a week before a count of 4,000,000 cells per c.mm. was attained; a second patient was dropped after 13 days because of severe headache and fever; and in three others, fever, cyanosis and nausea had become troublesome, necessitating cessation of sulphanilamide on the 9th, 10th and 13th days, respectively. Other toxic manifestations not sufficient to stop treatment were: fever, 15 patients, in only three of whom, however, the temperature reached above 100°F.; headache in four; marked cyanosis in three; and gastric disturbances in five. Only seven individuals apparently suffered no untoward reaction at all to the drug. Except for the patient mentioned, no marked effect was found on the blood cells, although several individuals showed a gradual diminution in the number of red cells. Toxic reactions to sulphanilamide are relatively mild and negligible; in no case need they be dangerous, since sufficient warning to withdraw sulphanilamide is provided by one sign or another.

REVIEW OF COLLATERAL LITERATURE

If an estimate is made of the 36 publications it is seen that of the 11 reporting successful results following drug treatment alone three can be accepted as actually supporting their conclusions with appropriate

evidence. Five additional publications likewise report success, but the evidence is rendered doubtful by supplementary treatment with local agents. This is, therefore, a small proportion of papers justifying the opinion of the therapeutic effectiveness of sulphonamide drugs. If, on the other hand, improvement rather than 'recovery' is taken as an index of efficacy, all but three of the 36 reports are in accord. It would seem, therefore, that the sulphonamide compounds may serve a beneficial purpose in trachoma if supplemented by one or more of the orthodox topical treatments. In fact, this procedure has been employed by several workers as already referred to above.

DISCUSSION

That adequate dosage is of paramount importance in the chemotherapeutics of infections is a precept formulated from repeated experience. In addition, it has become more or less axiomatic that wherever feasible the employment of large dosages over short periods is preferable to the employment of small dosages over prolonged periods. The reason for the preference is that, firstly, whatever destructive capacity the drug possesses may be exerted at once, and, secondly, by shortening the duration of treatment, there is less likelihood of the infectious agents becoming adapted or 'fast' to the particular drug.

A study of the dosages adopted by the different investigators reporting successful results from sulphonamide treatment of trachoma suggests either a complete apathy to the principles outlined above, or a practically complete intolerance of the virus of trachoma to these derivatives. Thus, the dosages employed vary from 15 grains to 90 grains or more a day, and the duration of treatment extends from a few days to 70 days or more. While variations in dosage and length of treatment are to be anticipated from case to case, differences of 5 to 6 times in daily dosage and 2 to 8 times in duration of treatment (with apparently equally beneficial effects at one or the other extreme) surpass the usual expectations. The few studies made on the blood level attained by the drug reveal variations up to 6 mg. per 100 c.c. of blood, although half this quantity was also reported effective. Moreover, if the blood level may be estimated from the dosages given, these same authors show that a considerably lower concentration as 20 grains per day for an adult is still effective in eliminating the virus of trachoma. It has been, consequently, a difficult matter to decide on proper dosage in this study.

Clinical experience in trachoma suggests that complete recovery in all patients and complete lack of reference in all individuals rendered asymptomatic is an almost impossible achievement. Yet sulphanilamide has apparently done exactly this in two large groups of patients. Even though the patients were Indians (American), and it is admitted that trachoma in Indians does not approximate the severity of the disease seen in native whites (for example, in Missouri, Kentucky, Tennessee, Arkansas, and other states), the record is better than one would expect.

It may be of interest in this connection to point out that recently another worker has reported that of 34 patients treated with sulphanilamide, 21 (62 per cent) suffered recurrences, 11 within six months after the end of treatment, and 10 within seven months to two and a half years. It is of further interest that in the present series of patients studied, one of the two discharged at the end of treatment as asymptomatic returned to the hospital since this report was written with an exacerbation requiring active treatment. The elapsed interval between discharge and recurrence was approximately four months.

The various degrees of improvement observed by the large majority of workers are more or less generally agreed upon, regardless of the drug, the dosage, or the method of administration. There is no doubt that within a few days the patient exhibits subjective improvement and 'feels better'; the disappearance of photophobia, pain, blurred vision, itching and other symptoms, adds to the patient's comfort, vision, and appearance. But this does not mean, of course, that

recovery or inactivation of the virus in the tissues has been effected. One wonders, nevertheless, how much of the improvement is the result of the specified treatment. Experiments conducted in the past by the present writers with various preparations, such as gentian violet, citric acid, yatoconin, quinine ointment, chaulmoogra oil, and other medication, revealed that all induced a measure of improvement, to a greater or less extent; consequently, the impression was unavoidable that the hospitalization, the daily irrigations, and the special treatments experimental patients always receive were unquestionably responsible for an appreciable portion, if not all, of the improvement. Comparison of the treatment described above with the usual treatment with metallic salts, and other means, indicates to the present writers that the patients treated with sulphanilamide would also have improved under the usual form of treatment. And in those cases where grattage was indicated, the results would have been more gratifying.

SUMMARY AND CONCLUSIONS

1. A study of sulphonamide therapy in trachoma has been undertaken in the manner described above.
2. Following the administration of sulphanilamide *per os* to 26 patients, the disease in 2 was arrested, 11 were improved, and 13 unchanged at the end of the treatment.
3. Following neoprontosil applied topically, as already outlined, a definite improvement was observed in all of nine patients. All were subsequently given some other form of treatment in order to render them asymptomatic.
4. A review of the correlated literature has been made and the results have been analyzed.
5. A conservative opinion at the present time would be that sulphonamide compounds cause a disappearance of the non-specific (that is, subjective) symptoms of trachoma and an improvement of varying degrees in the clinical condition; evidence of their curative capacity remains to be established.
6. It is the opinion of the present writers that in spite of the improvement, 'recovery' from trachoma is not the rule but the exception.
7. It, therefore, seems the wiser procedure to supplement sulphonamide treatment with one of the more usual forms of local therapy.

Treatment with Bacteriophage

(From the *British Medical Journal*, Vol. II,
20th September, 1941, p. 409)

THE American Medical Association, among other valuable services rendered through its journal, sometimes commissions a report by recognized authorities on the status of some form of treatment. Such a report on bacteriophage treatment, by M. D. Eaton and S. Bayne-Jones, appeared in 1934, and at that time we referred editorially to the cautious and, indeed, somewhat sceptical conclusions to which these authors were led. It is now considered that a further review of the position is necessary, and this has been prepared by A. P. Krueger and E. Jane Scribner, whose full and thoroughly documented account of more recent work on bacteriophage is a valuable source of information apart from the conclusions they draw from it. Seven years of further work enable this review to begin with a statement of the nature of bacteriophage, and an analysis of the mechanism of its action and the factors controlling this.

Bacteriophage is not a micro-organism but a protein of high molecular weight formed from a precursor within the bacterial cell. For lysis to take place a concentration of about 100 phage units per cell is necessary. Well-founded calculations enable the concentrations attainable in a lesion by therapeutic use to be assessed, and it immediately becomes clear that even after direct application the lytic threshold is unlikely to be reached. Systemic administration assumes—in so far as therapy is based on any such reasoned assumption at all—a chemotactic affinity of fantastic proportions between

phage and pathogen', an affinity of which in fact there is no evidence. It has been found in animal experiments that phage given intravenously is rapidly removed from the circulation by the reticulo-endothelial system. But apart from loss of activity by dilution and sequestration, phage applied in any way to a bodily lesion has to operate in a medium immeasurably less favourable than a tube of culture medium. Its activity is known to be greatly impaired by the presence of dead bacteria, which adsorb it irreversibly, by leucocytes and leucocytic extracts, and by serum. These are exactly the materials of which an inflammatory exudate is composed. Thus local circumstances in the diseased tissue are 'practically without exception inimical to the process of bacteriophagy'. Hence it is concluded that however phage preparations may act in the body—and it is not denied that sometimes they may act—lysis of bacteria as seen *in vitro* is not the mechanism. The accepted theoretical basis of phage treatment is thus fallacious. It is also deliberately concluded that the spontaneous development of phage plays no part in natural recovery—a most important decision, setting aside an attractive hypothesis which has captivated popular medical imagination in connection with several diseases.

What, then, are the other effects which phage treatment may produce? There is another possibility involving a direct action on micro-organisms—namely, that in the presence of phage bacterial dissociation may occur, leading to the production of less virulent variants. That this may happen *in vitro* is known; to what extent it occurs in the body is doubtful, and an opposite effect—the production of variants of greater virulence—is a possibility of which at least one example is said to have been observed *in vitro*. There is also evidence of several kinds that phage may act as a stimulus to phagocytosis. The other effects which phage preparations undoubtedly may have all depend on impurities. The preparation is a lysed bacterial culture, and therefore contains, as well as phage itself, constituents of the bacterial cell in solution, any products of bacterial growth, and the remaining constituents of the culture medium. The intravenous injection of such a hotch-potch of materials has an entirely non-specific action in inducing a leucocytosis, and perhaps in stimulating the mechanism of resistance in other unspecified ways. But the preparation also contains the antigens of lysed bacteria, and these are calculated to excite the formation of specific antibodies. It is quite possible that bacterial antigens in this form have a more rapid and perhaps even a greater immunizing power than a suspension of the intact bacteria from which they are derived—that phage is in fact merely a means for producing a more efficient bacterial vaccine. Each of these arguments applies not only to systemic administration but to local application. Whatever view may be taken about local immunity in Besredka's sense, there is no doubt that applications of this sort to the tissues cause a reaction which is protective against infection, if only by causing leucocytic infiltration. In these authors' opinion 'phage lysates in general should be agents *par excellence* for developing local immunity, since they contain several of the individual materials known to be active in this direction; it is our opinion that much of their therapeutic efficiency can be ascribed to this mechanism'.

The second part of their paper is devoted to an assessment of clinical results in various conditions: here the plain facts of experimental study are exchanged for a maze of varied observations strongly coloured with therapeutic enthusiasm, forming altogether a prodigious haystack in which to seek the needle of truth. Its main subdivisions are intestinal diseases, infections of the urinary tract, superficial or local septic infections, and septicæmia. It would be neither feasible nor profitable to review in any detail the conclusions reached on this aspect of the subject. They are in any case mainly indefinite; nothing more can be said, taking reported results as a whole, than that they are suggestive of good effect. The disease for which the evidence of this is clearest is thought to be cholera. Here it

should of course be remembered that conditions in the bowel are relatively free from those obstacles to phage action which are combined in concentrated form in pus. It is granted that there is clinical evidence of the immunizing and other actions by phage preparations which have already been set down as theoretically to be expected, but questioned whether these preparations excel or even necessarily equal products more specifically designed for the purpose, such as staphylococcus vaccine or toxoid and typhoid vaccine. Though it is often argued that phage preparations are at all events harmless, this is not entirely true: severe reactions have been seen which can be attributed to the presence in them of bacterial toxins or of the Duran-Reynolds spreading factor. The whole of this admirable survey should have a healthy effect in a sphere of therapeutics which cries out for clearer thinking and more judicial study.

The Common Sulphonamides: Nomenclature, Structure and Uses.

By D. G. ARDLEY, M.P.S.

(From the *Lancet*, Vol. II, 22nd November, 1941, p. 625)

WITH the inevitable increase in the number of compounds introduced into clinical practice for the chemotherapy of bacterial infections the need of an accurate and uniform nomenclature becomes urgent. Few modern British books on general medicine or the specialities make any attempt to achieve accuracy in the names used for these compounds, and the medical journals and encyclopædias tend to pander to the whims of their contributors instead of exerting strict control over the names employed. As a consequence, for example, all the names which happen to have been employed for the same chemical compound by various contributors to a textbook may appear in different parts of the index. Abstracts of articles from foreign journals often use for drugs names which are unfamiliar to readers in this country and in this way the chief point of the abstract may be lost. Conversely, proprietary names and erroneous nomenclature in English articles duly find their way into foreign abstracts to the mystification of readers. The practitioner who writes a

prescription for 'sulphonamide', $\frac{1}{2}$ gramme tablets, or the surgeon who orders a wound to be dressed with sulphonamide powder, does not realize that what he has ordered is meaningless. The writer of an article who describes the treatment of a patient with 'Prontosil' given by mouth in such and such a dosage overlooks the fact that there are three distinct chemical compounds to which this name is applied, and that all are given by mouth. The limit appears to have been reached by the author of an article on the use of various sulphonamide compounds who calmly announced at the outset that a particular brand name for sulphanilamide would be used to describe all the different compounds employed! It therefore seems opportune to suggest a few rules for general guidance. First, about dosage. The common practice of describing oral dosage in terms of number of tablets or volume of a suspension is inadvisable. A discussion once arose concerning an article on the treatment of gonorrhoea in which the dosage of sulphanilamide employed was in dispute until it was realized that the author was expressing dosage in drachms of a proprietary suspension. Dosage should always be expressed in terms of the active ingredient.

Most of the sulphonamides in common use have three kinds of name—a chemical name often occupying a line of print, a scientific synonym or pet-name, being the

chemical name in a shortened form, and a various number of trade names. The synonym is the one intended for use in scientific articles, but unfortunately not all the compounds have one, and in some cases the trade name is at present unavoidable. Whenever possible only the full chemical name or its shortened form

should be used, though it may sometimes be convenient to indicate once in an article which particular brand was employed.

SULPHANILAMIDE AND ITS EARLIER DERIVATIVES

Para-aminobenzenesulphonamide or para-aminophenylsulphonamide is the simplest and most widely

used of these drugs, and being the amide of sulphanilic

acid the name now commonly adopted of sulphanilamide is at once both accurate and brief, and the employment of proprietary names for this compound in medical literature is inexcusable. Of the forty or so trade names indicating proprietary brands of this compound the commonest ones in this country are Colsulanyde, Prontosil album and Streptocide, and sometimes the non-proprietary designations sulphonamide-P or P.A.B.S. are used. A proprietary brand much used in America is known as Prontylin. Some clinicians still do not realize that these names all stand for the same substance, and it is not unusual to hear of a patient's treatment being changed from one make of sulphanilamide to another, because he did not respond to the brand first ordered. Many other proprietary names for sulphanilamide, less commonly used than the four already given, are encountered, chiefly in foreign medical literature. In the case of a few trade names encountered in foreign medical journals there has been no clue to the composition of the drug, or the composition has been variously described in different articles so that it has been impossible to be certain what the compound was. Sulphanilamide was included in the Fourth Addendum to the B.P. 1932.

The simplest and most convenient classification of other sulphonamide drugs is to regard them as derivatives of sulphanilamide and as falling into two groups according as to whether substitution takes place in the amino (NH_2) or in the amide (SO_2NH_2) portion of the molecule. All the earlier compounds belong to the first class and are split up with release of sulphanilamide in the body. The more active substances introduced subsequently, such as sulphapyridine and sulphathiazole, fall into the second category, and these compounds do not depend for their action on the production of sulphanilamide.

The first compound to be employed was sulphonamido-chrysoidin, which is 4'-sulphonamido-2:4-diaminoazobenzene, introduced into commerce under the

name prontosil after having been called Steptozon. The name prontosil strictly refers, therefore, to this azo dye-stuff but most English clinicians use it to designate sulphanilamide. If the word is used at all it should never be employed without qualification, so that there is no doubt as to meaning. Sulphonamido-chrysoidin is also known as Prontosil flavum or Prontosil rubrum. A less common trade name is Pronzin

rubrum. A more soluble compound was later introduced for parenteral administration, which consists of a solution of the disodium salt of 4'-sulphonamidobenzene-2-azo-1-hydroxy-7-acetyl-aminonaphthalene-3 : 6-disulphonic acid, usually known in this country as Prontosil

Azosulphamide (Prontosil soluble)

soluble, and sometimes as Prontosil-S or Prontosil II. Occasionally the name prontosil is applied to this compound instead of to sulphonamido-chrysoidin, and in America, where it is given by mouth in place of the latter, it is known under the proprietary name of Neoprontosil, the 'descriptive non-proprietary name' proposed for this substance by the Council on Pharmacy and Chemistry of the American Medical Association being azosulphamide. The name streptozon has been given to both prontosil rubrum and prontosil soluble, the latter having sometimes been distinguished as Streptozon II or S, and curiously enough the designation Prontosil red is sometimes used for prontosil soluble rather than prontosil rubrum. The Rubiazols include the French equivalents of the German azo sulphonamides and rival them in confused terminology. It is, however, sufficient to remember that in this country the name rubiazol is applied to a compound which differs from sulphonamido-chrysoidin in containing a carboxyl (COOH) grouping, and hence is conveniently described as carboxysulphonamido-chrysoidin.

In common with most other compounds of the first group in which substitution takes place in the amino radical of sulphanilamide, these substances owe their activity mainly to the release of sulphanilamide itself in the body tissues, the coloured compounds being split at the azo linkage. Endeavours have been made to show that the azo linkage *per se* may play a rôle in their action, but all the important recent advances concern colourless compounds, and the dye-stuffs cannot but be regarded as being chiefly of historical interest.

Of the sulphanilamide derivatives belonging to the first group which are not dye-stuffs, the most commonly used in England is that formed by substituting one of the hydrogen atoms in the amino group by a benzyl group.

Benzylsulphanilamide

This compound is para-benzylaminobenzene-sulphonamide or benzyl sulphanilamide. It is known in England as Proseptazine or M.&B. 125, and in France as Septazine or 46 R.P. The drug is soluble in water only to the extent of about 1 in 25,000, compared to sulphanilamide which has a solubility of about 1 in 100. The sodium salt of the corresponding succinyl derivative of sulphanilamide—sodium para-succinylaminobenzene-sulphonamide or sodium succinyl sulphanilamide—has been issued for parenteral administration under the name Ambesid soluble. There is also a product Ambesid, and it might reasonably be expected that this would be succinylaminobenzene-sulphonamide itself, but in fact this is another proprietary name for sulphanilamide.

A widely used compound which is much more soluble than sulphanilamide and consequently more suitable for parenteral administration is Soluseptazine or M.&B. 137, known in France as Soluseptazine or 40 R.P. It is disodium-*p*-(*γ*-phenyl-propylamino)-benzene-sulphonamide-*α-γ*-disulphonate, the sodium sulphonate part of the molecule being the solubilizing groups. No convenient non-proprietary designation for soluseptazine has come into use.

A soluble sulphanilamide derivative for parenteral administration, and one having a high sulphanilamide content, has recently been placed on the market under the name sulphanilamide L.S.F. It is described as sulphanilamide lactoside sodium formaldehydesulphoxylate. Reference has also been made to a compound

called Sulphonamide E.O.S. and described as the sodium salt of the ethylsulphonic acid of sulphanilamide. It therefore appears to be sodium 4-sulphonamidophenylaminoethane sulphonate. It has been tried clinically in cattle and man. Mutch (1941) has described some investigations on its pharmacology and activity and has given details of its use in 34 cases of cerebro-spinal fever.

LATER DERIVATIVES

The first drugs of the second class were three disulphanilamide compounds, known originally as Disseptal A, B and C, and introduced from Germany. Of these the first, and the only one to come into use in England, is known as Disseptal or Uleron. It is also called Uliron, Ulirone, D.B. 90 or D.B. 373, and is para-aminobenzene sulphonamido-benzenesulphondimethylamide or sulphanilyldimethylsulphanilamide. Disseptal B is the corresponding monomethyl derivative, and is now referred to in German medical literature as Neo-Uliron. Disseptal C contains no methyl groups, being sulphanilylsulphanilamide. Sulphanilylsulphanilamide is available in America and on the Continent under the name Disulon, where it is used in the treatment of gonorrhœa. It is also known as 'disulphanilamide', a name which, unfortunately, has also been used for the dimethyl derivative (uleron). Claims that uleron is valuable for the treatment of gonococcal, staphylococcal and anaerobic infections have not been substantiated, and the subsequent use of sulphapyridine for the treatment of gonorrhœa and the activity of sulphathiazole in staphylococcal infections have led to its falling into disuse. In common with most other derivatives of the second class uleron is not broken down with the release of sulphanilamide but is eliminated partly unchanged and partly in a conjugated form.

Acetyl sulphanilamide

An event of outstanding importance in chemotherapy was the introduction of the compound derived from sulphanilamide by substitution of one hydrogen atom in the amide portion of the molecule by a basic pyridine group, giving 2-(*p*-aminobenzene-sulphonamido)pyridine. This was first known as T. 693, later introduced as M.&B. 693 and subsequently called Dagenan, a mutation on an Essex place name. To a non-chemist sulphanilylaminopyridine should not be too long to remember but the Americans christened the compound sulphapyridine, which name, although not accurately descriptive chemically, has been generally accepted. Sulphapyridine proved to have a much higher degree of activity than sulphanilamide, thereby extending the range of chemotherapy far beyond infections by sulphonamide-susceptible strains of streptococci. Pneumococcal infections were brought under control, a more potent weapon against gonococcal, meningococcal and gas-gangrene infections provided, and the effective chemotherapy of plague and staphylococcal infections brought nearer. A calcium compound of sulphapyridine has been placed on the market in Germany under the trade name Orsulon. It is issued in tablets for oral administration in the treatment of pneumococcal and other infections. In Stockholm a compound of sulphapyridine and salicylic acid, known as salicylazosulphapyridin, and marketed as Salazopyrin, has been used with success in rheumatoid arthritis and ulcerative colitis.

Sulphathiazole

An even more active compound than sulphapyridine is the corresponding thiazole derivative 2-(*p*-aminobenzene-sulphonamido)thiazole or 2-sulphanilylaminothiazole, usually called sulphathiazole, and also known in England as Thiazamide or M.&B. 760, in Switzerland as Cibazol or Ciba 3714, and in France as R.P. 2090.

It has proved its value in the treatment of infections with *Staphylococcus aureus*, some of the clostridia, *Pasteurella pestis*, and various organisms found in urinary-tract infections, including *Streptococcus faecalis*. Various compounds obtained by replacing one of the hydrogen atoms in the thiazole ring have been tried in therapeutics, and of these the name sulphamethylthiazole indicates the 4-methyl derivative—namely, 2-(*p*-aminobenzenesulphonamido)-4-methylthiazole, or 2-sulphanilyl-amino-4-methylthiazole (M.&B. 838). Owing to the danger of peripheral neuropathy from the use of these derivatives (*cf.* uleron which also contains methyl groups), and their greater liability to deposit crystals in the urinary tract compared to sulphathiazole itself, little more is likely to be heard of them.

Another heterocyclic derivative of sulphanilamide, the pyrimidine analogue of sulphapyridine, has recently been introduced in America; this is 2-(*p*-aminobenzenesulphonamido) pyridine or 2-sulphanilyl-amino-pyrimidine. Sulphadiazine, as it is called, appears from the preliminary studies of American workers such as those of Finland, Strauss, and Peterson (1941) and of Long (1941) and his associates at Johns Hopkins Hospital to have about the same degree of activity as sulphathiazole and sulphapyridine on pneumococci and meningococci, to have an activity on *Staph. aureus*, and to have a high degree of activity on *Klebsiella pneumoniae* (Friedländer's pneumobacillus). It has been tried in pneumococcal pneumonia, cerebro-spinal fever, staphylococcal, streptococcal, gonococcal and other infections but the data at present available concerning its activity, toxicity, absorption, distribution and elimination are inadequate to predict its ultimate place in chemotherapy.

Sulphapyridine and sulphathiazole being of low solubility in water are unsuitable for parenteral administration in solution, for which purpose their sodium salts are employed. The latter being compounds of weak acids with a strong base yield solutions which are highly alkaline. If one of the amide hydrogen atoms of sulphanilamide is replaced by an acetyl radical the compound *p*-aminobenzenesulphonacetamide is formed, which is known as sulphacetamide and was introduced under the proprietary name Albucid. It has been advocated for use in gonorrhœa, for which purpose

it is less effective than sulphapyridine but rather strikingly free from toxic effects, owing probably to its low solubility and consequent poor absorption from the alimentary tract. Its sodium salt differs from the sodium salts of sulphathiazole and sulphapyridine in not yielding a highly alkaline solution. Sodium sulphacetamide is issued as Albucid soluble or Sulphacetamide soluble. It is employed intramuscularly and as a 30 per cent solution for intravenous injection, and a 2.5 per cent solution has been advocated for application to the eyes in the prophylaxis of bacterial infection following injury by vesicant war gases. Albucid and albugid

soluble have been placed on the market in Canada under the names Sulamyd and Sulamyd soluble. Sulphacetamide differs from the acetyl derivative of sulphanilamide, into which the latter is partly converted in the body, since in sulphacetamide it is a hydrogen of the amide group which is replaced by the acetyl

radical, whereas with acetyl sulphanilamide substitution takes place in the amino group. Analogous conjugation takes place with sulphapyridine, sulphathiazole, sulphadiazine and a number of other sulphonamide drugs. Unlike these compounds sulphacetamide appears to be partly broken down in the body to sulphanilamide.

CHEMOTHERAPY INSIDE THE BOWEL

The absorption of a sulphonamide from the alimentary tract or from a wound chiefly depends on its solubility in water at body temperature. Thus the solubility and absorbability of sulphanilamide, sulphathiazole and sulphapyridine decrease in that order. Other factors, however, have an influence on degree and rate of absorption, and some compounds, much more soluble than sulphapyridine or sulphathiazole, have a low degree of gastro-intestinal absorption. The idea arose, therefore, of using a sulphonamide which is bacteriostatically active, fairly water-soluble and of low absorbability to combat infections which are largely confined to the alimentary canal. Marshall, Bratton, White and Litchfield (1940), who studied various compounds from this point of view, found that sodium sulphanilyl sulphanilate, *N*-(2-hydroxy-ethyl) sulphapyridine, *N*-(2-diglycosulphapyridine and sulphanilyl-guanidine fulfilled the requirements of water-solubility and limited absorption from the intestine. Since sulphanilylguanidine appeared to be the most active of these compounds against a number of pathogens it was selected for pharmacological and therapeutic investigation. (It may be recalled that sodium sulphanilyl sulphanilate once achieved a short-lived but world-wide interest for a supposed activity in virus infections.)

Sulphanilylguanidine is *p*-amino-*N*-guanyl-benzene-sulphonamide. Marshall and his colleagues suggest that the formulæ may both be considered correct for the compound as they are probably resonance isomers, easily transformed one into the other.

The blood levels reached after the administration of sulphanilylguanidine are low as a consequence of its limited absorption, and the concentration in the gastro-intestinal tract is correspondingly high. It is suggested for trial in bacterial infections which are chiefly localized in the intestines, such as bacillary dysentery, cholera and the early stages of the enteric fevers, and for reducing the hazards of intestinal surgery. In acute bacillary dysentery it will have to be established that sulphanilylguanidine has advantages over sulphathiazole and sulphapyridine, those 'veritable Excaliburs, with which dysentery apparently may be vanquished without fail' [Ravenel and Smith (1941)]. Other sulphonamides have proved inactive on *Vibrio cholerae* at ordinary therapeutic concentrations but Marshall and others have found sulphanilylguanidine bactericidal *in vitro* in a concentration of 200 mg. per 100 c.c., so that at the high levels reached in the gastro-intestinal tract it is possible that the administration of this compound may be of benefit in cholera. Its use in intestinal infections bears some analogy with the use of sulphonamides in infections of the urinary tract, where the concentration in the urine is, of course, enormously greater than in the blood and tissues.

Various sulphonamides have given unquestionable benefit in cases of ulcerative colitis, although the mechanism of the effect must necessarily remain obscure while the ætiology of this condition is unknown, and a few experiences in the use of sulphanilylguanidine in ulcerative colitis are encouraging. The drug is being known as sulphaguanidine, by analogy with sulphapyridine and sulphathiazole.

OTHER SULPHUR COMPOUNDS

Not all the sulphur compounds which are active anti-bacterial agents are sulphonamides; a number are sulphones, sulfoxides and sulphides. The sulphones

which have been investigated experimentally as well as clinically, may be regarded as derivatives of 4:4'-diaminodiphenylsulphone. This substance has proved excessively toxic to mice but not to some other laboratory animals, and its toxicity probably precludes its clinical employment in man. McEwen, Pizer and Paterson (1941) have reported the rather unexpected finding that the compound is of relatively low toxicity for cattle, producing no toxic effects in therapeutic doses. The di-acetyl derivative of 4:4'-diaminodiphenylsulphone is of low toxicity and has been used in France for the treatment of gonorrhoea under the proprietary name Radilone (1399 F.). The glucoside of 4:4'-diamino-diphenylsulphone has been studied for its activity in experimental bacterial and virus infections, and has been used clinically in the treatment of cerebro-spinal fever, trachoma and lymphogranuloma inguinale. A compound known as Promin and described as the sodium salt of *p,p'*-diamino-diphenyl-sulphone-N,N'-di-dextrose sulphonate has been tried in artificially induced animal infections with various coecal and bacillary organisms, and used clinically by mouth and intravenously. This drug has been found to possess a retarding influence in experimental tuberculous infections of guinea-pigs apparently greater than that conferred by sulphonamides. At present, however, the effective chemotherapy of clinical tuberculous infections remains, with that of brucellosis, and the introduction of virucidal agents, probable achievements of the future. Despite the number of compounds in clinical use and the far greater number which have been studied experimentally, the tremendous strides made during the past few years constitute but the beginning, though a highly successful one, of a new era in therapeutics.

The Record of a Blood Donor

(From the *Journal of the American Medical Association*, Vol. CXVI, 1st February, 1941, p. 415)

THE value of human blood and plasma for transfusion in certain diseases is now well established; its lack of specific value for other conditions may not be so well known to physicians and to the public. The effects of the injection of non-specific protein and of the materials contained in blood and plasma may be sufficient in themselves to develop non-specific benefits which may cause false impressions of values. This exceedingly brief evaluation of blood transfusion is by way of introduction to a problem created by the drama associated with the donation of human blood for medical purposes. The creation of blood banks and serum centres, and the efforts now being made to secure donation of blood from hundreds of thousands of persons, will in time establish routines which may make such records as that which follows impossible.

In the *Cosmopolitan* magazine for November 1940 appeared an article relative to Mrs. Rose McMullin, who in 1935 apparently permitted herself to be infected with *Staphylococcus aureus* in order that she might develop antibodies. It had been decided to use her blood for transfusion in the case of her niece, who was suffering from an infection with *Staphylococcus aureus*. The physicians in the Hahnemann Hospital in Philadelphia, according to the article, utilized this procedure on her suggestion. They took blood from Mrs. McMullin on several occasions and injected it into the niece. The niece recovered. Then in 1938, it is said, Mrs. McMullin responded to a request for blood to be used for a boy who was dying from *Staphylococcus aureus* infection in Delaware County, Pa. Some time later came an appeal from Chester, Pa., and again Mrs. McMullin responded. By this time apparently she began to be known as the 'golden lady', probably because of the *Staphylococcus aureus* infection. She is also occasionally referred to as 'the darling of the American Legion', since the American Legion is participating in the campaign to secure blood for transfusion for the military services.

According to the article in the *Cosmopolitan* magazine, 'Mrs. McMullin had donated her magical help

freely, refusing the usual donor's fee. All she accepted was travelling expenses'. Then Gabriel Heatter put Mrs. McMullin on his programme. From that time requests for her blood began to come in great numbers, not only for cases of *Staphylococcus aureus*, but also for infections with *Streptococcus viridans*, from patients with leukaemia and for other conditions. It would seem, according to the article in the *Cosmopolitan* magazine, that Mrs. McMullin has a heavy file of letters of gratitude from physicians and that 'she has given over 26,000 cubic centimetres of her golden life stream'.

In the files in the headquarters office of the American Medical Association, information has accumulated which must be placed with that in the *Cosmopolitan*. First is a letter from a physician in Johns Hopkins Hospital who inquired about the use of her blood for a case of myeloid leukaemia. In this instance, the doctor writes, the parents of the child had been informed by Mrs. McMullin's agent that she had recovered from leukaemia and that her blood contained the proper neutralizing bodies. It was stated that she would ask no fee but merely \$500 for her expenses. References were given to two physicians who were said to have used her blood for cases of leukaemia, but specific inquiry revealed that the blood had not been of the slightest use in these cases.

Another letter from a physician in Newark indicates that her blood was offered for a case of *Streptococcus viridans* infection, with a request for \$300 to cover expenses. A third letter from a physician in Louisiana concerned a patient with subacute bacterial endocarditis. Next comes a report from a physician in New York, enclosing extended correspondence with Mrs. McMullin, begun because the father of a 6-year-old girl with lymphogenous leukemia asked that a transfusion be made with the blood of Mrs. McMullin. An extended correspondence indicates that Mrs. McMullin did not insist that her blood would help a patient with leukaemia but said she would take a while to build up her blood so that it could be used in that direction. In October 1940 her blood was examined by a New York physician, who found that she had a moderate anaemia; he refused to use her blood until she could get a certificate from her own physician that it would be satisfactory.

Next comes a communication from a physician in Pennsylvania late in December. A farmer's boy in his community had *Streptococcus viridans* infection with subacute bacterial endocarditis. In this instance the Philadelphia *Inquirer*, having learned of the case, telephoned offering the services of Mrs. McMullin, who it seems was at that time in Oklahoma City giving her blood to another patient with *Streptococcus viridans* infection. The physician had difficulty locating Mrs. McMullin and after correspondence discovered that her blood was not of the right type. She was, however, apparently making a series of visits to various communities for the distribution of her blood. A physician from Missouri and another from Alabama who had experiences with Mrs. McMullin wrote that she states she will give her blood just for 'expenses' but that her expense sheets 'would make our national debt pale into pauper figures'.

There comes also at this time a letter from a physician in Missouri who requested that Mrs. McMullin send her serum in a small bottle, having it taken by one of the blood banks in New York. The price asked for these bottles of serum was \$100 per bottle. The amounts which came in these bottles varied from 210 to 51 c.cm. of serum.

In the case of one boy with streptococcal endocarditis, Mrs. McMullin provided enough blood for seven transfusions of approximately 200 c.cm. each over a period of two weeks. When the patient failed to respond, she insisted that the physician discontinue the sulphathiazole. This he did, but the fever went upward again immediately, so the sulphathiazole was again administered, whereupon there occurred an immediate drop in the temperature.

This is the record to date of a widely publicized blood donor. It provides many strange sociological and psychologic facets. The report indicates the need for some type of control over this form of medical activity.

Methods for the Local Application of Sulphanilamide

By F. HAWKING, D.M.

(From the *British Medical Journal*, Vol. II, 15th November, 1941, p. 685)

EARLIER papers have described the anti-bacterial effects of local applications of the sulphonamides to experimental wounds infected with the organisms of gas gangrene, and the concentrations in the blood and in the tissues around the wound resulting from such local applications. During this experimental work various practical methods have been devised, and these are here described in the hope that they may be helpful to those employing local applications of sulphonamide compounds to human lesions. For the sake of conciseness most references to other workers have been omitted. The compounds used have been either sulphanilamide or sulphathiazole.

POWDER

In shallow open wounds this is the simplest form in which to apply the substance. It can be distributed by means of a spoon, a pepper-pot, or an insufflator. Whichever method is used, enough powder should be applied to cover the whole surface liberally, and yet not enough to form large concretions, which take a very long time to dissolve. Gently massaging the powder into the tissues with a spatula will help to get it effectively distributed and dissolved. For use in the operating theatre on fresh wounds it is convenient to have a supply of the powder in 5-gramme lots, put up either in paper packets or in screw-capped bottles. In order to obviate the very slight risk of fortuitous contamination of the powder, during its manufacture or afterwards, by tetanus or other spores of pathogenic bacteria, it can be sterilized in such packets or bottles by dry heat at 150°C. for one hour. (If sterilized in the autoclave with the cap unscrewed the powder is apt to become crystalline and is no longer suitable for use in an insufflator.) For routine ward work the use of unsterilized powder would seem to be justifiable.

GAUZE

In narrow deep sinuses which are packed at regular intervals with ribbon gauze the powder can be inserted into the depths on the packing. This can be done most simply by pouring the powder on to the gauze as it is pushed in, but a better way is to incorporate the powder on to the gauze beforehand. For this purpose small glass pots with a metal screw cap, such as are used for ointments, are taken. A wide slot is cut in the lid. The pot and the gauze are sterilized separately. The gauze is then passed through a thick paste of sulphanilamide and water under sterile precautions and is placed in the pot, the end of the ribbon protruding through the slot. The top of the pot is covered with a piece of sterile oiled silk. For use in the wards the ribbon is pulled out as required. If the gauze is autoclaved after smearing with the paste most of the sulphanilamide forms powdery crystals, which cease to adhere to the ribbon.

TABLETS

It is difficult to transfer powder to the bottom of a deep sinus. The best method in these cases is the use of small tablets made of the compressed compound—e.g., tablets containing about 0.2 gramme of material and measuring about 8 mm. across. Such tablets were first suggested by Dr. A. S. Parkes; they were kindly prepared by the British Drug Houses Ltd. and May and Baker Ltd. The tablets can easily be inserted into the desired position by sinus forceps, and they are

then crushed to hasten disintegration; eventually they are completely absorbed and leave no residue which might act as a foreign body. With sulphanilamide, which is fairly soluble, tablets of the pure compound will probably be dissolved in a reasonable time, although it is advantageous to crush them in order to accelerate the process. With sulphathiazole, tablets of the pure compound (uncrushed) were found to persist in a sinus for over two days without much visible change. It is better to use tablets consisting of 0.1 gramme of sulphathiazole and 0.1 gramme of glucose, the glucose being added in order to promote the disintegration of the tablet; when these are crushed after insertion most of the material is dissolved in twenty-four hours. Tablets could also be used in a wound when it was desired to secure a steady supply of sulphonamide over a prolonged period; by choosing tablets of an appropriate size the duration of action could be varied as required. The surface of the tablets can be sterilized by dry heat at 85°C. for one hour; heating to 115°C. causes the tablets which contain glucose to turn brown. This degree of sterilization will not kill spores, but the position is the same as that described for the powder.

PASTES

The results described in this section form the preliminary part of a wider programme, which will be described in more detail when it has been completed. Briefly, the ideal sulphanilamide paste for application to wounds, burns, etc., should have the following properties:—

1. It should be satisfactory pharmaceutically—i.e., stable, non-odorous, non-rancid, etc.
2. Its physical consistency should be suitable for the required purpose; burnt surfaces might require a thinner preparation than that used for plugging wounds.
3. It should comprise only materials which are available under present war conditions. Thus, since cod-liver oil, which forms the base of two of the pastes described below, is now in short supply, a search for a suitable substitute forms part of the wider programme now in progress.
4. Sulphanilamide should be liberated from the paste at the optimum rate. Presumably the concentration of sulphanilamide in the fluid in contact with the paste should be as near saturation as possible, provided that: (a) The concentration is not so high as to injure growing tissues or to paralyse leucocytes. Jacoby, Medawar, and Wilmer found that fibroblasts and macrophages are killed by a saturated solution of sulphanilamide (concentration 1:60), are temporarily depressed by concentrations of 1:150, and are not affected at all by concentrations of less than 1:1,000. According to these findings, it might be advantageous if the paste exerted a slight restraint on the rate of solution of the sulphanilamide. (b) The amount absorbed is not so great as to produce a toxic concentration in the blood; probably this will not occur except when the areas to be dressed are large; it can be decided only by blood estimations of treated patients. (In a private communication Colebrook reports that one patient who was treated by sulphanilamide paste for a very extensive burn became cyanotic, and the concentration of compound in the blood was 8 mg. per 100 ml.) The whole question is under investigation.

It may here be noted that mixtures of sulphanilamide and liquid paraffin appear to be in use in some hospitals. According to experiments in this laboratory sulphanilamide is insoluble in paraffin and cannot diffuse across it. In mixtures of paraffin and sulphanilamide, however, the particles of sulphanilamide usually sink to the bottom of the paraffin layer until they come into contact with the underlying watery fluids, in which they dissolve. Hence, if sulphanilamide suspended in paraffin is injected into rabbits subcutaneously it is absorbed almost as quickly as if it were suspended in saline. This occurs because the mixture is unstable and in the body it separates into its component parts; if this separation were prevented—for example, by using petroleum jelly—little or no absorption would presumably take place.

5. The paste should be non-irritant to the tissues and innocuous to leucocytes. It should not delay healing; rather, if possible, it should stimulate it.

The complete solution of all these problems will take a considerable time, and meanwhile casualties occur which require treatment. Therefore this short description is given of the best pastes which have been found to date so that they may be available in hospitals, and clinical experience may be gained which may help to orientate the further researches in hand. For the pharmaceutical side of the present work I am indebted to the British Drug Houses Ltd., who kindly co-operated with their experience in these matters and devised pastes of different properties for my trial. The physiological action of these pastes was tested by injecting them between the muscles of rabbits and into the peritoneum of rats; the irritation which they caused was not appreciably greater than would have been produced by any foreign body in these positions. Three pastes are provisionally recommended to suit three different types of lesion:—

1. *Sulphanilamide*, 30 per cent; *oleic acid*, 1.4 per cent; *triethanolamine*, 0.35 per cent; *cetyl alcohol* and *beeswax*, each 1.4 per cent; *water* to 100 per cent.—This is a thin paste to spread over inflamed skin surfaces—e.g., impetigo—in order to apply sulphanilamide with as little other material as possible. It can be used on granulation tissue instead of powdered sulphanilamide, but if inserted into deep wounds it leaves a residue. The sulphanilamide is absorbed from this paste almost as rapidly as when the powdered compound is applied as such. This paste was kindly tested by Dr. A. Glucksmann of the Strangeways Laboratories, who applied it every other day to standard wounds in rats. He found that it caused very slight irritation, as shown by stimulation of collagen regeneration and slight retardation of epithelial regeneration; but this irritation was so slight as to be unimportant compared with bacterial infection.

2. *Sulphanilamide*, 30 per cent; *cod-liver oil*, 49 per cent; *oleic acid*, 3.5 per cent; *triethanolamine*, 1.05 per cent; *cetyl alcohol*, *beeswax*, and other ingredients to diminish rancidity, 3.5 per cent; *water* to 100 per cent.—This is a paste of medium consistency. The absorption

of sulphanilamide from it proceeds slightly more slowly than that which occurs when the compound is applied as a simple powder. Besides supplying a large depot of sulphanilamide, which will be taken up by any serous exudate to form an almost saturated solution, a paste of this kind provides an oily protective layer and will also prevent sticking of dressings. This paste was designed especially for the treatment of burns. Colebrook (personal communication) has observed the rapid disappearance of hæmolytic streptococci following its use in such injuries: he also found that it is unnecessary to change the dressings more often than every two or three days. Robson and Wallace have reported very satisfactory results in burns treated with a similar paste made up with albucid (*p*-aminobenzenesulphonacetamide), which is considerably more soluble than sulphanilamide and which accordingly may exert a greater effect upon the less sensitive organisms such as staphylococci and *Ps. pyocyanea*.

3. *Sulphanilamide*, 30 per cent; *cod-liver oil*, 60 per cent; *beeswax*, 10 per cent.—This is a stiff paste, to be used on gauze for packing wounds, in the same way as vaselined gauze is used. Its consistency can be modified by varying the proportions of cod-liver oil and beeswax. It provides a non-irritant, non-adhesive mechanical support to the sides of the wound, and at the same time gives off a supply of sulphanilamide, liberation of the compound being slow. It tends to become rancid, however, unless preventive measures are taken.

SUMMARY

Methods are described for the local application of sulphanilamide: (a) as a powder to open wounds; (b) as tablets or on gauze to deep sinuses; (c) as various kinds of paste to treat inflamed surfaces, burns, and wounds which must be packed.

Details are given of three pastes which may be recommended for use in three different types of lesion.

Acknowledgments are due to Colonel L. Colebrook for inspiration and advice; to the surgical staff of the New End Hospital, Hampstead, for facilities; to Miss M. Kuck for technical assistance; and to the British Drug Houses Ltd. for co-operation in devising and preparing the pastes.

Reviews

HANDBOOK FOR MIDWIVES AND MATERNITY NURSES.—By Mary Mayes, S.R.N., S.C.M. Third Edition. Revised by M. A. Gannon, S.R.N., S.C.M. 1941. Baillière, Tindall and Cox, London. Pp. xii plus 495, with 162 illustrations. Price, 8s. 6d.

THIS book gives a very comprehensive study of midwifery and maternity nursing.

It is obviously the work of an experienced and gifted teacher—it is so well written and explained that no pupil could fail to understand it readily. The knowledge is also presented in such a way that one reads with continued interest.

The numerous diagrams are also of valuable assistance to both teacher and pupil alike.

In addition the final chapters on 'Government Services', 'History of Nursing', etc., contain interesting general knowledge for all.

I. C.

A SHORT TEXTBOOK OF SURGERY.—By C. F. W. Illingworth, M.D., Ch.M., F.R.C.S. Ed. Third Edition. 1942. J. and A. Churchill Limited, London. Pp. x plus 692, with 12 plates and 201 text-figures. Price, 27s.

PROFESSOR ILLINGWORTH has succeeded admirably in his desire to produce a satisfactory textbook of surgery which is both short and comprehensive. This book is already well known and the present edition is the third since 1938.

The war has been responsible for rewriting of various sections on wound treatment, burns, shock, gas gangrene, and blood transfusion. Changes and amendments have been made elsewhere and a new chapter on 'Safety factors in surgery' has been added.

The arrangement and the phraseology of the work conform to the general type of surgery textbook but, unlike some others, the subject-matter is concise and cuts out all 'trimmings' including operative details.

Illustrations and x-ray photos are not profuse but are satisfactory in showing clearly what they are meant to show.

This book can be recommended to the student as being of reasonable length and sound teaching, easy to read, well bound, and well printed. It will be of use also to the practitioner to keep in touch with general surgery as a whole without attempting to be too specialized.

K. S. F.

TRAUMA AND DISEASE.—Edited by Leopold Brahdý, B.S., M.D., and Samuel Kahn, B.S., M.D. Second Edition. 1941. Henry Kimpton, London. Pp. 655. Illustrated. Price, 35s.

THIS interesting book is the joint effort of twenty-four authors including the editors. The subject of ætiological relationship between trauma and disease, though always recognized, has not been given the attention which its importance merits. In this volume what has been considered very carefully is the effect

of a single trauma either physiological or psychic, on the production of disease or its course. This admittedly is a difficult subject but the quick appearance of a second edition is sufficient evidence that this volume has justified its publication.

This is a book of considerable volume, consisting as it does of 655 pages and 18 chapters. This need not cause any surprise because no special branch of medicine and surgery has been neglected. This book will therefore be acceptable equally to the general practitioner and the specialist. It is no small praise for the authors. The bibliography and the index will be found very helpful. The printing and get-up are excellent.

P. N. R.

MASSAGE AND REMEDIAL EXERCISES IN MEDICAL AND SURGICAL CONDITIONS.—By Noel M. Tidy. Fifth Edition. 1941. John Wright and Sons Limited, Bristol. Pp. xii plus 463. Illustrated. Price, 17s. 6d.

THE fifth edition of this book needs no introduction to students and practitioners of massage and remedial exercises. It is an admirable textbook containing an account of various modern methods of treatment and indicating where further information can be obtained.

All the treatments recommended appear to have been personally tested.

The exercises described form an excellent collection, containing instructions for all conditions likely to be met in any massage department. They are well illustrated and easy to follow. Special discrimination has been made between passive movements—relaxed or forced—and active exercises.

Special attention is paid to the treatment of fractures approximate dates being given for beginning movements in the various joints.

This new edition contains a short and very useful section on the treatment of serious burns and of amputation stumps, especially as regards their preparation for the fitting of artificial limbs. There is also a short description of the modern treatment of wounds.

Since the first edition of this book came into my hands I have never been without a copy of it, and have referred to it innumerable times. Here in India, where most hospitals and medical colleges have no massage departments, and students are unable to realize the uses of massage and exercises, this book would be a valuable asset to medical students. It would help them to realize the variety of cases in which massage and exercises can be employed with advantage.

P. B.

Abstracts from Reports

REPORT OF THE MEDICAL OFFICER OF HEALTH, SIMLA MUNICIPALITY, FOR THE YEAR 1941. BY COLONEL E. S. PHIPSON, C.I.E., D.S.O., M.D., F.R.C.P., D.P.H., D.T.M. & H., I.M.S. (RETD.)

The population of Simla fluctuates greatly between the summer and winter periods. The rates per mille of population are based on an 'average' population which is obtained by addition of 5/12ths of the winter and 7/12ths of the summer populations.

The average population = $(5/12 \times 18,144) + (7/12 \times 52,187) = 38,003$.

There were 799 live births and 16 still births. The last number represents a proportion of 3.77 of the total births as compared to 8.84 in 1940 and 4.25 in 1939.

Four hundred and eight deaths, 249 males and 159 females, were registered in 1941. The total number of deaths gives a 'crude' death rate of 10.74 per mille of the population as compared to 10.79 per mille in 1940.

Respiratory diseases caused 160 deaths which constitute 39 per cent of the total deaths. Twenty deaths resulted from 'fevers' constituting 5 per cent of the total deaths. One hundred and ninety-eight deaths were recorded under the heading of 'all other causes' representing 49 per cent of the total deaths.

The total number of births recorded during the year was 799 and the crude infant mortality was 14.65 per 100 births.

The school medical service scheme included 25 Indian schools which were inspected by the two medical officers who examined a certain number of pupils at each visit and referred dental and eye cases to the specialists.

The records of individual examinations of school children during the year under report, reveal a general standard of health which can only be described as deplorable. According to the statistics given, only 12.47 per cent of boys and as few as 1.25 per cent of girls can be described as in 'good' health, that is, without any recognizable defect. Those with one defect are described as 'below par', and these amount to 22.99 per cent of boys and 4.28 per cent of girls, and those who are described as being in 'poor health',

that is, with more than one defect, form the majority, being 64.55 per cent in boys and no less than 94.47 per cent in girls, a sex difference which suggests a relation to the greater proportion of the day which girls spend in the seclusion of their own homes, all too often unhealthy and insanitary.

There have been many important developments during the past twenty years. Perhaps the most important of all was the increase in the water supply by the installation, in 1924, of the pumping plant at Guma, capable of delivering from the waters of the Nauti Khud a maximum of 600,000 gallons a day, an increase which almost doubled the supply available twenty years ago. The electricity supply, on which the water supply is dependent to an extent which the public do not perhaps fully realize—80 per cent of the water supply being now electrically pumped—was further strengthened by the erection in 1939 of a Diesel generating plant at Idgah, with a nominal output of 800 kilowatts. To this must be added the greatly increased efficiency of the precautions for ensuring the bacteriological purity of the supply by chlorination at the head of the rising main at Carignano, for the Guma water and 'chlorination' for this and for water from all other sources at Sanjauli reservoir.

Perhaps the next most striking improvement in the field of public health is the greater regard for the convenience of the public, and particularly for the poorer sections of the community, shown by the provision of valuable amenities, such as the ladies' park, on the site of Lowrie's hotel, and shelters for rickshaw coolies, in different parts of the town. In the realm of education, of the 11 municipal schools, 4 have been built by the municipality in the last twenty years; the school medical service is of comparatively recent growth, and the introduction of the supply of free milk to under-nourished indigent children, though latterly its results have been disappointing, is evidence of progress.

One of the earliest municipal experiments in maternity and child welfare in India was started in Simla some twenty years ago and the enterprise has developed into a considerable undertaking on which the municipal committee spend Rs. 10,000 a year, and which employs a staff of three fully-trained lady health visitors.

The improvements in recent years in the municipal markets and dairies have been very substantial, and though the new vegetable market, for reasons which need not be entered into, has proved to be a white elephant, it is on the whole, well designed for its purpose.

Municipal efforts for the control of tuberculousis are also of recent date, and though the scope of the present scheme is very restricted, there was nothing in its place twenty years ago, and they represent a forward step. The extension of the scheme is now under consideration by the municipal committee.

Among other improvements are the abolition of all areas where prostitution was officially tolerated, the medical examination of rickshaw coolies before licensing; their periodical cleansing and disinfection by municipal agency; the improvements in their housing arrangements and the introduction of a standard light rickshaw; and the covering by concrete slabs of the very dangerous open nullahs in the bazaar area which have been the cause of more than one fatal accident.

The milk supply of Simla is still far from satisfactory, and little or no progress can be recorded in the last twenty years or, indeed, in the last half-century. The difficulties are obvious; the milk supply is brought almost exclusively from outside municipal limits, and Simla is an island entirely surrounded by the territories of Indian States, where the municipal committee has no jurisdiction in sanitary or any other matters.

There is one respect in which Simla would seem to have actually retrogressed in the past twenty years, and that is in housing conditions for the poorer classes, and in the state of congestion in the bazaar area. The municipal committee have recently taken up this matter, and a number of insanitary properties have been surveyed with a view to condemnation or improvement and one may hope that some progress in this direction may at last be made.

It is fortunate indeed that in the past twenty years there have been compensating improvements in the direction of water supply, electricity and drainage and that at least these very important factors in the health of the station have received in the past and are still receiving some, at least, of the attention they deserve. The year 1942 promises to impose a practical test of Simla's resources in many directions, not least in the field of public health.

KASHMIR MEDICAL MISSION HOSPITAL OF THE CHURCH MISSIONARY SOCIETY REPORT FOR 1941

THE Kashmir Mission Hospital is one of the most important public institutions in Kashmir. The hospital is able to cope, to a greater or less extent, with the sickness and disease of the valley of Kashmir, partly because villages near the river can send in patients by water; and to others district visits are paid.

It is interesting to note the prevalent diseases as met with in district work. Of 5,000 cases, worms (ascarides) formed 29 per cent of the whole, the juvenile population being almost universally affected. Next come diseases of the alimentary system, 28 per cent, chiefly due to want of variety and excess of starch in the ordinary rice diet. Respiratory troubles, 8 per cent, were chiefly chronic bronchitis. Tuberculosis of the lungs, 0.5 per cent, is beginning to make its appearance in the villages. Rheumatism, 7 per cent, like the two preceding is doubtless owing to exposure to cold and damp and insanitary houses. Skin diseases, 4 per cent, were chiefly scabies and favus, both of a severe type and also eczema. Eye affections formed 10 per cent of the whole, and were chiefly trachoma, entropion, trichiasis, pterygium and conjunctivitis. About 1 per cent of the cases had goitre, which in some districts, with limestone springs and probable drainage contamination, is endemic. Seven per cent of the patients were suffering from disease necessitating operation.

The nature and extent of the medical and surgical work is notable. A large number of eye operations were performed and tumours removed. On kangri-burn cancer our work has been regarded as authoritative.

Maternity and infant welfare work.—In the Mission hospital about one-third of our patients are women and children. We have comparatively little maternity work. But what there is, is of the utmost importance and gravity. Osteomalacia is common in Kashmir. Many patients give a history of one or more living children and then labours of increasing difficulty, growing deformity, and finally they are brought into hospital with acute dystocia.

Acknowledgments.—Our thanks are due to His Highness the Maharajah for the continued support of his three beds and for the gift of rice on His Highness' birthday and to His Highness' Government for the State grant. To bed and cot supporters and shareholders and to all subscribers and donors to our funds, who, in spite of many calls on their charity due to the war, have nevertheless generously helped us, we tender our grateful thanks.

REPORT OF THE CHEMICAL EXAMINER TO GOVERNMENT, PUNJAB, FOR THE YEAR 1940

Total work done.—Compared with the year 1940 the total number of cases investigated in the chemical examiner's department during the year under report rose from 4,763 to 4,836 and the number of articles examined went up from 12,778 to 12,886 giving an increase of 73 under the former and 108 under the latter. The increase is under one head only, viz, 'general analysis' both for cases and articles while there is a decrease under almost all other heads.

Percentage of detection.—So far as the percentage of detection is concerned there is decrease under several heads, viz, from 60.38 to 55.41 under human poisoning cases, from 94.82 to 94.10 under blood stain cases and from 93.32 to 89.96 under cases relating to sexual offences. The only increase is from 37.21 to 57.14 per cent under cattle poisoning cases.

Fatal human poisoning cases.—Of the total number of 953 cases examined for human poisoning 582 were fatal including 9 cases of criminal abortion and poison was found in 522 cases. The percentage of detection was 48.69 as compared with 55.63 in 1940. The cause of death was other than poisoning in 275 cases as against in 238 cases in the previous year. If these non-poisoning cases are excluded the percentage of detection comes to 93.62 as compared with 94.69 in 1940. The fall in percentage is due to the growing tendency among medical officers to send the viscera of all such cases to the chemical examiner to Government, Punjab, for examination even when there is little or no suspicion of poisoning. The practice is not appreciable as medical officers do not appear to exercise their discretion with proper care in such cases. Lahore as usual sent the largest number of cases, viz, 53 followed by Amritsar 38, Kasur 33, Delhi 30 and Lyallpur 22. There is not much variation as compared with the figures of the year 1940 except that Amritsar occupies second position and Jullundur comes much down on the list. Opium, arsenic, dhatura, alcohol, strychnine, mydriatic (belladonna) and cyanide were the chief poisons used.

Fatal cattle poisoning cases.—Of 42 cases examined under animal poisoning cases as against 43 in 1940 only 34 cases were fatal and the percentage of detection was 55.88 as compared with 35.90 in the previous year. Arsenic was the chief poison used though Abrus precatorius was also found in 5 cases. The largest number of cases was received from Rawalpindi 8, Lahore 6, and Sialkot 3.

Stain cases.—The total number of stain cases examined in 1941 was 1,891 consisting of 1,356 murder cases, 384 rape cases, 144 sodomy cases and 7 cases of miscellaneous nature with 4,373 exhibits as against 2,131 cases and 4,796 articles in the previous year. Out of these, 1,355 cases comprising 3,114 articles were

referred to the Imperial Serologist, Calcutta, the corresponding figures for the year 1940 being 1,596 and 3,567, respectively.

General analysis of cases.—The total number of articles examined for general analysis in 1941 was 3,696 consisting of 2,395 samples of beverages, 39 samples of water, 59 samples of food, 189 samples of miscellaneous articles, 838 samples of drugs and 176 explosives as against an aggregate of 3,009 articles in 1940.

Staff.—There were several important events among the members of the staff, viz, reversion of Lieut.-Colonel D. R. Thomas, O.B.E., I.M.S., chemical examiner, to the military duty from 13th August, 1941, grant of one year's extension in service to Dr. Syed Tufail Hussain, assistant chemical examiner, from the 16th April, 1941, re-employment of Dr. Udho Ram from the 20th August, 1941, as chemical examiner and death of Dr. Salig Ram Khanna, 1st assistant to chemical examiner, on 17th April, 1941.

KING EDWARD VII MEMORIAL PASTEUR INSTITUTE AND MEDICAL RESEARCH INSTITUTE, SHILLONG: THE TWENTY-FOURTH ANNUAL REPORT FOR THE YEAR ENDING 31ST DECEMBER, 1940

ANTIRABIC SECTION

In addition to the Pasteur Institute, Shillong, 25 public centres and 46 private centres, at which anti-rabic treatment was available to the public, were maintained during this year.

The total number of persons applying for treatment throughout the province amounted to 2,857. Shillong received 487 of these persons and the remainder attended the various centres. Treatment was completed in the case of 2,434 persons. This represents an increase of 544 over the corresponding figure in 1939. In addition, four persons applied for, and were placed under treatment, when they were in the late incubation stages of hydrophobia. Treatment in these cases was not completed, owing to its interruption by the onset of hydrophobia in each case, followed by inevitable death.

Of the 2,857 persons applying for treatment, 192 were treated as 'advice cases'. This means that they were either not treated at all, or their treatment was stopped before completion of the course, because circumstances showed that they were at no risk. Among the persons placed under treatment and presumed to be at risk, 225 absconded without completing the course. All efforts to induce them to finish the treatment were unavailing, and there is no record of their eventual fate.

Results of treatment.—There were four deaths from hydrophobia among the 2,434 persons fully treated, giving a mortality rate of rather more than 0.16 per cent. The inclusion of the four additional persons referred to above who died during treatment, brings up the mortality rate among the 'Total Treated' to 0.34 per cent. All the eight deaths occurred among Asiatic patients. One death from hydrophobia occurred among patients treated in Shillong, a *mali* who received no less than 30 severe wounds from a stray dog.

There was one case of paralytic accident during the year. He received the full 14 days' treatment and the onset of paralysis appeared one day after treatment was completed. This was an unfortunate case. Paralysis following antirabic treatment, except in the most serious ascending myelitis (Landry type), usually tends to gradual recovery, complete or incomplete after a greater or less lapse of time, in the absence of serious complications. In this case such complications unfortunately occurred and a fatal termination resulted.

ASSAM MEDICAL RESEARCH SOCIETY

The Society continued to confine itself to the study of malaria and its control during the year.

Finance.—All the constituents of the Society maintained their contributions at the usual level in 1939-40.

The Assam Railways and Trading Company, Limited, were enrolled as constituents in 1940-41 and the Assam-Bengal Railway ceased their contribution with effect from 1939-40 as a measure of retrenchment.

Special researches.—(a) An experimental scheme of malaria control by spray killing adult mosquitoes with a mixture of 1 part of pyrocid 20 and 19 parts of kerosine was carried out in two areas in a tea garden and a rural area respectively. Weekly spraying with such a mixture reduced the malaria incidence by 60 per cent as shown by the hospital figures. In the sprayed area the parasite indices among adults and children showed a definite reduction in December at the end of the spraying season, while in the unsprayed area in close proximity they showed a distinct rise. The infant malaria parasite rate showed a reduction by 50 per cent in December in the sprayed area while it rose by 50 per cent in the unsprayed area. The cost of weekly spraying for a period of 8 months came to Re. 0-8-7 per head. There was no reduction in the larval output nor even any decided fall in the mosquito population in the sprayed area but the most noticeable change is the great fall in the rates of mosquito infection in the sprayed area. When the mixture is sprayed once a week the mosquitoes apparently live long enough to breed but not long enough to transmit infection.

(b) Special studies on infant indices were undertaken in some hyperendemic areas in Upper Assam. As a result of these studies it was found that in such areas the period of effective transmission is probably from May to December. The infants below 2 months inherit some degree of immunity from their mothers and the index in infants 2-3 months old is the best index of the quantum of seasonal infection being free from the immunity factor of the younger infants and the relapse factor of the older infants.

(c) In the course of the resurveys in Shillong and Gauipur intensive mosquito dissections were made to find the vector. In Shillong *A. maculatus* was the only vector found. Thirteen out of 793 or 1.6 per cent were found infected in 1940 and among these 9 out of 550 or 1.6 per cent were found infected in July, August and September.

Treatment schemes.—(a) This was continued in Doom Dooma where treatment of the disease was reinforced with anti-larval work. But treatment has been discontinued since 1941 due to its high cost and reliance placed only on anti-larval control which is giving quite satisfactory results.

(b) Two groups of villages, one under Tezpur Local Board and the other under Kamrup Local Board, were taken up for treatment during the height of the malaria season with funds provided jointly by the Government and the Local Boards concerned.

Technical guidance in other control projects.—This was furnished in 13 centres other than the experimental areas referred above. Periodical inspections were carried out and recommendations for intensifying the work made from time to time. The Society also furnished technical guidance in malaria control measures in progress in seven tea gardens. In all the centres the incidence of malaria was held under check due to the control measures.

RESEARCH WORK

Captain A. C. Vardon, I.M.D., continued his work on the reversion of water vibrios and their relation to *V. cholerae*. His findings were published in a paper entitled '*Vibrio cholerae* and other Vibrios', *Indian Medical Gazette*, LXXV, 91, p. 522.

The Director, with Dr. Naresh Chandra Roy, commenced an investigation into the therapeutic effect of sulphonamide drugs on rabies virus infection and this was still in progress at the end of the year under review.

A study is also being made of the relationship between the serum agglutination and the findings by blood culture in enteric fever cases among the civil population in Assam and it is hoped to compile the results shortly.

Correspondence

BACILLARY DYSENTERY AND M.&B. 693 (SULPHAPYRIDINE)

SIR,—I was called to see a patient, aged 26 years, in a collapsed condition with pulse almost imperceptible and temperature 103°F. He had numerous stools, mixed with profuse blood, mucus and sloughs for three days and intense pain in the lower abdomen, especially the ileo-cæcal region. There was much prostration. Bacteriophage and other treatment were given at the onset of the disease. He was immediately put on M.&B. 693. His general condition improved considerably and the stools were greatly reduced. The intense pain which was the most distressing symptom disappeared within twelve hours. Blood and slough disappeared on the fourth day of treatment. He was completely cured on the sixth day.

A child, aged 2 years, started illness with temperature 104°F., diarrhoea, nausea and intense tenesmus. The stools contained blood and slough. He was given a course of bacteriophage and then anti-dysenteric serum 2 c.cm. but without any effect. I then saw him and stopped all treatment and put him on M.&B. 693. The child had 6 to 7 tablets in all. The result was dramatic within 18 hours. Pain had gone and the child slept all day long. He had healthy stool on the fifth day of M.&B. 693 treatment.

I have treated about 25 cases of bacillary dysentery of severe type by M.&B. 693 and out of 25 cases, 24 recovered successfully and one died being complicated with malaria. It appears to me as a specific for bacillary dysentery. Its special action is the relief of pain within 8 to 12 hours. Blood disappears first and the stool becomes normal within 3 to 6 days. It is relatively cheaper than serum or any other form of treatment. The earlier the treatment is started, the better is the result. I have also used M.&B. 693 in many amœbic infections with good result. The result is far superior to emetine and other drugs such as carbarson, yatren, enterovioform and kurchi alkaloids.

S. M. ROY, L.M.P.

THE BARODA PHARMACY,
P. O. PUKURPAR (PABNA),
27th April, 1942.

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR A. N. CHOPRA, Additional Assistant Director-General, Indian Medical Service, is appointed to officiate as Additional Deputy Director-General, Indian Medical Service (Retd.), *vice* Lieutenant-Colonel S. L. Bhatia, M.C., granted leave.

Major C. A. Bozman, Port Health Officer, Bombay, is appointed to officiate as Additional Assistant Director-General, Indian Medical Service, *vice* Major A. N. Chopra.

Major W. S. Morgan, an Agency Surgeon, is appointed to officiate as Chief Medical Officer in Central India and Residency Surgeon, Indore, with effect from the forenoon of the 20th April, 1942.

Major M. Sendak, Senior Medical Officer, Port Blair, is appointed to officiate as Port Health Officer, Bombay, with effect from the afternoon of the 20th April, 1942, until further orders.

Major B. N. Khan is appointed Deputy Assistant Director-General (Medical Stores), Medical Store Depot, Raipur, with effect from 29th April, 1942.

Major B. A. Porrit is appointed Deputy Assistant Director-General (Medical Stores), Medical Store Depot, Madras, with effect from the afternoon of the 25th April, 1942, *vice* Major B. N. Khan, appointed as Deputy Assistant Director-General (Medical Stores), Raipur.

INDIAN LAND FORCES

Permanent Commission

To be Captain (on probation)

V. R. Damle. Dated 29th March, 1942, with seniority in his present rank from 29th March, 1937, and in the rank of Lieutenant from 29th March, 1936.

LEAVE

Lieutenant-Colonel M. A. Nicholson, C.I.E., an Agency Surgeon, Chief Medical Officer in Central India and Residency Surgeon, Indore, is granted leave from the 20th April to the 9th July, 1942 (both dates

inclusive), with effect from the afternoon of the 18th April, 1942.

PROMOTIONS

Majors to be Lieutenant-Colonels

M. Taylor, O.B.E. Dated 18th April, 1942.
W. Lawie. Dated 28th April, 1942.
F. R. W. K. Allen. Dated 5th April, 1942.

Captains to be Majors

C. F. Garfit. Dated 1st February, 1942.
F. W. Whiteman. Dated 18th April, 1942.
W. Mackie. Dated 20th April, 1942.

24th April, 1942

S. Ahmad.
T. F. O'Donnell.
H. B. Wright. Dated 7th May, 1942.

INDIAN LAND FORCES

(Emergency Commissions)

Lieutenants to be Captains

S. C. Ghosh. Dated 1st July, 1941.
A. Waheed. Dated 15th July, 1941.

12th April, 1942

Notes

BOVRIL LIMITED

EVEN DISTRIBUTION OF SUPPLIES

Lord Luke's review

PRESIDING at the forty-fifth annual general meeting of Bovril Ltd., held in London on 26th March, 1942, the Lord Luke, K.B.E. (chairman), said that since the issue of their report they had suffered a sad loss in the death of their vice-chairman, the Duke of Atholl. He had had a very distinguished career. He had been a brave soldier, an active member when in the House of Commons, and a great chieftain in his own country. He had joined their Board fifteen years ago and had been a helpful director, having been popular with the Bovril staff and employees both here and abroad.

Elasticity of organization

The Bovril organization, which had been built up during all these years, could show considerable elasticity at a period like this, not only in the production of Bovril but particularly of emergency rations and other food products, and by intensive work by day and night, etc., the output of all these was at least three times what it was in 1939.

During the period under review considerable trouble had been taken to distribute the supplies of Bovril as evenly as possible.

Nation's general nourishment never better

As chairman of the Ministry of Health's Committee on Nutrition, he had listened to some of the best informed dietitians, health experts, and statisticians discussing the question of the nation's diet.

There had been general agreement on the main facts, but he was sure progress would have been painfully slow if we had not come to a period of rationing. The last two years have given an opportunity that had so wisely been taken advantage of, and he should not be surprised if the nation was better nourished than ever before.

Monotonous meals

One, of course, heard talk of the monotony of our meals simply because we missed that infinite variety of tasty extras that used mostly to come from overseas in ships with great refrigerators. Obviously we had to forget such dainties for the present, though after the war they should begin to come again. However, we must hope that the improvements in the main features of the nation's nutrition would not be discarded and cast aside lightly.

No increase in the price of Bovril

They were rather proud of the fact that since Bovril was first marketed, over half a century ago, its price had never been raised during a period of war. There was no increase during the 1914-18 war, nor had the price been raised during this war, in spite of the general increase in prices all round. He hoped that they would be able to maintain this record, as he was anxious that they should do so in order to avoid penalizing the many thousands of regular consumers of Bovril who relied on it especially during trying times.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

ENTERIC FEVER IN CALCUTTA

By L. EVERARD NAPIER, C.I.E., F.R.C.P. (Lond.)
R. N. CHAUDHURI, M.B. (Cal.), M.R.C.P. (Edin.),
T.D.D. (Wales)

and

M. N. RAI CHAUDHURI, M.B. (Cal.)
(From the School of Tropical Medicine, Calcutta)

Introduction.—In western countries the present-day attitude towards the enteric fevers in India is reflected by Manson-Bahr in the 1940 edition of his invaluable book. He considers it to be the scourge of recently arrived young Europeans in India, 'but, fortunately, liability to infection decreases with length of residence, due apparently to a kind of acclimatization. The well-known immunity of native races to typhoid is probably due either to mild attacks of the disease in childhood or to the immunizing effect of living in constant contact with typhoid infection. The typhoid and paratyphoid infections among Europeans in the tropics appear to be more virulent, and to cause a death rate twice as heavy as that commonly observed in England. According to English statistics, the death rate is given as about 1:8 attacked, but in India only recently the death rate is stated as rather over 1:3'.

'Enteric fever' is a comprehensive term designating fevers due to infection with *Bacterium typhosum* (*Erberthella typhi*), as well as with some of the *Salmonella* group of organisms. The word 'typhoid', though often used synonymously with enteric fever, should be applied strictly to the former infection. Distinction is seldom made between typhoid, paratyphoid, and possibly allied infections in the statistics of enteric fever.

Although a typical case of typhoid fever can usually be recognized clinically, certainly after the first week, the diagnosis, either positive or negative, based only on signs and symptoms is not always reliable; autopsies performed on fatal cases of so-called typhoid fever diagnosed clinically have on many occasions revealed an altogether different condition. Conversely, many typhoid cases, especially the atypical ones, are passed as unexplained pyrexia, escaping recognition for want of proper bacteriological investigation. On the other hand, it is not uncommon to come across cases that appear to be typhoid clinically, but in which the diagnosis cannot be bacteriologically confirmed even after repeated examinations, while no other cause can be found. It is probable that some of these cases are instances of infection due to allied enteric organisms, such as *Bact.*

metalkaligenes and *Alkaligenes faecalis*. We have observed that these cases are liable to develop a more serious course than the bacteriologically diagnosed cases of typhoid, and the patient often dies. Published figures of typhoid mortality from different provinces include all typhoid-like fevers, and therefore do not represent bacteriologically diagnosed typhoid infection.

A better appreciation of the clinical course, and prognosis in this group of fevers will not be obtained until a larger percentage of cases are diagnosed bacteriologically, and not simply clinically, or by the Widal reaction which is susceptible to misinterpretation. The Army authorities recognized this fact even in the last war, and though the cynically minded will point out that, by refusing to recognize anything but a bacteriological diagnosis, they have devised a means of reducing the incidence of enteric to about a tenth of its previous proportions, their action certainly clarified the position and excluded many cases of undiagnosed fever that were not enteric in origin.

In order to ascertain how far our own experience tallies with the foreign and the local conceptions of enteric fever in India, we undertook an analysis of enteric cases treated by us during the last four years.

The patients

The subjects of this analysis are 77 patients admitted to the hospital attached to the Calcutta School of Tropical Medicine during the last four years, in which a diagnosis, either clinical or bacteriological, of enteric fever was made. The Widal control cases were patients in the same hospital. All the patients were from a class in which anti-typhoid inoculation is rare. Except in one case there is no evidence that any patient was inoculated.

The causative organism was isolated in 38 cases and in 39 the diagnosis was dependent on other observations, usually on the Widal reaction.

Epidemiology

Seasonal prevalence.—The monthly incidence of the cases, according to the date of admission, is given below; the largest number of patients were admitted in July. Cases however occur at all times of the year.

Cases		Cases	
January	.. 6	July	.. 12
February	.. 6	August	.. 5
March	.. 6	September	.. 7
April	.. 3	October	.. 8
May	.. 8	November	.. 4
June	.. 6	December	.. 6

Race.—The series included 33 Bengalis, 20 Europeans and Anglo-Indians, 21 Indians from other provinces, 1 Persian and 2 Jews. The

distribution according to bacteriologically positive and negative groups was as follows:—

	Positive group cases	Negative group cases
Bengalis ..	15	18
Anglo-Indians ..	7	7
Europeans ..	2	4
Punjabis ..	5	3
United Provinces ..	3	3
Beharis ..	1	2
Madrasis ..	3	0
Jews ..	2	0
Assamese ..	0	1
Persian ..	0	1

Occupation.—The following table gives the occupation in 31 cases; the rest were women or children or gave no information regarding their occupations.

	Bacteriologically positive	Bacteriologically negative	All
Students ..	6	4	10
Office workers ..	2	6	8
Professional	3
Medical ..	1	1	..
Legal	1	..
Engineers ..	1	1	2
Excise officer	1	1
Manual workers ..	1	3	4
Laboratory assistants ..	1	1	2
Sweeper	1	1
TOTAL ..	12	19	31

Age.—The youngest patient in this series was 2½ years and the oldest 51 years. Twelve were under 12 years of age. In the bacteriologically positive group, the incidence varied from 2½ to 41 years. There were ten cases in the positive series and 11 cases in the negative series, between 11 and 20 years. About 90 per cent patients of the positive series and 77 per cent of the negative ones were aged 30 years or under.

Sex.—There were 51 males and 26 females in this series, but no conclusion can be drawn from this, as beds in the female wards of the hospital are more limited. The ratio of male to female beds is about 3 : 1, so that, if anything, the figure suggests a relative female preponderance. In the positive group there were 26 males and 12 females, while the negative series included 25 males and 14 females.

The distribution curve (age and sex) is given below:—

Age in years	Under 10	10 to 20	21 to 30	31 to 40	41 to 50	51 to 60
Bact. +ve series						
Male ..	8	7	9	1	0	0
Female ..	4	5	2	0	1	0
Bact. -ve series						
Male ..	3	7	9	5	0	1
Female ..	4	8	0	2	1	0
TOTAL ..	19	27	20	8	2	1 = 77

Family history.—Only two patients gave a history of recent typhoid infection in their families; both were in the bacteriologically positive group.

Past history.—Five patients, three in the bacteriologically positive group, gave a history of previous attack of enteric and only one a history of inoculation.

Clinical features

Onset.—There was a gradual onset in the majority of the cases that were admitted early. There was a definite chilliness at the onset in 11 cases of which four were bacteriologically positive, pains all over the body in two cases, nausea and vomiting in two, sweating in two, and headache in 12 cases of which five were bacteriologically positive.

Temperature.—This took one of the forms shown in the tabular statement below. The figures indicate the number of cases in each group.

	Bacteriologically positive	Bacteriologically negative
High continued (above 103°F.)	5	6
High remittent (above 103°F.)	16	8
Moderate remittent (101°F. to 103°F.).	10	14
Moderate continued ..	4	4
Intermittent ..	3	7
	38	39

Special clinical features

Exanthema.—One Indian patient developed rose spots on the chest on the ninth day of illness.

Bradycardia.—The pulse rate was definitely slow (100 or under with a temperature of 102° or over) in eight cases (10.4 per cent) only, of which two were bacteriologically positive; thus a slow pulse was relatively uncommon in this series of cases.

Tongue.—This was usually coated; the observations on this point on admission are shown below:—

	Bact. +ve cases	Bact. -ve cases	All
Coated ..	28	28	56
Clean ..	2	5	7
Stomatitis	1	1
			64

Spleen.—This was palpable in 22 cases, 12 of which were bacteriologically positive.

Liver.—This was palpable in 18 cases, ten of which were bacteriologically positive.

Bowels.—In 23 cases no abnormality of the bowels was noted; in 41 there was constipation, and in 13 diarrhoea, of which four had a dysenteric condition.

Complications.—The complications noted were as follows :—

Acute oedema of the lung ..	1	Tympanitis ..	10
Broncho-pneumonia ..	4	Abdominal rigidity ..	1
Bronchitis ..	20	Tender gall-bladder ..	1
Toxic symptoms, delirium, etc. ..	4	Bed sores ..	1
		Phlebitis ..	1
		Slight hæmorrhage from bowel ..	1

Intercurrent infections.—Each of the following conditions was noted once as an intercurrent infection :—tuberculosis, cholera, kala-azar, and ascaris infection.

The blood picture

A blood count was done soon after admission in 48 cases; some of the features are given below :—

Hæmoglobin.—This was done with the Hellige hæmoglobinometer, the results were recorded in grammes of hæmoglobin per 100 c.cm. of blood. It varied from 5.9 (43 per cent) to 16.5 (120 per cent) grammes. The frequency distribution is given below :—

Grammes of hæmoglobin per 100 c.cm. of blood	Cases
Under 9	3
9 to 11	12
11.1 to 13.75	22
Above 13.75	8

Red cells.—The red cell count varied from 2.20 to 5.76 millions per c.mm. as shown below :—

Red cell count in million per c.mm.	Cases	Leucocyte count in thousands per c.mm.	Cases
Under 3 ..	1	Under 5 ..	13
3 to 4 ..	11	5 to 7 ..	13
Above 4 ..	35	7.1 to 10 ..	13
		Above 10 ..	9

Leucocytes.—The total leucocyte count varied from 1,500 to 15,400 per c.mm. The frequency distribution is given in the table above.

Comment.—There is thus nothing very characteristic in the blood picture and little diagnostic assistance, except of a negative nature, can be expected from it. There is slight anæmia in the majority of cases, but the average white cell count is probably above the normal in this country, where a count of under 5,000 is not uncommon in apparent health.

Diagnosis

Bacteriological.—A blood culture* was taken on admission, or immediately typhoid was suspected, and blood for Widal at the same time and every five days subsequently. Stools were examined daily for five days.

	Cases
(a) Blood only	18
(b) Stools only	8
(c) Urine only	1
(d) Blood and stools	6
(e) Blood, stool and urine	2
(f) Marrow, blood and stools	3
	38

Sternal puncture was done in eight cases, in five of the positive series of which three gave a positive culture, and in three of the negative series. In no case was the sternal puncture alone positive.

In 38 cases organisms of the enteric group were isolated; in 33 *Bacterium typhosum* was isolated and in five *Bact. paratyphosum A*.

In 29 cases it was isolated from the peripheral blood; these included three paratyphoid cases.

The duration of the disease at the time the blood was taken is shown in the table below :—

Time of first positive culture

	Blood	Stools
1st week	9	3
2nd "	11	10
3rd "	3	3
4th "	3	1
Later ..	5	2

In two cases of the last group (blood), there was a clinical relapse.

In two instances a second culture was positive in the 4th and 5th weeks, respectively, but in these cases there was also a clinical relapse.

Enteric group organisms were isolated from the stools in 19 cases, of which two were paratyphoid A.

The duration of the disease in these cases when the organisms were first isolated is shown in the table above.

In four cases, a second positive culture was obtained during the 2nd, 3rd, 4th and 5th weeks, respectively.

Bact. typhosum was isolated from the urine in three cases after the 4th week.

In all except one case the clinical picture was in keeping with the bacteriological diagnosis. In this case, the clinical course was irregular and it seems possible that he was a

*The syringe is oil-sterilized and skin cleansed with iodine, washed off with spirit; the blood (5 c.cm.) is put directly into a bottle of nutrient digest broth provided by the bacteriological laboratory.

temporary carrier; the O-agglutination was positive in a dilution of 1 in 100 to *B. paratyphosum A*, only once of seven tests.

Serological diagnosis

The diagnosis was made on the clinical picture supported by the results of the Widal* reaction, in 39 cases.

TABLE I

	Number of cases		Percentage of cases negative or positive in each dilution	
	H	O	H	O
All negative ..	39	21	64	34
Positive 1 in 25	6	2	36	66
1 in 50	7	11	26	62
1 in 100	5	13	15	44
1 in 200	4	9	7	23
1 in 400	0	2	0	8
1 in 800	0	3	0	6

*The Widal reaction was done in the bacteriological department of the School under the charge of Lieut.-Colonel C. L. Pasricha, I.M.S., and later of Dr. G. Panja.

Dr. K. P. Banerjee was personally responsible for most of the tests and we have to thank him for the data regarding the control cases which he very kindly extracted from the ward and laboratory notes.

The Dreyer technique was used; the antigens were prepared by the standard method and the titre standardized against high-titre sera received from Oxford.

Controls.—This opportunity was taken of analysing the results of the H- and O-agglutination readings in the Widal of 61 patients in the hospital during the same period, (1939-40) in which a diagnosis other than enteric was eventually made. The results are shown in tabular form (table I) classified according to highest dilution in which a positive reading was obtained. The highest agglutinations were with typhoid antigen in each case. In 12 cases more than one test was carried out; the highest reading only is considered.

Enteric cases.—Tables II and III show the results of the agglutination tests with O and H antigens, respectively, with the enteric group organism which was demonstrated, or which was assumed to be the causative organism, as the case may be, according to (a) the highest positive dilution in which agglutination occurred, (b) the week of the disease, and (c) whether a bacteriological diagnosis was made. In tables II-a and III-a these data are summarized and the numbers and percentages of cases in which a positive Widal reaction at 1 in 100, 1 in 200, and 1 in 400 dilutions, respectively, at different weeks of the disease was obtained are shown. In these tables the agglutination referred to is against the specific antigen, *Bact. typhosum* or *Bact. paratyphosum A*, as the case may be.

The agglutinations were much higher with the former antigen, and in fact in the five cases of paratyphoid the agglutination was :—(i) negative up to the 17th day; (ii) negative up to

the 57th day, when it was 1 in 100; (iii) never above 1 in 100 which it reached on the 17th and 34th days; (iv) never higher than 1 in 100 which it reached on the 34th day; and (v) 1 in 400 throughout observation, but also 1 in 200 *Bact. paratyphosum B* and 1 in 400 *Bact. typhosum*.

In (i) the *Bact. typhosum* agglutination was also negative, and in (iv) it was only 1 in 50, but in the rest it was higher than the specific agglutination.

Comparison of bacteriologically positive and negative cases

Maximum titre.—In nearly every instance the bacteriologically positive cases show a higher percentage of positive Widal results, whether the O or the H antigens were used. The difference in the individual groups is often not significant, but grouped together it becomes very significant.

Any fallacy that might arise through the Widal reaction influencing the diagnosis in these bacteriologically negative cases would lead

TABLE IV : Showing the time of peak of the agglutination curve

		1st week	2nd week	3rd week	4th week	5th week	6th week	7th week and up
O-agglutination	Positive	..	3	7	8	6	7	4
	Negative	..	3	9	11	5	3	3
H-agglutination	Positive	1	5	5	9	4	7	4
	Negative	1	3	10	4	4	2	3

The peak of the agglutination curve.—Table IV shows the time of the highest points in the O-agglutination curve in 35 bacteriologically positive and 34 bacteriologically negative cases. In both graphs the highest point is in the 4th week. With the H-agglutination the peak is in the 4th week in 35 bacteriologically positive cases and in the 3rd week in 27 bacteriologically negative ones.

to the selection of cases with a high Widal reaction in this group.

Conclusion.—Taking both the facts presented above into consideration, the finding of a lower agglutination in the bacteriologically negative cases does seem to suggest that they were perhaps not all cases of enteric. As, however, particularly in the later weeks, the difference between the percentages of positive Widal's in the two groups

is very small, it is apparent that, even if we give this interpretation to the observation, not many non-enteric cases were included.

Comparison between the Widal in the control group and in the enteric cases at different weeks
O-agglutination

The lowest possible dilution it would be worth considering is 1 in 100. In the control group 44 per cent were positive in this dilution. If this is compared with the percentages in table II-a, it will be seen that during the 1st week 70 per cent were positive in this dilution, but the numbers are few so that the difference is not significant. In all the later weeks the difference is significant, but with 44 per cent positive in the control group a Widal in this dilution is only of negative value.

At a dilution of 1 in 200 the percentage of positive Widal in the controls drops to 23 per cent and is never lower than 60 per cent in the bacteriologically positive group: the differences are all significant, but with a 1 in 4 (almost) chance of a false positive, the value of a positive result is still not high.

At a dilution of 1 in 400 only 8 per cent are positive in the control group, whereas in the bacteriologically positive cases the percentage of positive cases rises from 17 in the 2nd week to 48 per cent in the 3rd, 67 per cent in the 4th, to a maximum of 78 per cent after the 4th week.

Controls with positive Widal.—There were five of these:—Case (i) was a case of malaria in which there is no record of his having been inoculated, but he was also positive in a high dilution to paratyphosus A and B as well as to typhoid, so the chances are that he had been inoculated, case (ii) was a doctor who had possibly previously had typhoid and now had cholecystitis, case (iii) was also a doctor and had cholelithiasis (a few days later the Widal was positive 1 in 100 only), case (iv) was a medical student (positive 1 in 400) with influenza, and case (v) had a very obstinate macrocytic anemia (positive 1 in 800).

Bacteriologically positive cases with low-titre Widal late in disease.—There were six cases in this category:—Case (i) was negative up to the 32nd day, case (ii) showed a very late rise and was positive 1 in 100 in the 9th week, case (iii) was positive 1 in 100 in the 10th week but later rose to 1 in 800, cases (iv) and (v) were positive 1 in 100 only after the 4th week, but during the 4th week with 1 in 200 and 1 in 400, respectively; that is, the titre was falling, case (vi) seems to have been a carrier (*paratyphosus A*) for he was clinically not enteric nor was the Widal ever more than 1 in 100.

Conclusion.—As with the O antigen a positive Widal 1 in 200 may occur in one non-enteric case in four, a Widal result of this calibre though suggestive is not of very great positive diagnostic importance.

A 1 in 400 agglutination only occurred in 8 per cent of controls in the first examination, so that a Widal result of this calibre has a very considerable diagnostic value; it occurred in 20 per cent of bacteriologically positive cases in the 2nd week, 52 per cent in the 3rd, 70 per cent in the 4th and in 77 per cent after the 4th week.

The difference between 8 per cent and 21 per cent is not significant, but in the 3rd and

subsequent weeks the difference is very significant.

As the Widal was positive in a 1-in-200 dilution in the 1st and 2nd weeks in 72 per cent of cases, a negative reaction in this dilution is suggestive but not strong evidence against a diagnosis of enteric; by the 4th week however only one in eight cases of the bacteriologically diagnosed enteric cases failed to reach this titre, so that a negative Widal in this titre at this stage has a considerable negative value.

A negative Widal at 1-in-100 dilution occurred in only three cases after the 3rd week; one was apparently a carrier of *Bact. paratyphosum A*, another was positive at a higher titre earlier in the disease, and the third was negative up to the 32nd day. Thus, very great negative value can be attached to a continuous negative Widal at this dilution, but it does not entirely exclude enteric.

H-agglutination

H-agglutination 1 in 100 is positive in the control series in 9 out of 61 cases (14.8 per cent) and in the bacteriologically positive group in 3 out of 10 cases (30 per cent) in the 1st week and in 58.6 per cent in the 2nd week. The difference between the controls and the 1st week results is not significant, but between the control and the subsequent weeks' results it is very significant.

H-agglutination at 1 in 200 was only found in 6.6 per cent of the controls, in 20 per cent of the bacteriologically positive cases in the first week, 48.2 in the 2nd and in higher percentages later; the percentages in the 2nd week and later are very significantly greater than in the controls.

In a dilution of 1 in 400 no H-agglutination was positive in the control series, and in the bacteriologically positive cases the percentages were 10, 13.7, 32.2 and 48.2 per cent in the 1st to 4th weeks; all these percentages are significantly higher than the nil percentage of the control cases.

Conclusion.—H-agglutination 1 in 100 is suggestive, as less than 15 per cent of controls gave this agglutination; at 1 in 200 it is strongly suggestive, and at 1 in 400 practically diagnostic of enteric.

As, however, even at 1 in 100 in the 3rd and 4th weeks the H-agglutination is negative at least once in four times, a negative test at this dilution is not of any great value.

Summary of conclusions on the diagnostic value of the Widal reaction.—Thus, we could say that a positive O-agglutination of 1 in 400 or H-agglutination of 1 in 200 is very suggestive, an H-agglutination of 1 in 400 practically diagnostic of enteric, and that a negative O-agglutination at a dilution of 1 in 100 in the 2nd or 3rd week or one at a dilution of 1 in 200 in the 4th week are strong evidence against enteric. As the H-agglutination failed to rise to a titre of 1 in 100 in 25 per cent of enteric cases

in the 4th or later weeks, a negative reaction in this titre is of little diagnostic significance.

Rising titre.—A 'two-tube' increase was reported in 21 (TH) and 32 (TO) in the bacterially positive cases, and in 15 (TH) and 22 (TO) in the negative ones.

Specific value.—In two out of the three blood-positive paratyphoid cases, *Bact. paratyphosum*

patient, furnishes about 2,000 calories, and represents a minimum. The daily intake of protein is about 60 grammes (roughly one gramme per kilo body-weight). Fat supplies 20 to 25 per cent of the total calories. The rest of the energy is furnished by carbohydrates; it is given as lactose (less sweet and does not produce gas), dextrin, glucose and/or sugar in the order

TABLE V : Summarizing the conclusions on the interpretation of the Widal test

	Positive diagnosis	Negative diagnosis	Significance
O-agglutination	Positive 1 in 200	Negative 1 in 200 in 1st and 2nd week	is suggestive.
	" 1 in 400	" 1 in 200 in 4th week or later	is very suggestive.
	" ..	" 1 in 100 in 2nd or 3rd week	is very suggestive.
	" ..	" 1 in 100 in 4th week	is almost conclusive.
H-agglutination	Positive 1 in 100	Negative 1 in 100 in 3rd week or later	is suggestive.
	" 1 in 200	" ..	is very suggestive.
	" 1 in 400	" ..	is almost conclusive.

H-agglutination was higher than the corresponding *typhosum* agglutination and on the third day they were equal, whereas in all three the *typhosum* O-agglutination was the higher.

In the 26 bacteriologically positive typhoid cases, all H-agglutinations were negative in 2; of the rest the H-agglutination was higher with *Bact. typhosum* than with the *Bact. paratyphosum* A or B in 22 cases, and equal to one another in two. Whereas the O-agglutination was highest with *Bact. typhosum* in 23 cases, highest in *Bact. paratyphosum* A in two, and equal with *Bact. typhosum* or *Bact. paratyphosum* B in one.

Both these observations suggest a greater specific value for the H-agglutination; this fact is usually accepted.

TREATMENT

The treatment was mainly dietetic and symptomatic; in a few cases certain specific treatments were superimposed, of which details are given.

Diet.—Practically every adult patient was given the diet shown in table VI. We seldom had occasions to reduce it in any case of the bacteriologically diagnosed group; on the contrary there were many instances in which we extended the diet, especially in the later stages of the illness, by incorporating egg-flip, jelly, thin bread and butter, biscuits, mashed potatoes, etc., the consumption of some solids was encouraged early in order to maintain mouth sanitation. If for some reason a reasonable amount of diet could not be given, glucose was administered parenterally as a supplement.

The amount of food required obviously varies in the individual case, the points considered are the patient's dietetic habit, his weight, appetite, degree of toxæmia, etc.

This diet, which was designed to meet the lower requirements of the average Indian

of preference. Plenty of water is given between feeds; *dab* or barley water may be preferable for private patients.

Unless there are definite contra-indications, such as tympanites or severe toxæmia, the patient is pressed to take the full dietary quota; high fever, slight toxæmia, lack of appetite, etc., which are the usual symptoms of the disease, are not looked upon as excuses for starving the patient.

As the convalescence began, the diet was gradually increased by addition of eggs, bread and butter, etc., if these had not already been given, and thereafter, the patient was given fish, soft rice, and puddings until a full diet was attained.

TABLE VI : Typhoid diet

Article	Quantity	Protein	Fat	Carbo- hydrate	Calories
		Grammes			
Milk ..	40 oz.	37.5	41	54.5	720
Chicken soup	4 oz.	12	1	2	65
Oranges ..	6	4.5	0	40.5	180
Sugar ..	4 oz.	0	0	113	452
Glucose ..	4 oz.	0	0	113	452
Bread ..	2 oz.	4	0.5	30	140
		58	42.5	353	2,009

Feeds

- 6 a.m.—Milk (8 oz.) with sugar (3 teaspoonfuls).
- 8 a.m.—Glucose (1½ oz.) with sufficient water.
- 10 a.m.—Milk (8 oz.) and bread (2 oz.) with sugar (4 teaspoonfuls).
- 12 noon.—Orange juice (6 oranges) with glucose (1 oz.).
- 2 p.m.—As at 6 a.m.
- 4 p.m.—Glucose (1½ oz.) with sufficient water.

6-30 p.m.—Chicken soup (4 oz.).

10 p.m.—As at 6 a.m.

During night.—As at 6 a.m.

Symptomatic treatment.—A simple alkaline diaphoretic mixture was given to all patients. Constipation (present in the large majority) was dealt with by a simple enema on alternate days, with or without liquid paraffin by mouth. Moderate diarrhoea was encountered in a few cases; this usually responded to some modification of diet, such as the substitution of peptonized milk or whey for ordinary milk. Some had Mellin's food. A chalk mixture, or bismuth with Dover's powder, or a starch and opium enema at night was given in a very few cases in which it was necessary.

For meteorism, turpentine stupes to the abdomen, with or without oil of cinnamon by mouth, was found sufficient in most cases. The milk was eitrated or peptonized and glucose was reduced or replaced by lactose or dextrin. A few cases were given fractional doses of calomel with good result. None required injections of pituitrin or eserine.

Hyperpyrexia was usually combated by hydrotherapy. To ensure sleep at night bromides or phenobarbitone were given whenever required. The more seriously ill patients with feeble pulses were given brandy and intravenous glucose. A few had 5 per cent glucose saline by the drip method; others had cardiazol, coramine, or camphor-in-oil injections. None had injections of suprarenal cortical extract.

Retention of urine, which occurred in a few cases, responded to applications of a hot-water bag over the bladder and a warm enema, but often a change of posture was sufficient. Catheterization was rarely necessary.

Quinine was given in five cases—three of the positive and two of the negative series—during what should have been the convalescence period of illness, as they were running irregular intermittent temperatures. Quartan parasites were found in one case. The temperature was readily controlled in all of them. Six patients had quinine in the earlier stages of the illness before a diagnosis was made, presumably as a therapeutic test to exclude malaria. Except for perhaps a slight temporary febrile action, the drug had no effect on the fever.

Specific treatment

Anti-typhoid serum was used in three patients; two had 30 c.cm. intramuscularly for three consecutive days. In the other, which was the only really severe toxic case in the 'positive' series, an Indian boy aged 8, Felix's Vi anti-typhoid serum was given in doses of 20 c.cm., 40 c.cm. and 40 c.cm. on three consecutive days; he was unconscious when the first dose was given and at the third dose had a violent reaction and became pulseless, but we believe that the treatment determined the turning point in the disease and eventually he recovered.

Typhoid 'phage was given to eight patients, in one case intravenously in a minute dose. There was no evidence that this influenced the course of the disease to the slightest degree.

Sulphapyridine was given to eight cases, pronosil to one and sulphanilyl-guanidine to one case; no significant effect was observed.

Hospital routine.—All the patients were treated in the open wards; the usual 'typhoid precautions' were taken and no secondary cases occurred.

Just before discharge the faeces and urine were examined in the bacteriological laboratory at least three times; no carriers were detected.

Results of treatment.—Few of our patients lost weight during treatment and those who did regained it before leaving hospital.

Typical weight chart. The patient was admitted at end of second week and had a relapse; 'FEB' indicates the febrile periods.

Relapses occurred in seven cases (see below).

There were no serious complications, such as hæmorrhage or perforation; but in one case there was apparently slight bleeding from an ulcer; the blood was only detected in the stools on one day.

There were no deaths in the positive series and two deaths in the negative series; all the patients remained in hospital until convalescence was established.

Relapses

Relapses occurred in seven cases—five of the positive and two of the negative series—the percentage relapse rate thus being 9 only. The number of days of apyrexia after which the relapse occurred was:—

	Positive series	Negative series
Under 5 days ..	0	1
5 to 10 days ..	4	1
11 to 15 days ..	1	0
	5	2

The relapse occurred on an average on the ninth day of normal temperature; the earliest was on the third day and latest on the fifteenth day.

The febrile period of the relapses varied from 7 to 17 days as shown below :—

	Positive series	Negative series
7 to 10 days ..	2	2
11 to 17 days ..	3	0
	5	2

The type of temperature was remittent in all cases except one—

	Positive series	Negative series
Remittent fever	4	2
Intermittent fever	1	0
	5	2

All had a slow rise and in all the temperature fell by lysis.

The bowels were constipated in five cases; none had diarrhoea.

Complication.—Only one of these patients had a recurrence of phlebitis that he had had during the original attack. The course was uneventful in all other cases during the relapse. None had more than one relapse. All of them recovered.

The *causative organisms* were isolated from the blood in four cases and from the urine in one case during the relapse. During the original attack the blood was positive in one and the stools in four of these patients.

DISCUSSION

Enteric in India.—Fifty years ago typhoid was never diagnosed in Indians, and it was, therefore, not understood why it was so common amongst Europeans, especially amongst European soldiers. This failure to diagnose typhoid in Indians is not easy to explain, in view of the fact that it is a very common disease amongst Indians today. The authors' view is that in the past it was probably a very common disease in childhood when it escaped diagnosis, and that adults were therefore protected by their previous experience. Now that India has enjoyed two generations of improved sanitation, typhoid is

rarer in childhood and therefore commoner in adult life when it is more easily recognized.

To-day it is certainly widely prevalent amongst Indians in this country, and it sometimes breaks out in epidemic form. For instance, 'from Bombay presidency about 5,000 to 8,000 cases of enteric fever are reported every year and Bombay city accounts for more than 2,000 cases out of them. There were two widespread epidemics here, one in 1937 and another in 1938' (Sulakhe, 1941). According to the *Calcutta Municipal Gazette, Health Number*, 1940, the death rate from typhoid in Calcutta during a period of 10 years (1927 to 1937) was on an average 0.78 per mille. It broke out in epidemic form in a Calcutta hotel in 1938. Outbreaks were reported in Delhi in 1935. There was a small outbreak of 13 cases of paratyphoid A in Lahore district in 1940.

The severity of the disease in India.—The writers are impressed by the fact that the disease tends to be milder in Indians than in Europeans, though many will not agree with this. Our experience reported above certainly supports this view for we had no deaths in 38 bacteriologically diagnosed cases and only two in the whole series of 77, that is a mortality of less than 3 per cent.

On the other hand, newly arrived foreigners are liable to be more dangerously ill as a result of infection with local strains of organisms. Thus, Murray (1938) reported a large percentage of serious cases amongst 31 European patients admitted into the Presidency General Hospital, Calcutta, following a typhoid outbreak in an hotel.

Incidence of paratyphoid infection.—The relative frequency of the various enteric infections in India does not seem to have been clearly established. Manson-Bahr (1940) writes 'paratyphoid is the most common infection in the East (India, etc.)'. Box (1937) states that paratyphoid A is prevalent in India and other tropical countries. Lakin (1937) also holds the same view. Yodh (1937) reporting on 60 cases stated that *Bact. typhosum* was the causative organism in most of the cases. Minchin (1939) found only three cases of paratyphoid A and two of paratyphoid B among 444 cases of enteric fever. Sulakhe (*loc. cit.*) in a series of 75 cases considered all cases except one to be due to infection by *Bact. typhosum*. Others in this country have found a higher percentage of paratyphoid A cases, but never above 16 per cent of the total enteric cases.

In the present series, five were cases of paratyphoid A infection, an incidence of 13 per cent, among 38 patients from whom the organisms were actually isolated. In none was paratyphoid B found.

Thus, while there is no support for the view of the majority of the statements in British textbooks, that paratyphoid A is the common enteric infection in India, it does seem possible that there are many more cases of paratyphoid

fever than are diagnosed. A much lower agglutination titre is obtained with the para-typoid organisms than with *Bact. typhosum*, and in our bacteriologically positive series, the para-typoid titre of the O-agglutination did not rise above 1 in 100, except in one case though the H-agglutination was 1 in 800. It will be seen that on the Widal reaction alone not a single case was diagnosed. Karunakaram and Pillai (1942) believe that many cases are missed through failure to do early blood cultures, and bring evidence in support of their, and our, opinion.

Season.—The maximum number of patients of this series were admitted in the month of July; cases however came at all times of the year. Sulakhe (*loc. cit.*) obtained the maximum incidence in June, July and August.

Culture.—Although it is commonly stated that the bacterial culture of blood for enteric organisms is only positive in the first ten days, organisms may be isolated much later in the disease. Minchin (*loc. cit.*) reported positive blood cultures in 50 per cent of his cases; 11 per cent were positive after 15 days of illness. Murray (*loc. cit.*) obtained a positive blood culture in one case six weeks after the commencement of illness. In our series the causative organisms were isolated in almost half the cases; the blood was positive in 37.6 per cent and the stools in 24.6 per cent cases. In nine cases the blood culture was positive in the 1st week, in 11 during the 2nd week, and in 11 later than the 2nd week.

Diagnosis on the Widal reaction.—Minchin (*loc. cit.*) takes a Widal of 1 in 200 dilution as positive evidence of typhoid. Lewin (1938) considers that in an uninoculated person a 1 in 100 H- and a 1 in 200 O-agglutination give a diagnostic error of 3 per cent.

The comparative study of our Widal results of enteric and non-enteric cases shows that, in the population with which we deal, mostly uninoculated, a positive H-agglutination of 1 in 100 is suggestive, 1 in 200 is very suggestive and 1 in 400 is almost conclusive, while a positive O-agglutination of 1 in 200 is suggestive and 1 in 400 is very suggestive of enteric diagnosis.

The H-agglutination has a greater positive value, but a negative H-agglutination is of little significance as the H-agglutinins may fail to appear. On the other hand, a negative O-agglutination, or one positive only at 1 in 200, in the later weeks is strong evidence against enteric. A far more significant point in the diagnosis by Widal reaction is an early negative or weakly positive result, with a subsequent steady rise in titre.

Mortality.—The death rate in Minchin's series was 13.7 per cent and in that of Sulakhe 25 per cent. Rajoo (1942) reported a death rate of 20.22 per cent in 356 cases. Minchin included three groups of patients on different diets. The mortality rate did not differ much between these groups, but the cases in the high calorie-diet

group showed least complications. The high mortality in Sulakhe's series was probably due to the fact that most of the cases came to the hospital late in the course of the disease; five cases came with serious complications and died within 48 hours after admission.

In the present series, the mortality is 2.6 per cent.

Complications.—The absence of serious abdominal complications is also a notable feature in this series. Only one patient had slight bleeding from the bowel; none had perforation. Both Minchin and Sulakhe reported hæmorrhages in 3.6 and 4 per cent of their cases, and perforation in 0.9 and 2.6 per cent respectively. Rajoo (*loc. cit.*) reported 23 cases of hæmorrhage, 11 of which were fatal in a series of 356 cases. Murray had two cases (6.4 per cent) of fatal hæmorrhage.

Thirteen per cent of our cases had definite tympanites, while Minchin's percentage was only 11.5.

Relapses.—A relapse occurred in 9 per cent of our cases, while Minchin and Sulakhe had 6.5 and 5 per cent, respectively.

Possible causes of the rarity of complications and the low mortality.—These seem to call for some comment. No claim can be made for the efficacy of any specific treatment, with the possible exception of the action of serum in one very severe case; few cases caused us any anxiety during the course of the disease and, as noted, none had serious complications.

The nursing was good, probably as good as that in any of the best hospitals in India, but in some of the other published series with higher death rates the nursing was also good.

This brings one to the question of diet. There is a deeply ingrained, and in our experience, quite inexplicable, prejudice in this country against a liberal diet in typhoid fever. The high-calorie diet was started after the Boer war when, the story has it, all the typhoid cases in Ladysmith during the siege were fed on 'bully beef' and did remarkably well. The high-calorie diet was placed on a more scientific footing by Coleman (1909) and other workers, and it has been the practice in America for over thirty years. In Great Britain there has been little typhoid, except for a few recent outbreaks that obtained much publicity, for the last three decades, so that textbooks were slow to revise their teaching; nevertheless, most standard textbooks now advocate a liberal diet.

The rationale of the high-calorie diet is shortly this :—

The continuous temperature puts up the metabolic requirements of the patient by about 40 per cent. If he is not given a liberal diet he will have to live on his own tissues; superfluous tissues are soon exhausted, so that he has to burn vital tissues, and one of the earliest calls is on muscle, including the intestinal muscle; when this is reduced blood vessels are laid bare and the peritoneum is left without support, so that both hæmorrhage and perforation are likely

to occur. A liberal diet should obviate this and in practice it has been repeatedly shown that it does so.

The main objection raised against the high-calorie diet, that the waste products of protein metabolism are toxic substances which add to the already existing toxæmia, is more theoretical than real. The objection to the giving of solids, namely that they are likely to push their way through ulcers, entirely ignores the physiological fact that digestible pieces of solid food do not pass through the pylorus in this state, but, if in solid form at all, as a fine emulsion. The argument that the digestive functions are depressed in fever is also without foundation.

Of the truth of the oft-repeated objection that relapses are more common when a liberal diet is given, we are unconvinced by practical experience, though our relapse rate was slightly higher than that of some other physicians; it is better to have a relapsing patient than a dead one, even if feeding does increase the relapse rate, and in our experience relapses have always been even milder than the original attack.

As modern teaching cannot be ignored, many physicians in this country profess to give a high-calorie diet, but in actual practice always find some excuse for modifying it. It is necessary to be very firm both with the patient, who seldom has any inclination to take food, and with the nursing staff, who are inclined to pander to the patient, and his relatives. Constant encouragement is often necessary to make a patient take his full diet, especially if it is a monotonous fluid diet; he will often welcome the variety provided by solids, such as toast, bread and butter, or biscuits, and soft puddings. There will of course be occasions when tympanites may make some modification, and even temporary reduction, essential, but in our experience the judicious use of purgatives, such as small doses of calomel, at any stage of the disease reduces the frequency of these occasions.

Although our hospital typhoid diet is only 2,000 calories, we believe that on the average every adult patient took the full diet on nine days out of ten during the whole febrile period, and that many took much more than this. Thirty-eight consecutive cases without a death indicates a maximum death rate of 7.6 per cent (on the usual 0.05 significance level); nevertheless, we do not feel that we can claim that these deviations from the usual practice in this country can have accounted for the more benign courses that most of our cases ran.

Other possible explanations are that this hospital is not an emergency one, so that the desperately ill cases, which for example helped to swell Sulakhe's death rate, are seldom admitted, that as in our hospital blood cultures are taken as a routine in nearly all febrile cases on admission we diagnosed a large number of

CHOLESTEROL AND ANÆMIA

By SUSHILA NAYAR, M.B.B.S., M.D. (Pb.)

Lady Hardinge Medical College, New Delhi

PART I

BLOOD CHOLESTEROL CONTENT OF ANÆMIC INDIANS

A CONSIDERABLE amount of work has been done on variations of blood cholesterol in different diseases, and it has been considered that the blood cholesterol content might be a useful guide for diagnostic purposes. Thus, cholesterol estimations are useful in the diagnosis of xanthomatosis, and nephrosis. Under these conditions, and in some cases of pregnancy and diabetes, the blood cholesterol increases, while in pernicious anæmia and secondary anæmias (Muller, 1930; Muller and Heath, 1933; Chatterjee and Ghosh, 1938; Benda, 1924; Bloor and MacPherson, 1917; Denis, 1917; Donomae, 1927; Dubin, 1918; Feigl, 1919; Köhn, 1925; MacAdam and Shiskin, 1923; Stepp, 1918) the blood cholesterol falls.

(Continued from previous column)

mild cases than is usual in hospitals in India, or that some of the fatal cases, clinically diagnosed as enteric, are really other blood infections of a more severe nature, e.g., *Bacterium metalkaligenes* or *Alkaligenes faecalis* infection.

Acknowledgment.—We acknowledge the help we received from the bacteriological department of the School and are particularly grateful to Dr. K. P. Banerjee for his assistance in extracting data.

In the present state of our knowledge it is rather difficult to say to what these variations in cholesterol are due, nor do we know the part played by cholesterol in the defence mechanism of the body. Chatterjee (1940) draws attention to the possible protective rôle of cholesterol in erythropoietic tissues and in support of this he claims to have treated successfully thirteen cases of advanced macrocytic hyperchromic anæmia of pregnancy with intramuscular injections of cholesterol. In view of this observation of Chatterjee it was thought of interest to try this simple treatment in a larger number of cases of

anæmia of pregnancy at the Lady Hardinge Hospital, and with this idea in view the present investigation was undertaken.

The data presented in part I of this paper relates to the hæmatological and biochemical findings with anæmic blood and for comparison figures for blood cholesterol obtained for normal and normal pregnant women are incorporated. The second part of this paper will deal with the results obtained with cholesterol therapy in anæmia. The results are presented in table I. Blood cholesterol was estimated by the method of Myers and Wardell (1918)

TABLE I

Initial blood count

Case number	Red cells millions	Hæmoglobin Sahli units	MCV cu. μ	Serum cholesterol mg. %	Serum proteins gm. %	REMARKS
1	0.5	12	145	51.6	..	Primigravida, 30 weeks pregnant.
2	2.1	30	115	101.2	..	2nd para, 30 weeks pregnant with mild osteomalacia.
3	0.74	15	109	83.4	..	10th para, 30 weeks pregnant.

21	3.45	34	64	108	..	Primigravida, 30 weeks pregnant.
22	0.77	15	155	25	7.5	4th para, 26 weeks pregnant. Febrile: ?mild urinary infection.
24	0.72	17	168	121.2	6.4	3rd para, 8½ months pregnant.
25	1.08	25	100	57	..	7th para, 32 weeks pregnant, premature delivery on admission, malaria and bacillary dysentery.
29	1.2	19	109	less than 20	..	8th para, 28 weeks pregnant, fever and cough from 3 weeks, diarrhoea.
31	1.6	20	48	less than 20	..	Primigravida, 4½ months pregnant, ankylostomiasis, heavy infection.
37	2.4	48	66	81	..	18th para, 24 weeks pregnant, bleeding piles.
43	1.56	24	108	55.5	..	Delivered 5 months before admission.
44	1.42	26	..	45.4	..	Non-pregnant, chronic diarrhoea, hypochlorhydria.
45	0.59	8	110	39.2	9.37	Non-pregnant, tropical macrocytic anæmia, splenomegaly, chronic malaria.
46	1.17	23	99	22.1	..	Non-pregnant, tropical macrocytic anæmia, malaria.
48	0.93	9	84	27.5	9.37	Non-pregnant, macrocytic hypochromic anæmia, malaria, irregular menstrual periods.
49	0.97	10	73	20	4.9	Non-pregnant, microcytic hypochromic anæmia, ankylostomiasis.

Normal serum cholesterol

<i>Pregnant</i>			<i>Non-pregnant</i>		
Maximum	Minimum	Mean	Maximum	Minimum	Mean
247	112	179.5	152	100	126.0

employing 1 c.cm. of blood serum and serum proteins were determined by the micro-kjeldahl method employing direct nesslerization.

Discussion.—A glance at the table shows that the blood cholesterol content of normal Indians is lower than that of Europeans. These results are in keeping with the findings of Boyd and Roy (1928), Ghose (1933) and Bose and De (1936) on normal blood cholesterol content. Whether these lower values are due to climatic conditions, or lower cholesterol content of the diet, is difficult to say. Most of my blood cholesterol figures for anæmic patients are comparable with those of Chatterjee (1940), but there are a few cases where my figures are extremely low. All these cases were suffering from a coincident complication of bacterial, protozoal or helminthic infection. These findings confirm the findings of other workers (Achard *et al.*, 1928; Okey and Boyden, 1927; Mcquarrie and Stoesser, 1932; Marino, 1933) that cholesterol appears to be regularly lowered in febrile infectious diseases. In the majority of acute infectious diseases, such as pneumonia, cholesterol is reduced at the height of the disease, returning to normal during convalescence (Denis, 1917; Kipp, 1920; Stepp, 1918).

In syphilis (Rosen and Karsnow, 1926), leprosy (Boyd and Roy, 1928) and tuberculosis (Eichelberger and McCluskey, 1927; Henning, 1922), it has also been found to be somewhat low.

In view of these findings one is led to conclude that cholesterol plays an important part in the defence mechanism of the body, but whether the fall of blood cholesterol is a cause or result of infection it is difficult to say. Cases of secondary anæmia investigated by me were very few, but the blood cholesterol estimations in these were found to be as low as in cases of pregnancy anæmia, cases with extremely low blood cholesterol again having a coincident infection. These findings seem to support the Bodanskys' (1940) suggestion that the factor affecting blood cholesterol content may be some disturbance of the reticulo-endothelial system rather than the red cell and hæmoglobin content of the blood.

Summary and conclusions

1. Blood cholesterol in Indians is lower than that in Europeans.
2. Blood cholesterol in patients suffering from anæmia is low irrespective of the type of anæmia.
3. Level of blood cholesterol does not seem to run parallel with the red cell count and the hæmoglobin concentration of the blood.
4. Infections, bacterial, protozoal and helminthic, seem to lower still further the blood cholesterol content of anæmic persons.

PART II

CHOLESTEROL THERAPY IN ANÆMIA

Fifty-one cases of anæmia were investigated at the Lady Hardinge Hospital, Delhi. At first, I confined myself to cases of macrocytic hyperchromic anæmia in pregnancy, but later on some orthochromic normocytic and hypochromic microcytic cases of pregnancy anæmia and a few non-pregnant cases were also included for the sake of comparison.

Forty cases out of the 51 presented a macrocytic hyperchromic blood picture, five were orthochromic and normocytic, and the remaining six were hypochromic and microcytic. Of the macrocytic hyperchromic and normocytic orthochromic group of 45 cases, 41 were pregnant and four were non-pregnant. Five out of the pregnant group were normocytic orthochromic to begin with but became macrocytic and hyperchromic during their stay in hospital. Out of the six microcytic hypochromic cases, two were pregnant and four were non-pregnant*.

Investigations.—A complete blood count was done on each case on admission and then regularly at weekly intervals in severe cases and at fortnightly intervals in less severe ones.

At first serum cholesterol and serum proteins were estimated in every case before putting the patient on anæmia treatment, but towards the end it became difficult to get chloroform so that some of the cases could not have their serum cholesterol estimated. Results of these estimations have been given in tabular form in part I of this paper.

Therapy.—At first all the cases were put on intramuscular injections of 5 per cent solution of cholesterol in olive oil, 2 c.cm. daily or on alternate days (cases 1 to 21 inclusive). Results were not encouraging, so that majority of the cases had to be shifted on to liver therapy. One of the early very severe cases died on the sixth day after admission. It was felt that she might have pulled through if she had been treated with liver injections from the beginning. Thereafter it was made a rule to put all cases with an initial red cell count under one million per c.mm. on hepatex injections from the start and change over to cholesterol therapy later when their red cell count had risen above one million.

The results of therapy are given in table II†.

* Full case histories of these 51 cases have been given in the appendix to a thesis submitted to the Punjab University for the degree of M.D. in January 1941.

† There are certain anomalies in this table which were not noticed until too late to refer the matter to the author, *e.g.*, it is not clear why cases 21 and 37 appear twice, in the second instance under the heading 'microcytic hypochromic anæmia' which is certainly not descriptive of both of them.—EDITOR, I. M. G.

TABLE II
Pregnant group

Case number	INITIAL BLOOD COUNT			FINAL BLOOD COUNT			Stay in hospital, weeks	Treatment	Puerperium	REMARKS
	RBC millions	Hb. %	MCV cu. μ	RBC millions	Hb. %	MCV cu. μ				
1	0.5	12	145	3.5	50	81	11	First cholesterol, then hepatex, then again cholesterol.	Normal	Deterioration on cholesterol during pregnancy. Rapid improvement on hepatex. Progress maintained on cholesterol after delivery.
2	2.1	30	115	4.35	68	68	9	First cholesterol, then hepatex, then iron, cholesterol added to iron later.	Normal	Deterioration on cholesterol, slow improvement on hepatex during pregnancy. Rapid improvement on hepatex after delivery. Progress maintained on iron and cholesterol plus iron after delivery.
3	0.74	15	109	0.635	12	..	6/7	First cholesterol, then hepatex.	Heart failure and death following labour.	Deterioration on cholesterol. Premature labour and death before liver therapy could be of help.
4	1.6	32	126	2.9	46	109	9½	First cholesterol + iron, later hepatex + iron. Again cholesterol + iron for the second time, and later hepatex + iron again.	Still undelivered.	Deterioration on cholesterol and rapid improvement on hepatex observed both times.
5	1.63	28	109	2.02	35	95	13	First cholesterol, then hepatex.	Puerperal sepsis, white leg.	Deterioration on cholesterol during pregnancy and puerperium complicated by puerperal sepsis. Some improvement on hepatex in spite of puerperal sepsis.
6	1.2	29	145	4.63	81	85	17	First cholesterol, then hepatex, then cholesterol again. Iron given all along.	Puerperal sepsis.	Deterioration on cholesterol during pregnancy and septic puerperium. Satisfactory response to hepatex. After puerperal sepsis had cleared up there was satisfactory response to iron and cholesterol.
7	1.3	28	102	1.25	25	96	2½	First cholesterol, then hepatex.	Went home undelivered.	Deterioration on cholesterol. Patient went home before effect of hepatex could be observed.
8	2.1	36	102	1.77	34	..	4½	Cholesterol only	Mild sepsis.	No response to cholesterol. Patient went away before response to another form of therapy could be tested.

TABLE II—*contd.*

Case number	INITIAL BLOOD COUNT			FINAL BLOOD COUNT			Stay in hospital, weeks	Treatment	Puerperium	REMARKS
	RBC millions	Hb. %	MCV cu. μ	RBC millions	Hb. %	MCV cu. μ				
9	1.7	40	115	2.14	46	..	3	Cholesterol only, later iron added.	No sepsis	Delivered on the day of admission. Response to cholesterol in puerperium seen.
10	1.18	23	102	2.27	42	..	2½	Cholesterol only	Normal	Delivered on the day of admission. Response to cholesterol in puerperium seen.
11	2.86	60	104	4	65	85	7	Cholesterol only, then iron + cholesterol, then hepatex only, lastly iron only.	Normal	Poor response to cholesterol and cholesterol + iron during pregnancy. Satisfactory response to hepatex, and after delivery to iron.
12	2.01	41	85	3.12	45	80	9½	First cholesterol only, then cholesterol and iron, later hepatex + iron.	Puerperal sepsis.	Patient's condition deteriorated on cholesterol during pregnancy and septic puerperium. Blood picture became macrocytic. There was rapid improvement on hepatex.
13	2.9	48	80.3	3	47	76	9½	Cholesterol first, later hepatex.	Flaring up of tuberculous infection of lungs and abdomen.	Case of pregnancy and pleurisy with effusion and anæmia. Deterioration of blood condition on cholesterol, blood picture became macrocytic and hyperchromic. Improvement on hepatex in spite of the chest complication.
14	1.9	45	76	3.4	50	73	9	First cholesterol, later hepatex.	Went home undelivered.	Came with bacillary dysentery, improvement of blood count at first probably due to spontaneous improvement after dysentery had subsided. Later deterioration on cholesterol, blood picture became macrocytic and hyperchromic. Slow improvement on hepatex.
15	3.6	58	81	3.96	65	82	11½	First cholesterol only, then cholesterol + iron, then hepatex + iron.	Normal	Poor response to cholesterol and iron, slight deterioration on cholesterol alone. Response to hepatex + iron too was unsatisfactory while the pregnancy continued, but there was no further deterioration, better response to hepatex + iron after delivery.

TABLE II—*contd.*

Case number	INITIAL BLOOD COUNT			FINAL BLOOD COUNT			Stay in hospital, weeks	Treatment	Puerperium	REMARKS
	RBC millions	Hb. %	MCV cu. μ	RBC millions	Hb. %	MCV cu. μ				
16	2.07	33	100	2.04	37	109	10	Cholesterol first, then cholesterol + iron, then hepatex only.	Went home undelivered.	Slight deterioration on cholesterol, poor response to iron + cholesterol and to hepatex, but no further deterioration on hepatex.
17	2.9	50	77	2.9	50	84	2½	Cholesterol only	Went home undelivered.	No response to cholesterol.
18	2.4	42	88	2.68	40	74	5½	Cholesterol first, later iron.	Normal (manual removal of placenta).	No response to cholesterol.
19	2.7	45	94	3.4	50	..	9	Cholesterol only	Went home undelivered.	Admitted for pulmonary tuberculosis, anæmic, pregnant, satisfactory response to treatment. General improvement might account for improvement of blood count.
20	2.64	39	83	3.309	38	..	6	Cholesterol only	Flaring up of pulmonary tuberculosis.	Delivered on the day of admission in normal puerperium. Improvement first, later deterioration of general condition and of blood count too.
21	3.45	34	64	4.3	70	70	5½	Cholesterol first, later iron.	Normal	Deterioration on cholesterol. Improvement on iron.
22	0.77	15	155	3.8	80	83	14½	Hepatex + cholesterol, then cholesterol only, again hepatex and then cholesterol + iron.	Mild puerperal sepsis.	Response to hepatex + cholesterol and hepatex alone satisfactory, poor response to cholesterol and cholesterol + iron during pregnancy and septic puerperium, satisfactory response in puerperium after puerperal sepsis had cleared up.
23	0.5	12.5	156	3.5	60	80	9	Hepatex first, then cholesterol, later iron + cholesterol.	Normal	Response to hepatex seen during pregnancy, but better after delivery. Response to cholesterol during normal puerperium satisfactory.
24	0.72	17	168	3.08	60	109	6	Hepatex first, later cholesterol.	Normal	Response to hepatex satisfactory. Response to cholesterol during normal puerperium satisfactory.
25	1.08	25	100	1.8	35	102	5	Hepatex first, later cholesterol.	No sepsis	Satisfactory response to hepatex. Progress maintained on cholesterol during normal puerperium.

TABLE II—*contd.*

Case number	INITIAL BLOOD COUNT			FINAL BLOOD COUNT			Stay in hospital, weeks	Treatment	Puerperium	REMARKS
	RBC millions	Hb. %	MCV cu. μ	RBC millions	Hb. %	MCV cu. μ				
26	0.89	20	140	3.6	70	88	9½	Hepatex first, later cholesterol.	Normal	Satisfactory response to hepatex. Progress maintained during the rest of pregnancy and normal puerperium on cholesterol.
27	0.8	15	136	2	25	133	1½	Hepatex only	Mild puerperal sepsis, malaria, bacillary dysentery.	Satisfactory response to hepatex in spite of puerperal sepsis and dysentery (patient later died of intestinal sloughing).
28	0.5	12	129	2.5	55	91.5	4	Hepatex only	Normal	Delivered after two days of admission. Satisfactory response to hepatex during normal puerperium. Rate of progress about the same as on cholesterol under similar conditions.
29	1.2	19	109	3.15	62	97	6	Hepatex + iron, later liver juice + cholesterol.	Normal	Response to hepatex and liver juice + cholesterol satisfactory.
30	1.25	22	91	1.55	31	119	8½	Hepatex first, then iron, then hepatex again.	Still undelivered.	Slow improvement on hepatex. Deterioration on iron alone in spite of MCV not being raised.
31	1.65	20	48	2.6	46	93	8½	Iron only at first, then hepatex + iron, cholesterol added for one week in between.	Still undelivered.	Deterioration on iron alone in spite of low MCV. Slow response to hepatex, better to hepatex + cholesterol and later to hepatex + iron.
32	0.8	15	91	0.5	10	109	1	Hepatex only	No sepsis, malaria.	Deterioration, premature labour and death.
33	0.65	15	98	5/7	Hepatex only	Mild sepsis	Taken home in a moribund condition three days after delivery.
34	0.55	12	92	3/7	Hepatex only	No sepsis	Premature labour, heart failure and death.
35	1.5	35	99	..	22	..	1	Hepatex and blood transfusion (three ounces).	No sepsis (diabetes).	Premature labour following blood transfusion, heart failure and death.
36	0.7	15	116	3/7	Hepatex + cholesterol.	Died undelivered.	Coincident diphtheria, heart failure and death.
37	2.55	27	65.6	3.6	62	99	12	Iron only	Normal	Satisfactory response to iron; iron was stopped once during pregnancy and once during puerperium. Both times there was a setback.

TABLE II—contd.

Case number	INITIAL BLOOD COUNT			FINAL BLOOD COUNT			Stay in hospital, weeks	Treatment	Puerperium	REMARKS
	RBC millions	Hb. %	MCV cu. μ	RBC millions	Hb. %	MCV cu. μ				
<i>Puerperal group</i>										
38	1.2	20	109	1.1	21	109	3½	Cholesterol only	Mild sepsis, malaria.	Poor response to cholesterol during puerperium complicated by sepsis and malaria.
39	0.8	12	6/7	Hepatex only	Mild puerperal sepsis.	Deterioration, heart failure and death.
40	1.08	15	76	6/7	Hepatex only	Mild puerperal sepsis.	Deterioration, heart failure and death.
41	1.1	17	79.3	3.25	52	92	8	Iron first, then hepatex.	Mild urinary infection.	Poor response to iron in spite of low MCV. Satisfactory response to hepatex.
42	1.39	21	94	2.5	45	100	5	Hepatex first, then cholesterol.	Normal	Satisfactory response to hepatex, progress maintained on cholesterol.
43	1.5	24	108	3.6	60	103	11	Cholesterol only	Normal	Slow but steady progress on cholesterol.
<i>Non-pregnant group</i>										
44	1.4	36	80	4.0	67	76	12	Cholesterol and dilute HCl.	..	Steady improvement (patient came in with diarrhoea which was controlled with treatment).
45	0.6	8	110	2.5	40	74	14	Iron only, then cholesterol + iron, then hepatex + iron.	..	Poor response to iron only, slow improvement on iron + cholesterol. Better response to hepatex + iron.
46	1.1	23	99	3.65	60	85	8½	First cholesterol + iron, then hepatex injections.	..	Slow response to cholesterol + iron. Response to liver extract much more satisfactory.
47	0.84	22	163	4.38	75	81.1	13½	First hepatex + iron. Later cholesterol + raw liver juice.	..	A case of subacute combined degeneration and pernicious anemia. Satisfactory response to liver therapy. Cholesterol did not expedite progress.
<i>Microcytic hypochromic group</i>										
21	3.45	34	64	4.3	72	70	6½	First cholesterol, then iron.	..	Delivered at full term. Response to treatment satisfactory.
37	2.55	27	65.6	3.6	62	99	12	Iron only	..	Delivered at full term. Final blood count below normal standards.
48	0.9	9	84	4.2	67	70	14	Cholesterol + iron.	..	Non-pregnant. Response to treatment satisfactory.
49	0.9	10	73	2.5	42	89	4½	Iron + hepatex	..	Non-pregnant. Response satisfactory.
50	1.87	18	89	3.7	62	81	6	Iron + dilute hydrochloric acid.	..	Non-pregnant, achlorhydria. Final blood count below normal standards. No improvement during the last fortnight of patient's stay in hospital.

TABLE II—concl'd.

Case number	INITIAL BLOOD COUNT			FINAL BLOOD COUNT			Stay in hospital, weeks	Treatment	Puerperium	REMARKS
	RBC millions	Hb. %	MCV cu. μ	RBC millions	Hb. %	MCV cu. μ				
51	3.8	45	74	3.4	62	86	2½	Iron only	..	Non-pregnant. RBC count did not improve, hæmoglobin increase satisfactory.

Effect of therapy on blood cholesterol.—Second and third blood cholesterol estimations were done on some cases to observe the effect of therapy on blood cholesterol. The results of these estimations are given in table III :—

TABLE III

Case number	CHOLESTEROL PERCENTAGE		Interval, weeks	Therapy	Blood condition
	1st	2nd and 3rd			
4	100	108	4.7	Mostly liver Cholesterol	Improved.
5	< 20	111	2		No improvement.
6	36.9	66.7	16.7	Liver first, cholesterol + iron later. Cholesterol	Improved.
14	66	111	2		Improved. Later deteriorated on same treatment.
22	< 25	66.6	2	Liver mostly. Cholesterol + iron.	Improved.
		20	18		Improved.
29	12.8	114.2	4.7	Liver + iron, later cholesterol was added.	Improved.
30	15	88.8	5.5	Liver + iron	No improvement.
31	28	84.3	5	Liver Cholesterol	Improved.
43	56.5	75	6/7		Improved.
		100	3	Iron, cholesterol + iron.	Improved.
45	39.2	52.6	2		
46	22.1	69	7.5	Cholesterol, later liver—12 injections.	Improved.
48	27.5	20	13.5	Cholesterol + iron.	Improved.

Discussion

Cholesterol as a substitute for liver therapy.—A glance at table II shows that cholesterol cannot replace liver in the treatment of macrocytic hyperchromic anæmia in pregnancy. During uncomplicated puerperium the patients did improve on cholesterol therapy, but how

much of the recovery was due to spontaneous remission and how much to the effect of cholesterol, it is difficult to say. Spontaneous recovery, however, seems to be rather a slow process as shown by two cases in the present series (42 and 43) who came to hospital four or five months after delivery in a grossly anæmic condition. They came from fairly well-to-do families and had been having a fairly well-balanced diet.

In the non-pregnant macrocytic cases also response to liver therapy was much more rapid and satisfactory than to cholesterol alone or combined with iron.

An objection might be raised that some of my cases were suffering from coincident diseases, such as malaria, hookworm, diarrhoea, etc., and were not idiopathic cases of pregnancy anæmia. Napier (1940) has discussed this question and has come to the conclusion that exclusion of all cases suffering from coincident diseases does not serve any useful purpose. The disease should be studied against the background of particular standards of health and sanitation in any country. Therefore, I investigated my cases as they came into hospital without any sorting out. But even if a few of such cases were excluded the results of the therapy show clearly that cholesterol cannot replace liver in the treatment of pregnancy anæmia, whether idiopathic or complicated by coincident disease.

Cholesterol as an adjuvant to liver therapy.—In the present series of cases, eight cases (1, 2, 3, 4, 6, 22, 26 and 36) were given both cholesterol and liver during the first few days of their stay in the hospital. Two out of these eight patients died, giving a mortality rate of 25 per cent. Eleven similarly severe cases (23, 24 and 27 to 35) had liver therapy only. Five out of these eleven died giving a mortality rate of 45.4 per cent. These numbers are too small to come to any definite conclusions but the observations suggest that cholesterol may act as a useful adjuvant to liver therapy. Best and Taylor (1939) state that recent work on cholesterol metabolism has shown it to be closely related to sex hormones, cardiac glucosides, and the so-called 'organizer' of the embryonic tissues, and that it may be the mother substance of these important substances.

We know that large amounts of sex hormones are excreted during pregnancy and the foetus also removes large amounts of cholesterol. This might lead to a relative deficiency of cholesterol for forming cardiac glucosides. Death in pregnancy anæmia is due to myocardial failure and it is conceivable that administration of cholesterol might help the myocardium to tide over the critical period.

Cholesterol as an adjuvant to iron.—Some microcytic hypochromic cases were also treated with cholesterol. They failed to improve till iron was introduced. The number of cases treated in this group again was too small to come to definite conclusions, but the results showed the final blood count of the cases who had iron *plus* cholesterol to be higher than in those who had iron only.

Napier and Das Gupta (1937) found the size of the red cells in the Assam coolies to be comparatively smaller, and they failed to raise their hæmoglobin to the usual standards for the urban population. It is possible that this might have been due to cholesterol deficiency. Napier and Majumdar (1938) have shown that iron acts better when combined with improved dietary conditions. Mitra (1939) has found the diet of the Assam coolies to be very poor in fats, especially animal fats. These observations suggest that the important factor in the diet which helps the action of iron may be cholesterol, which is an important constituent of red cell envelope.

Effect of therapy on blood cholesterol.—Tables I and III show that there is no constant relationship between the blood cholesterol content and red cell and hæmoglobin concentration of the blood. Of the twelve cases where second and third cholesterol estimations were done two (22 and 48) showed extremely low blood cholesterol figures at the end of the treatment in spite of their blood count having risen to the normal level. In three cases (5, 14 and 30) blood cholesterol had increased though there was no improvement of the anæmia.

In the remaining seven cases both the blood count and blood cholesterol had improved. Six cases out of these seven had been given cholesterol injections at some time or other during the course of the treatment; the seventh case had been treated with liver only.

Selection of cases for liver therapy.—There is a school of thought who recommend that therapy in anæmia should be guided by the mean corpuscular volume and liver treatment should be reserved for cases where mean corpuscular volume is high, and cases with normal or low MCV should be treated with iron. My experience has been that patients suffering from pregnancy anæmia, even when the colour index is orthochromic and the MCV is within the normal range, do better on combined liver and iron therapy than on iron alone. I tried a few cases of this type on iron or combined iron and cholesterol therapy. Their blood picture

deteriorated and became definitely macrocytic and hyperchromic (e.g., 12 and 30). They improved when hepatex injections were added to iron therapy. We know that in pregnancy generally there is a mixed deficiency of iron and the specific hæmopoietic substances supplied in liver and marmite. Anæmia caused by iron deficiency is microcytic and hypochromic, whereas anæmia caused by the deficiency of the specific hæmopoietic substance is macrocytic and hyperchromic. If the two deficiencies balance each other the blood picture will be orthochromic with a normal MCV. A blood film under the microscope will show marked anisocytosis macro- and microcytes being more or less equal in numbers. This type of anæmia will naturally not respond to treatment with iron alone.

Summary of conclusions

1. Cholesterol cannot take the place of liver in the treatment of tropical macrocytic anæmia in pregnancy. In the advanced stages of the disease response to liver therapy may also be poor, but is certainly better than cholesterol.
2. The death rate in the cases in which cholesterol and liver were given was lower than in those in which liver alone was given. Therefore, it is suggested that cholesterol may be usefully combined with liver therapy in the treatment of severe cases of macrocytic anæmia in pregnancy.
3. In normal puerperium cholesterol seems to be effective in hastening recovery, and the response in these cases seems to be as satisfactory as with liver, especially when cholesterol is combined with iron.
4. In the puerperium complicated by sepsis liver treatment is more effective than cholesterol treatment.
5. In tropical macrocytic anæmia in the non-pregnant, cholesterol helps the hæmopoietic action of iron to a certain extent, but even here improvement is much more rapid on liver therapy.
6. Results of treatment in the microcytic hypochromic group suggest that cholesterol helps the hæmopoietic action of iron, but the number of the cases treated was too small to enable one to come to a definite conclusion.
7. Blood cholesterol is very low in all cases of severe anæmia, irrespective of pregnancy.

Acknowledgment

I am grateful to Dr. Epps, the then professor of medicine at the Lady Hardinge Medical College, for her kind permission to carry out these investigations on the patients admitted in her wards and I thank the rest of the staff in the medical unit for their help and co-operation. My thanks are due to Dr. Soman, the then professor of pathology, for giving me facilities for hæmatological studies and to Dr. Benjamin, assistant to the professor of pathology, for doing some of the blood counts.

importance to this organism and believe that symptoms produced in the human body are not due to this protozoa alone but are perhaps caused by some other concurrent factor or factors. On the other hand, there are quite a large number of workers who definitely maintain that this flagellate does play an important pathogenic rôle and its presence in the gut produces symptoms which deserve the serious attention of the physician. Alvarez, Silverton and Bernardino (1938) are of opinion that the fact that the infection as well as the symptoms disappeared after treatment with atabrin proved beyond doubt the pathogenicity of this flagellate. Chopra, Das Gupta, Sen and Ahmed (1939) concluded that in some cases, at least, particularly in children, this flagellate may produce intestinal disturbance.

Since Galli-Valerio (1937) pointed out the efficacy of atabrin in the treatment of giardial infection, a number of workers have brought forward copious evidence with regard to the beneficial effect of this drug. They are: Martin (1938), Heilmann (1938), Gruneis (1938), Porges (1938), Romano, Rey and Meiller (1938), Bacigalupo (1937, 1938), Konu, Basnuevo, Stolonzo and Anido (1938), Cain and Sikorav (1938), Love and Taylor (1940), Mondoul (1939), Chopra, Das Gupta, Sen and Ahmed (1939), Menk and Mohr (1939), DeMuro (1933), Niño (1939), Acosta Silva (1938), Balena (1939), Gruneis and Pilgerstorfer (1939) and Galizzi (1939). Prior to this, however, giardiasis was considered to be a condition which was not easily amenable to treatment, although there are records of successful treatment with neosalvarsan (Lauda, 1934), neosalvarsan and yatren (De Paula and Silva, 1938), spirocid or salvarsan (Breuer, 1938), naphthalene purified by sublimation (Borges, 1931), intramuscular injections of pyretrines (Componovo, 1936), di-hydranol (Thonnard-Neuman, 1931; Mackie, 1931), bismuth salicylate (Zahorsky, 1928), yatren (Luchini and Perez de Nucci, 1927), stovarsol (Pawan, 1926; Basu Mallik, 1926), intramuscular injection of solu-salvarsan (Virnich, 1937) and bismuth sublimate in large doses with other drugs (Enault, 1937). Fredrich (1938) stated that every person harbouring giardia needed an energetic course of treatment and that, since there is no certain cure for the condition, the best results were obtained by intraduodenal introduction of salvarsan and duodenal lavage. Petrowych (1931) emphasized the pathogenicity of giardia and found that the best results were obtained by intravenous injections with neo- and novo-salvarsan with periodical duodenal lavage with 25 per cent magnesium sulphate solution.

Martin (1937) and Tanguy (1937) employed the French equivalent, quinacrine, in the treatment of giardiasis and found that dosages, similar to that given orally for malaria, eradicated the infection. De Muro (1939) has,

however, pointed out that acranil—a hydrochlorate of a new acridinic compound (Bayer)—was even better than atebirin. Grott (1939) stated that whereas atebirin produced a toxic effect in certain cases, this did not result when acranil (previously known as 'Sostol') was used. Vortina (1940) treated cases of giardiasis with acrichine.

In this article, we have recorded a few cases of giardial infection which were successfully treated with quinacrine (May & Baker). The mode of treatment was as follows: 3 tablets of 0.1 gramme of quinacrine per day administered orally for 5 days, the process being repeated after an interval of one week or 5 days. Some patients required a third course of treatment for the complete eradication of the flagellate and the symptoms.

No protozoa, other than *Giardia lamblia*, were encountered in the faecal samples of the cases recorded here. A daily examination of stool samples was carried out from the commencement of treatment and we detected a rapid diminution in the number of organisms eliminated with the excreta.

It is emphasized that the possibility of a giardial infection in cases with vague abdominal pains should always be borne in mind and that the microscopical examination of the stool is of the utmost importance in all such cases.

A brief history of six cases of giardiasis which were treated with quinacrine (May & Baker) is given below:—

Case 1.—Hindu, male child. Age 7 years. Vague abdominal pains for past two years; occasional diarrhoea, and often a rise of body temperature up to 103°F. for one or two days; general health poor. Examination of stool showed a large number of giardia cysts. Quinacrine treatment started: $\frac{1}{2}$ tablet, *t.i.d.*, for five days. Examination of stool from second day of treatment onwards showed a rapid decrease in the number of cysts. An interval of one week was allowed during which no medicine was administered. Few cysts were seen when the second course was started. At the end of this course, giardia had completely disappeared from the stool. The child has since showed a marked improvement in his general health and has not complained of further abdominal discomfort.

Case 2.—Hindu, female. Age 25 years. This was an interesting case. She had undergone an operation for clinical appendicitis and uterine displacement. Afterwards she often complained of abdominal pain which was attributed to the adhesion resulting from the abdominal operation. She gave no history of diarrhoea or dysentery. After a mild purgative, an examination of the stool revealed both vegetative and cystic forms of giardia.

Quinacrine treatment started: 2 gm., *t.i.d.*, for five days. Second day after treatment—the stool was negative for giardia. After an interval of seven days, a second course was administered. The abdominal pain disappeared altogether and she felt very much better. Subsequent history for past seven months—no abdominal pain or discomfort.

Case 3.—Hindu, male child. Age 5 years. Complained of abdominal pain below the umbilicus after meals. At times he felt sick and vomited undigested food. No rise of temperature and no diarrhoea. The

father of the child said that the boy was usually constipated. Examination of the stool showed a fairly large number of giardia cysts.

Two courses of quinacrine effected a complete cure.

Case 4.—Christian, female child. Age 10 years. Complained of pain in the abdomen, usually in the afternoon. This would last for two or three days, after which the symptoms would abate for some time.

During one of these attacks she was brought to us and general examination showed nothing unusual. There was no history of diarrhoea or dysentery. An examination of the stool, however, revealed a heavy giardial infection, which quickly responded to treatment with one course of quinacrine. Her stool has since remained negative for giardia and there has been no further complaint of abdominal pain.

Case 5.—Hindu, male. Age 25 years. The patient was somewhat neurotic and complained of abdominal pain with a history of diarrhoea and dysentery. He also complained of passing froth and mucus in the stool. He had been treated for amoebic dysentery before he came to us and had had a course of emetine injections. (Presence of ameba in the stool was, however, not confirmed by microscopical examination before he went through the course of emetine.)

After a mild purgative, an examination of the stool showed a very large number of giardia cysts. Quinacrine was given for five days at the end of which his stool still showed a few giardia cysts. The second course was given after an interval of seven days. At the end of this course, his stool was negative for giardia and the patient felt better. However, a third course was given after an interval of seven days and this caused a marked improvement in the general health of the patient. His abdominal pain has completely disappeared and he has developed a normal appetite.

Case 6.—Hindu, male child. Age 10 years. Had been complaining of abdominal pain accompanied by loss of appetite and general debility for the past three years. He was treated by various *vaid*s and *hakims* before he came to us. Examination of his stool showed a very large number of giardia cysts. Quinacrine in the usual doses for one week led to a marked improvement in his general health and the patient complained of no further abdominal discomfort or pain. Three days after treatment the stool was negative for giardia. The boy now looks cheerful and his appetite has returned to normal.

FURTHER EXPERIENCE OF THE TREATMENT OF SUPERFICIAL KERATITIS WITH RIBOFLAVIN

By O. P. VERMA, M.B., B.S.

Field Worker attached to the Nutrition Research Laboratories

(Nutrition Research Laboratories, I. R. F. A., Coonoor, S. India)

In a recent paper (Aykroyd and Verma, 1942) the occurrence in India of superficial keratitis due to riboflavin deficiency was reported for the first time. The treatment of 13 cases by the injection of riboflavin, with dramatic results, was described. Since the above paper was prepared, a further series of 50 cases has been observed and treated in a similar manner with similar results. While this type of keratitis is probably very common in India, its aetiology is not yet generally recognized by clinicians. A brief account of the successful treatment of a larger number of cases will be of value in confirming the results previously obtained and in drawing the attention of medical practitioners to the condition.

The literature of riboflavin deficiency was reviewed in the earlier paper and a further review is unnecessary here.

Description of cases

The present series of cases, like the previous one, was observed and treated in the Government Ophthalmic Hospital, Madras. The characteristic signs and symptoms were described in the earlier paper. These include photophobia, itching, burning, pain and lacrymation, usually involving both eyes. Opaque dots and streaks are to be seen in the superficial layers of the cornea, with superficial ulcers in some cases. In the second series of 50 cases, vascularization of the cornea was present in about 60 per cent. The pannus was always superficial and confined to the periphery of the cornea. Squamous blepharitis and phlyctenular conjunctivitis were observed in 2 and 3 cases respectively.

Angular stomatitis and fissured tongue were present in 85 per cent. In the cases not showing a fissured tongue, the tongue appeared smooth, with flattened papillae. Nearly all cases complained of a burning sensation in the mouth when food was taken. In one case the lips were denuded of epithelium and were raw, fissured and tender. This case showed squamous blepharitis without keratitis.

In 95 per cent of the male cases there was dryness, scaliness and itching of the skin of the scrotum. The scrotal lesions were in general not very pronounced.

Treatment

This consisted of the oral or parenteral administration of pure riboflavin. All cases responded rapidly to treatment with riboflavin;

within 24 hours there was subjective improvement and all signs and symptoms usually disappeared within 3 to 10 days, depending on the severity of the case. The vision improved owing to the disappearance of superficial opacities. The vessels in the cornea 'closed down' and the angular conjunctivitis disappeared *pari passu* with the other signs. Coincident blepharitis also responded to the treatment. It would be interesting to observe the effect of riboflavin on chronic intractable cases of squamous blepharitis uncomplicated by keratitis.

The usual parenteral dose was 2 milligrammes given daily until the eye condition was cured. Relief also followed oral administration, but larger daily doses—4 to 6 mg.—were required and the curative effect appeared to be in general less rapid. The injection of the vitamin appears to be the treatment of choice. Proprietary preparations of pure riboflavin could not be obtained for the investigation. Solutions of riboflavin for oral and parenteral administration were made up in the Nutrition Research Laboratories.

In the case referred to above, showing severe blepharitis but no keratitis, rapid healing of the lesions of the lips was observed. This is a point of interest, because American workers (Sebrell and Butler, 1938, 1939) have reported a 'reddened, denuded condition of the lips' as a characteristic sign in ariboflavinosis. For some unexplained reason, this sign was rarely present in the cases of ariboflavinosis observed in Madras. The other oral lesions responded to treatment, though less rapidly than the eye lesions.

Recurrence within a few weeks was observed in a proportion of cases—the liability to recurrence was commented on in the previous paper. Little further information about susceptibility to recurrence could however be obtained in the present investigation, owing to the fact that it was carried out during a period in which Madras City was being steadily evacuated and the number of out-patients attending the Ophthalmic Hospital was falling day by day.

Riboflavin treatment was tried in 3 cases of trachomatous pannus. The results were doubtful. A little subjective relief was obtained but the pannus persisted. The cornea appeared to regain lustre and vision improved owing to the disappearance of some opacities. Further investigation of the possibility of obtaining some relief of trachoma by riboflavin treatment is necessary. It is possible that the administration of riboflavin will prove a valuable adjuvant to other forms of treatment in various eye diseases.

The following 8 cases, 3 male and 5 female, may be taken as characteristic of the group:—

Case 1.—Female, aged 30 years. Complained of photophobia, burning, watering and itching in both eyes for one month. The corneas showed superficial opacities and angular conjunctivitis was present. A

conjunctival smear revealed Morax-Axenfeld bacilli in plenty. The patient had marked angular stomatitis and fissured tongue. Four mgm. of riboflavin were given intramuscularly daily for five days. All ophthalmic signs and symptoms disappeared and the smear became negative. The mouth condition showed improvement.

Case 2.—Female, aged 32 years. Complained of photophobia, burning, watering and dullness of vision for two months. She showed superficial keratitis and superficial opacities in the centre of the cornea of both eyes. Vision was R 6/12, L 6/60. She had angular stomatitis and fissured tongue. Riboflavin was given partly by injection and partly by oral doses, the total amount given being 20 mg. in eight days. All the irritative symptoms disappeared. Vision after the treatment was R 6/9, L 6/24. The opacities had not completely vanished.

Case 3.—Female, aged 30 years. Complained of photophobia, burning, itching and lacrymation. A thick exudate was present at the angles of both eyes. The patient stated that the condition had persisted for four months. There was superficial keratitis and angular conjunctivitis. Angular stomatitis and fissured tongue were also present. Conjunctival smears showed abundant Morax-Axenfeld bacilli. The patient had been treated in the hospital for three weeks with the usual routine treatment without relief. Riboflavin was given orally in 5 mg. doses for seven days, without any local treatment. All the symptoms and signs disappeared and the smear became negative.

Case 4.—Female, aged 18 years. Complained of photophobia, burning, lacrymation and dullness of vision for three months. There was superficial keratitis, more pronounced in the right cornea. Vision was R 6/24, L 6/36. Angular stomatitis and fissured tongue were present. She had tender calves and could not walk. The knee jerks were absent. Riboflavin was given for four days in 2 mg. doses, intramuscularly. All the eye symptoms vanished and the vision became R 6/18, L 6/24. There was marked improvement in the oral condition. No change occurred in the legs. She was then given yeast 15 grammes *t.i.d.*, for four days, with improvement in the leg condition.

Case 5.—Female, aged 15 years. Complained of itching of the lid margins for three months and a burning sensation in the mouth. The lid showed squamous blepharitis and there were seborrhœic scales on the eye-brows. There was well-marked denudation of the lips and fissured tongue. No keratitis was present. The patient was given injections of riboflavin, 2 mg. daily, for 11 days. The itching of the lid subsided, and the squamous blepharitis disappeared. The lips were healed and the patient ceased to complain of burning in the mouth.

Case 6.—Male, aged 30 years. Came with complaints of photophobia, burning, itching and dullness of vision. The patient showed superficial keratitis in both eyes. There were a few small central opacities. Angular stomatitis was present. The tongue was smooth and without fissures. Vision was R 6/6, L 6/24, and there was no improvement with glasses. Riboflavin, 2 mg. intramuscularly for five days, was given. All the irritative symptoms disappeared and the vision became R 6/6, L 6/6.

Case 7.—Male, aged 17 years. Complained of photophobia, watering and burning of both eyes of two months' duration. Superficial keratitis was present in both eyes. Angular stomatitis with fissured tongue was present. The scrotum was rough, dry, scaly and itchy. The vision was R 6/18, L 6/24. Riboflavin was given for 13 days in 4 mg. oral doses. All the signs and symptoms were relieved and vision became R 6/6, L 6/9.

Case 8.—Male, aged 10 years. Had watering, photophobia, and burning sensation in the eyes for one month. Showed phlyctenular conjunctivitis along with superficial keratitis in both eyes. Riboflavin was given orally and parenterally; the total amount administered being 18 mg. The phlyctenular conjunctivitis and keratitis disappeared in nine days.

INDISCRIMINATE DRUG THERAPY

A PLEA FOR WAR-TIME DRUG ECONOMY

By ANTHONY CAPLAN, M.D. (Lond.),
M.R.C.P. (Lond.)

Senior Medical Officer, Kolar Gold Field Hospital

'As the war progresses, the need for strict economy in the use of drugs increases. Sources of a number of crude drugs and of the raw materials for the manufacture of synthetics are now closed to this country, and this, together with the necessity of conserving foreign exchange and avoiding the waste of shipping space by the importation of non-essential drugs and chemicals, renders the problem of finding adequate alternatives pressing'.—Extract from preface to the *Extra Pharmacopœia*, volume 1, 1941.

Drug economy is surely as necessary to the war effort in India as it is in England. A marked increase in the local manufacture of drugs since war began has certainly helped to relieve the drug problem in India, but many raw materials are scarce and valuable shipping space is still being taken up with certain essential drugs which have to be imported from abroad. Quite apart from drug economy being necessary as a war-time measure, sound arguments can be put forward to show that a reduction in the consumption of drugs would be beneficial to a public made drug-conscious by extensive advertising campaigns. One thing is certain, the patient would not suffer; on the contrary a greater quantity of essential drugs would be available to those who really need them.

Recent notable advances in therapeutics may well be the forerunner of a new era in medicine when therapeutics will be established on a scientific basis. The attainment of this ideal will, however, be deferred so long as the abuse of newly introduced therapeutic substances continues. That such an abuse exists is an every-day experience; that it is far too common

(Continued from previous column)

Summary

Fifty cases of superficial keratitis have been treated by the oral and parenteral administration of riboflavin. Rapid relief of signs and symptoms was obtained.

Acknowledgment

The facilities for the investigation provided by the Superintendent and staff of the Government Ophthalmic Hospital, Madras, are gratefully acknowledged.

there can be little doubt. Indeed, the worst examples of indiscriminate therapy are connected with recent advances in therapeutics, *e.g.*, the treatment of anæmias, avitaminoses, endocrine dysfunctions, and chemotherapy.

This note is written with the object of drawing attention to the more blatant examples of indiscriminate prescription of drugs which have come to the writer's notice during recent months.

The treatment of the anæmias

Anæmia is extremely common in this country, and in my experience the microcytic type, associated with an iron deficiency combined with an excessive blood loss, is very much more common than the macrocytic type associated with a deficiency of Castle's intrinsic and extrinsic factors, although it is fully realized that anæmias of multiple origin are by no means rare. It seems hardly necessary to point out that the treatment of anæmia is hopeless without an expert opinion on the blood picture; yet how many cases are there of so-called anæmia, at the present time, diagnosed by a cursory glance at the patient, being treated with expensive parenteral liver preparations? And how many more cases are there of a pure iron-deficiency anæmia being treated with 'injections of liver'? And how frequently are 'liver injections' given as a tonic? Accurate replies to the above questions would emphasize the urgent need of moderation in parenteral liver therapy.

Illustrative case.—

Female, *æt.* 50, suffering from an anxiety state and microcytic anæmia. Hb. 52 per cent, red cells 3,900,000, C.I. 0.66. She complained of 'neuritis all over' of many years' duration, the relapses always coinciding with periods of maladjustment to her environment. The anæmia was greatly improved with a standard iron preparation, but she decided to seek expert advice for her 'neuritis' and returned with the following substances. An oral liver preparation, a parenteral liver preparation, a parenteral vitamin-B preparation, nicotinic acid, a 'liver stimulating' medicine and a sedative. Approximate cost Rs. 100. An iron preparation was conspicuous by its absence.

Vitamins and tonics

It is not the intention of the writer to suggest that an abundance of vitamins is obtained by all and sundry. On the contrary, a more liberal distribution of vitamin preparations in the right quarters is an urgent necessity if the major and minor degrees of avitaminoses so commonly seen in practice are to be prevented. It is contended that expensive vitamin preparations are frequently issued as a 'tonic' to people well able to obtain a sufficiency of vitamins in a well-balanced diet, and in whom no sign of vitamin deficiency can be detected. In addition certain vitamins are given as a specific for conditions not even remotely connected with an avitaminosis.

Not very many years ago the routine 'tonic' was a gentian and rhubarb mixture with a dash of bromide, and it is questionable whether

this was less effective in 'toning up the system' than many of its modern expensive counterparts. The question may legitimately be raised as to what is the effective therapeutic agent in a bottle of medicine given as a 'tonic'. Is it its colour (of the medicine and bottle), its taste, its price, its country of origin (especially before the present war), or its pharmacologically active contents? Or is it the doctor's re-assurances—aptly described as 'tincture of kindness'—that go with it? I personally believe the latter to be the most important factor, for if the patient can be convinced that his 'system' is about to be 'toned up', he will certainly feel 'toned up' at his next visit—irrespective of the contents of the bottle. Nowadays the doctor's 'tincture of kindness' is hardly necessary in initiating this simple psychotherapeutic cure; vested interests combined with extensive advertising campaigns have ousted the medical man as an expert on 'tonics'. Surely this aspect of therapeutics is worthy of further research, for if the contents of the bottle are of secondary importance why waste expensive—and otherwise useful—drugs?

In this respect the attitude of the patient is not an unimportant factor. There is little doubt that many patients would consider they were not getting their money's worth if they returned from the doctor's consulting room without at least a bottle of medicine. A course of injections would of course be much more satisfactory—especially amongst certain types of women who are always in need of fresh material to strengthen their case at the not uncommon competitive discussions on their ailments—real and imaginary. It is surely the duty of the medical profession to discourage this bottle of medicine habit and to enlighten the public on the greater importance of preventive medicine. For example, there can be no justification for the prescribing of 'tonics' to previously healthy patients convalescent from an acute febrile illness such as lobar pneumonia, or after an operation such as appendicectomy, when all the patient needs is adequate rest, sleep and an abundance of good food.

The medical profession itself is unfortunately not completely immune from the influences of fashion and advertisements. It seems fashionable at the present time to use parenteral vitamin-B preparations (or is vitamin E now taking its place?) for any disease connected with the spinal cord or peripheral nerves. None will deny the extreme value of this vitamin in beri-beri and certain forms of peripheral neuritis, but it is difficult to appreciate the rationale of the exhibition of the vitamin in 'neuritis', syphilitic myelitis and acute anterior poliomyelitis, examples of which the writer has recently seen.

The following experience may be of interest in demonstrating the care to be taken in assessing the value of a therapeutic substance and as an example of the possibilities which exist in

saving drugs. A certain plant had gained a local reputation in the cure of 'sore tongue', and it was decided to give it a trial in cases of angular stomatitis and glossitis. Six cases were treated with recommended quantities of the leaf *plus* a light diet and the results were uniformly good, the mouth and tongue lesions disappearing within 7 days. A specimen of the leaf was sent to Dr. W. R. Aykroyd at the Nutrition Research Laboratories, Coonoor, who kindly identified it as *Sesbania grandiflora*. He suggested that 1½ pints of milk included in the light diet would in itself produce an improvement in the condition. A further series of cases were then treated with the sesbania leaves *plus* an ordinary hospital diet: *i.e.*, mutton 6 oz., rice 12 oz., vegetables 4 oz., bread 4 oz., coffee 1 pint (no milk), and the results were equally satisfactory. It was then decided to treat a control series of cases with the ordinary hospital diet alone, and it was noted that the condition was cured in approximately the same time. All cases of angular stomatitis or glossitis due to a vitamin-B₂ deficiency are now treated with ordinary hospital full diet which apparently contains a sufficiency of vitamin B₂ to cure the condition. Previously marmite had been used, which means that a considerable saving in a potent and scarce remedy has accidentally been effected.

Endocrine preparations

Endocrine substitution therapy has made tremendous strides in recent years and many conditions in which a true endocrine deficiency exists can now be greatly relieved or even cured. But endocrine therapy has its limitations and may even be dangerous if used indiscriminately, for it must be remembered that, firstly, endocrine products—natural or synthetic—are potent substances having a specific physiological effect, and, secondly, the sexual hormones are allied in chemical structure to carcinogenic substances. Accurate diagnosis and some familiarity with the dose of these preparations is therefore highly desirable. Without any pretence to being a gynaecologist the writer considers that the following cases illustrate the misuse of endocrine preparations:—

Case 1.—Multipara, *æt.* 25, two children *æt.* 2 and 4. Complained of indefinite lower abdominal pain since birth of second child. Nothing abnormal found on examination apart from slight tenderness and thickening in the left fornix probably secondary to cervical tear. Laparotomy some months later by a surgeon revealed a long and tortuous appendix, and a few cysts in both ovaries. An appendicectomy was performed. The post-operative treatment included a course of follicular hormone which was continued for three months.

Case 2.—Primipara, *æt.* 20, ten weeks' amenorrhœa. Morning sickness for past six weeks. Vomiting never severe and patient in good health. Had been receiving a course of luteal hormone for the past four weeks with no improvement.

Case 3.—Multipara, *æt.* 30, two children *æt.* 3 and 6. Three months' amenorrhœa. Sudden onset of bleeding from vagina with passage of 'large clot'. Patient had been treated during the past week with

luteal hormone and wheat-germ oil. Exploration of uterus revealed retained products of conception; fetus was almost certainly passed in the 'large clot'.

Sulphonamide group

The introduction of the sulphonamide group of drugs has proved to be the greatest therapeutic advance probably of all time, but it is not a panacea for all the ills of man—and beast. The value of this group of drugs in certain specific diseases is firmly established, and further research with new products indicates that many more diseases may be combated with these valuable drugs. A controlled experiment on the value of the sulphonamides in almost any bacterial infection is legitimate and is to be encouraged, but the indiscriminate use of the drug—often in inadequate dosage—in any febrile state without an attempt at an accurate diagnosis is, at the present time, wasteful and to be discouraged. Instances of the waste of sulphonamides—too numerous to mention—are almost daily occurrences, and they emphasize the fact that care and accuracy in diagnosis is the doctor's first duty to his patients.

Quinine

It should hardly be necessary to point out the following important facts: Firstly, malaria is extremely common in this country, secondly, quinine is a specific for malaria, and, thirdly, the major supply of quinine from the Dutch East Indies has been completely cut off. By simple deduction the urgent need for economy of quinine is obvious. Economy can be effected by limiting the use of this essential drug to *bona-fide* cases of malaria, and ceasing forthwith the issue of quinine preparations for conditions such as 'influenza' and feverish colds in which, as far as is known, there is no scientific evidence to show that the drug is of the slightest value. Ideally quinine should be withheld from all suspected cases—excepting in cerebral malaria and other fulminating types—until the diagnosis is confirmed by a blood smear. The ideal unfortunately is not practicable in all parts of the country, but that greater care is needed in the clinical diagnosis of malaria is well illustrated in the following comparison of statistics. Hospitals A and B dealt with an equal number of patients from the same localities. Hospital A performed about 80 blood examinations every year and B about 5,000. During the same year, hospital A reported over 11,000 cases of malaria and hospital B under 800.

Polypharmacy

The lengthy prescriptions used by our fathers and grandfathers have almost completely disappeared, and now is as good a time as any to ask ourselves whether our own prescriptions could be cut down without therapeutic loss to the patient. Are all the drugs included in our common 'fever' mixture, cough mixture, stomachics and tonics therapeutically effective,

(Concluded on opposite page)

THE GALL-BLADDER AND ITS VEINS

By F. V. STONHAM

MAJOR, I.M.S.

ANATOMY textbooks describe and depict a cystic vein corresponding to the cystic artery terminating in the right branch of portal vein. Works on operative surgery usually do not refer to the cystic vein at all, but many surgeons, I believe, regard this vessel as non-existent, and consider that the venous blood of the gall-bladder always passes directly to the liver through anastomoses between small venous channels of the two organs. In performing the classical type of operation cholecystectomy it is customary first to dissect out and identify the biliary ducts, and then the cystic artery and its parent trunk as well. It does not appear usual to bother about any venous channels, though it is usually considered to be preferable to commence the dissection of the gall-bladder from the region of the ducts to avoid obscuring the field by the blood which oozes from the denuded area of the liver. The disadvantages of commencing the dissection from the fundus seem to have been somewhat exaggerated. However, with the exception of Thorek's technique (1938) which has recently been strongly endorsed by Bailey and Love (1939) in which the gall-bladder is partly removed and the remainder coagulated by diathermy and sutured, and in some cases where the organ is removed by the clamp method advocated by Tucker (1938), it is almost universal practice to insert a drainage tube down to the site of the operation. This is done partly to allow exit of the blood and bile which exudes from the raw area of the liver, and also bile from any accessory hepatic duct which may have been overlooked and divided, and partly because the comparative frequency of post-operative hæmorrhage following cholecystectomy has earned for this operation some notoriety. This is perhaps somewhat undeserved since, in my experience, except in difficult cases where operative trauma makes drainage imperative nothing much seems to come out of the tube. However, on account of the great frequency of anatomical variations which may be encountered in this region, which have been

(Continued from previous page)

and would the patient suffer if certain ingredients were omitted or reduced in quantity? Further information on these points would help us to decide as to what necessary drugs are real necessities.

Acknowledgments

I have much pleasure in acknowledging my thanks to the chief medical officer, Kolar Gold Field Hospital, Dr. W. B. Roantree, and Messrs. John Taylor & Sons for permission to use the case reports, and to Dr. Aykroyd for his report on the sesbania leaf and valuable criticisms.

so ably described by Flint (1923) and since the technical difficulties in this operation may at times be very formidable, drainage is some safeguard against the consequences of closure of the abdomen with a divided unrecognized accessory artery or duct which has not been secured.

The likelihood of venous bleeding, so far as I am aware, is seldom considered. In *post-mortem* examinations, especially in cases of asphyxia due to hanging or opium poisoning, I have not infrequently observed a cystic vein of large size, which would be quite capable of causing severe or dangerous bleeding. It is possible that in some cases of hæmorrhage during or following operations on the biliary tract the origin has not been arterial, but venous. Compression of the gastro-hepatic omentum would be expected to control bleeding from veins connected with the portal system as well as branches of the hepatic artery because in both cases the compression would be proximal. The above-mentioned observation has prompted me to carry out fifty dissections on fresh subjects most of which were young and healthy, and death had been due to violence. Venous drainage of the gall-bladder was found to be of the following types:—

Type I: the commonest (figure 1).—Direct anastomosis occurs between the small venules of the gall-bladder and the liver. These can be traced on histological study of a section passing at right angles through the area where the gall-bladder is attached to the inferior surface of the

Fig. 1.—Type I. Small venules anastomose with vessels in the liver.

liver by connective tissue. In addition, small straight veins are formed by the anastomosis of venules on the inferior surface of the gall-bladder, which again break up into small branches before they enter the liver. These vessels run roughly at right angles to the long axis of the gall-bladder. They are small and not always apparent to the naked eye unless congested.

Type II: nine cases (figures 2, 4 and 5).—A single venous trunk of comparatively large size corresponding to the cystic artery joins the right branch of the portal vein, as in anatomy textbooks, or terminates elsewhere.

Type III: two cases (figure 3).—The cystic veins are as in type II but are multiple.

Type IV : two cases.—This is a combination of types I and II. Though the gall-bladder varies considerably in position in relation to the

Fig. 2.—Type II. Cystic vein joins the right branch of the portal vein passing in front of the hepatic duct.

Fig. 3.—Four cystic veins (arteries have been omitted from diagram for clearness). Three join the portal vein and one passes in front of the ducts and ends in a right gastric vein which passes direct to the liver.

Fig. 4.—Portal vein enters the liver in front of the ducts and arteries.

Fig. 5.—Single cystic vein joins an abnormal right gastric (coronary vein).

vertebræ and in its distance from the midline as seen in radiographs, and while the ducts and vessels very commonly exhibit anatomical

anomalies, the healthy gall-bladder is remarkably constant in shape, size and in its relation to other viscera.

Cases of congenital absence of this organ are rare. Kennon (1933) has described a case of double gall-bladder and cystic ducts. The principal variations that are encountered are in connection with its relation to the liver and to the visceral peritoneum. In the series under discussion all the gall-bladders appeared healthy except one, and only one contained stones and this occurred in a young female, and the stones consisted of a few hard white calcium stones and there was no macroscopic evidence of previous inflammatory mischief. I am aware that the gall-bladder is sometimes entirely buried in the substance of the liver but I have not yet encountered a case either at operation or dissection. Sometimes the viscus is suspended from the liver by a species of mesentery and these cases are eminently suited to removal by Tucker's (1938) simple and rapid operation. Murray (1933) has described a case of torsion in a gall-bladder which was attached only by a pedicle consisting of the cystic duct and the blood vessels and he found reference to only two such cases in the literature. It is, however, extremely common to find the gall-bladder enclosed in a peritoneal fold continuous with the gastro-hepatic omentum, which unites the under surface of the liver to the transverse mesocolon and the transverse colon itself. This is referred to as the cholecystico-duodeno-colic ligament, which is probably better named by the less accurate but briefer term cystico-colic 'ligament'. This 'normal' structure is very apt to be regarded as an 'adhesion' due to previous inflammation. In one case I found that this structure had drawn the transverse mesocolon upwards forming a deep hollow in its under surface and the branches of the colic vessels arched upwards and passed in close relation to the caudal aspect of the gall-bladder before they reached the bowel. In no case were the vessels of the gall-bladder found to anastomose with the colic vessels. Such a union if it occurred would almost certainly be of pathological consequence. Oozing from this site not infrequently occurs at operation when inflammatory adhesions are separated. In all cases where a cystic vein of type II or III was present the gall-bladder was either very loosely attached to the liver, or else it lay, often loosely invested, in a cystico-colic ligament. Apparently it is the closeness of this attachment to the liver which determines the manner of the venous return.

The gall-bladder, liver, and part of the pancreas are developed from the foregut from a diverticulum which passes into the septum transversum. It at once bifurcates into pancreatic and hepatic elements.

That part which is destined to form the liver and gall-bladder again bifurcates, and presumably, to begin with, each has its own independent

blood supply. Subsequently, when the gall-bladder becomes firmly united to the liver, anastomosis between the venous systems of the two organs results in disappearance of the cystic vein. In cases where this does not occur, or its occurrence is hampered after rotation of the gut by abnormal coalescence of the dorsal part of the free edge of the ventral mesogastrium with the transverse colon and its mesentery, the cystic vein persists.

The cystic vein usually passes anterior to the hepatic duct and arteries and joins either the right branch of the portal vein, the main trunk of the portal, or terminates in the coronary vein. It is pointed out that the last vein, not uncommonly, does not end in the portal vein, but follows the course of either the right, or, as in one case, the left gastric artery; and passes up in front of the portal vein and enters liver independently (figure 5). This was seen in four cases. In one case the portal vein twisted spirally round the left side of the arteries and ducts and then bifurcated and entered the liver as an anterior relation, the right branch receiving the cystic vein (figure 4). The surgical importance of such an abnormality is obvious. In another case a well-defined cystic vein accompanied the artery but terminated in a number of small branches which became lost in the capillary plexus of the gastro-hepatic omentum.

A well-developed cystic vein if engorged may be almost equal in calibre to that of a normal common duct, though usually it is not a large vessel. Diagrams in surgical textbooks are often misleading because the ducts, arteries and the portal vein are frequently depicted as though they were each of about equal size. The hepatic artery and its branches are much smaller than usually drawn and are comparatively thin walled. Though easy enough to recognize in dissecting room subjects, in the fresh cadaver they are remarkably like veins when empty and collapsed, and often require careful tracing to their origin to establish their identity beyond doubt. The portal vein is a much larger vessel than usually shown and is as thick as the average fountain pen or thicker. It more commonly passes behind and definitely to the left of the ducts and hepatic artery (except near its origin) than directly behind them as one is usually informed by works on surgical anatomy.

Summary

(1) The results of fifty dissections to investigate the venous return of the gall-bladder have been described.

(2) In at least eighteen per cent of bodies a well-marked cystic vein corresponding to the cystic artery was found. (Injection methods were not used and I admit the possibility that in some cases a small cystic vein may have been overlooked.)

A WATER EMULSION OF PYRETHRUM EXTRACT FOR SPRAY-KILLING ADULT MOSQUITOES*

By PAUL F. RUSSELL
FRED W. KNIPE

and

T. RAMACHANDRA RAO

Introduction

THE results of Ross (1936), De Meillon (1936), Covell *et al.* (1938), Russell and Knipe (1939, 1940, 1941), and Russell *et al.* (1942) leave no doubt that wherever the mosquito vector of malaria spends its daytime hours inside houses, cowsheds, or outbuildings, routine spray-killing with pyrethrum sprays will effectively interrupt the transmission of malaria. This measure is based on the principle that, if the resting places of the vectors are effectively sprayed at suitable intervals, no female anopheline will live long enough to allow sporozoites to come to maturity. Transmission by *A. culicifacies* was effectively stopped by adopting a weekly spraying interval, in certain villages where it was tried experimentally in Pattukottai Taluk (see Russell *et al.*, 1942).

Pyrethrins, the active toxic principles of pyrethrum, are extremely lethal to mosquitoes, since they are absorbed through the cuticle and destroy nerve tissue.

In spray-killing for malaria control, the usual practice has been to dilute pyrethrum extracts with kerosene. This paper reports the successful use of water as a diluent, with considerable lowering of costs.

Preparation of spray

The spray reported herewith was a water emulsion of a concentrated kerosene extract of

*These studies were made under the auspices and with the support of the International Health Division of the Rockefeller Foundation, co-operating with the Madras Health Department, and the Pasteur Institute of Southern India. The authors are indebted to N. R. Sitapathy, assistant engineer, and T. S. Rama Rao, technical assistant, for their collaboration.

(Continued from previous column)

(3) Variations in the peritoneal investment of the gall-bladder have been described, and the likelihood of this having influenced, the arrangement of its venous return has been indicated.

(4) The cystic vein is potentially of surgical importance.

Indian grown pyrethrum*, and was prepared as follows:—

I. Stock extract

1. Twenty pounds of dried chopped pyrethrum flowers were soaked with 5 gallons of water-white kerosene in an air-tight container for 24 hours, and the resultant liquor decanted.
2. The flower residue was again soaked with 5 gallons of water-white kerosene for another 24 hours, and the resultant liquor decanted.
3. The flower residue was then placed in a long narrow tube, with a sieved funnel at the bottom. Then another 2 gallons of kerosene was allowed to drip—drop by drop—through the residue for about 12 hours. The remaining residue was pressed for the last obtainable drops of liquor.
4. All three liquors were mixed together and stored for future use in dark-coloured, air-tight containers. This was the stock extract.

Approximately 10 gallons of extract were obtained from 20 lb. of flowers and 12 gallons of kerosene. Nearly two gallons of kerosene were lost, due to absorption by the flowers. A more efficient press would have saved some of this loss.

II. Spray emulsion

Emulsions were prepared from stock extract in two dilutions as follows:—

A. Stock extract	1 gallon
Water	7 gallons
Emulsifier (sodium lauryl sulphate or 'Gardinol')	184 grammes
B. Stock extract	1 gallon
Water	3 gallons
Emulsifier (sodium lauryl sulphate or 'Gardinol')	92 grammes

The water must be clean and should be filtered through thick cloth before being used. It is preferable to use soft water, but when sodium lauryl sulphate is added, even hard water will make a good emulsion.

The emulsifier, sodium lauryl sulphate, known under the trade name 'Gardinol', was used at the rate of 23 grammes per gallon of emulsion. This quantity was arrived at after experiments which determined the amount required to keep the emulsion in good suspension for the necessary time. Smaller quantities allow quick separation of extract and water. (See also Ginsburg, 1935.)

Physical properties

Since the emulsion is mainly water, the droplets discharged by the nozzle of a spray-gun are a little heavier than in the case of kerosene sprays, and therefore do not rise so well as the latter. Regardless of this fact, the spray is effective. In fact, on many occasions it has been seen to penetrate upwards through thatched-roof crevices, similarly to kerosene sprays.

* A water emulsion prepared from a normal dilution of Pyroicide-20 was equally effective. The cost was greater because of the higher price of Pyroicide-20.

Toxic properties

During several trials conducted in a special insecticide testing chamber, the emulsion gave good results. Tests were made simultaneously with other insecticides. The toxicity was approximately as good as that of either a normal kerosene dilution of Pyroicide-20 (19 to 1), or of a kerosene diluted extract of Indian grown pyrethrum. In direct hits, even in extremely small dosage, the kill was always one hundred per cent. Likewise, in cages kept on the floor of the testing chamber, the kill was usually one hundred per cent. In one series of nine tests it was 99.8 per cent. Even when cages were kept at the roof of the chamber, with the spray directed downwards and away from them, the kill averaged 60 per cent. With free, uncaged mosquitoes in the testing chamber, the kill averaged over 90 per cent. These facts indicate that the toxicity of the emulsion was high. The slightly lower figure for roof cages, when the spray was directed downwards, can be explained as due to the nature of the droplets which are heavier than in kerosene diluted sprays.

Both emulsions, A and B (see above), gave approximately equal results in the testing chamber.

Field trials

Both emulsions were given extensive field trials in two large villages (Tamarankottai and Sendakkottai) of Pattukkottai Taluk during the malaria season of 1941 (July to November). In both villages spray-killing with these emulsions appeared to interrupt malaria transmission effectively, bringing about a notable reduction in spleen rates. In the village where the stronger emulsion was used the spleen rate dropped from 70 per cent in 1940 to 31 per cent in the malaria season of 1941. Where the weaker emulsion was used, the rate fell from 48 per cent in 1940 to 16 per cent in 1941. In unsprayed villages used as experimental controls, there were no reductions in spleen rates in 1941. Detailed data are being published (Russell *et al.*, 1942).

Costs

The prices of the materials used in our spray-killing experiments were as follows:—

				Rs. As. P.
Kerosene	0 14 3	per gallon*
Pyrethrum flowers	1 0 0	„ pound
Sodium lauryl sulphate	2 1 0	„ „
Pyroicide-20	45 0 0	„ gallon

* An Indian rupee consists of 16 annas, each anna of 12 pies. At current exchange, a rupee is worth approximately U.S. \$0.30 or £0-1-6.

On this basis the costs of the sprays used were as follows :—

	Per gallon of mixture Rs. As. P.
Pyrocode-20 (1 : 19 mixture with kerosene)	3 1 7
Indian grown pyrethrum extract in kerosene (1 gallon to 1 pound, further diluted with 1 : 1 kerosene)	1 7 10
Water emulsion of Indian pyrethrum extract (formula B)	0 13 11
Water emulsion of Indian pyrethrum extract (formula A)	0 7 9

The total cost (materials, labour, etc.) of spraying in villages with water emulsions during one season of 22 weeks has been approximately :—

Sendakkottai (population : 1,645) using emulsion A—3 annas *per capita*.

Tamarankottai (population : 7,620) using emulsion B—4 annas *per capita*.

Use in the field

In practical use, a spraying overseer took to the field only the *stock extract*. Each morning, before starting his spraying rounds, the overseer would prepare the *emulsion* required for the day. It is essential that the emulsion be freshly prepared every day, as pyrethrins in an emulsion quickly lose their toxic properties.

Before a quantity of the emulsion is poured into a spray-gun, this stock container should be thoroughly shaken. During spraying, the labourers soon learn to keep the emulsion in good suspension by frequently shaking the spray-gun.

Other emulsifiers

Probably any commercial emulsifier would be suitable for making a water emulsion spray such as we reported here. Other experiments, for example, were conducted with Permal EML, which was available in India. It was satisfactory when made up in the following formula :—

Stock extract	1 gallon
Water	7 gallons
Permal EML	2.4 pounds

Costs will vary somewhat according to the prices of the emulsifiers. It is quite likely that some suitable local product may be found. Ordinary soap was fairly good if the water was quite soft, but was found unsatisfactory for use with hard water. Soft water was seldom available.

Summary

This paper reports a water-emulsion pyrethrum spray which is cheap and effective. Its advantage is low cost. The disadvantage of slightly heavier droplets of a water instead of a kerosene spray can be overcome by properly

(Concluded at foot of next column)

A MODIFIED METHOD OF RETICULOCYTE COUNT

By A. N. BOSE, M.B.

and

J. K. GHOSH, M.B.

Bengal Immunity Research Laboratory

In the assay of liver extract preparations, whether on pernicious anæmia cases or in laboratory animals, reticulocytosis has always been taken to be the index of therapeutic activity. When working with laboratory animals such as guinea-pigs or rabbits, it is essential that a rapid at the same time accurate method should be adopted for the counting of the reticulocytes. Usually workers have used some modified methods as have been suitable to them. During the study of Jacobson's (1935) guinea-pig method of liver extract assay, a large number of reticulocyte counts had to be done by us and certain difficulties overcome. It was found that a drop or two of the blood could not be properly oxalated; and with a highly oxalated blood the cells did not maintain their proper contour for a long time and tended to break up and undergo granular disintegration. A stain of brilliant cresyl blue more than 0.5 per cent in strength tended to throw out precipitates more quickly, whereas a stain of 0.5 per cent in physiological saline (0.9 per cent) kept fairly well for a long time. It was also noticed by us as well as by Napier and Das Gupta (1940) that wet preparations gave more accurate results and required less time than dry slide preparations. Clumping of red blood cells which tended to occur in certain specimens was always traced to be associated either with a defect in the strength of the saline taken for dilution or with the

(Continued from previous column)

directing the spray nozzle and by using slightly greater amounts of spray material.

Practical tests in two villages with this water emulsion spray gave good results.

concentration of the cresyl blue solution or a partly coagulated drop of blood. A peculiarity was, however, noticed in the case of reticulocytes. In specimens where the red cells were undergoing granular disintegration, reticulocytes stood out prominently without any signs of breaking up. Probably this was due to their reticular structure.

The following modification of Osgood and Wilhelm's method (1934) gave accurate results in counting :—

A 0.5 per cent solution of brilliant cresyl blue in 0.9 per cent NaCl was kept in stock in the ice chamber. When required, small amounts were taken and used for 4 to 5 days. After a time, an initial centrifugalization at high speed for one hour was done to separate out any particles which had precipitated from the stock stain. Blood was taken direct from an ear vein by a needle puncture. One drop of blood and 4 to 5 drops of the stain were thoroughly mixed over a clean glass slide and then taken by a narrow pipette into a Kahn tube containing a small volume (about 1 c.cm.) of sterilized and absolutely clear saline of 0.9 per cent strength. The tube was immediately placed in a water-bath at 37 to 38°C. for 5 minutes. After this, a small drop was taken on a slide, a large rectangular coverslip was placed over it, and the specimen examined under the oil-immersion lens. At least 1,000 to 1,500 corpuscles were counted from one end to the other. Percentages of reticulocytes were then calculated from the total counts. Any slide which showed stain particles along with the corpuscles was rejected without counting. The advantages of this method are :—

- (a) the reticulocytes stained very distinctly,
- (b) the red blood cells remained separate and discrete without showing any tendency towards clumping,
- (c) the specimen remained completely free from any stain particles which previously used to interfere much with the identification of genuine reticulocytes,
- (d) owing to the dilution with saline in the Kahn tube the number of corpuscles in one microscopic field was reduced and thus it became very much easier to count them without the use of an Ehrlich's eyepiece or some similar device as is used by other workers.

[Note.—Dr. C. R. Das Gupta has tested this method, but did not find that it exhibited any advantages over the method (Aii) described by Napier and Das Gupta; also it took longer to carry out.

The method of testing liver extract described by Jacobson is not a generally accepted method for testing the efficacy of liver extracts.—EDITOR, *I. M. G.*]

FURTHER WORK ON PYRETHRUM IN THE TREATMENT OF PEDICULOSIS

By D. N. ROY

and

S. M. GHOSH

Department of Medical Entomology, School of Tropical Medicine, Calcutta

AMONG the various substances used for controlling the infestation of the head with louse, mention may be made of kerosene, xylol, oil of turpentine, cresol, lysol, acetic acid, etc., but none of them is satisfactory as either it has no action on nits or it causes considerable irritation of the scalp especially when the skin presents an eczematous condition which is so often caused by head-lice.

In a previous communication reference has been made of the good results obtained in the treatment of human louse infestation with pyrethrum (Roy, Ghosh and Chopra, 1941). The important point which came to light may be recapitulated. Pyrethrum prepared in the form of an extract by heating the powder in water or mixed with white vaseline proves fatal to lice, but fails to act on nits. This necessitates the continuation of the treatment during the whole period extending over the incubation period of eggs.

Observations made in Calcutta by the wristlet method indicate that the duration of the egg stage varies from 5 to 8 days in summer and from 7 to 10 days in winter.

It will thus be seen that though pyrethrum used in the forms stated above efficiently acts on adults yet suffers from the disadvantage that it does not act on nits on account of the fact that it cannot penetrate either the egg-shell or pass through the operculum.

We now present a report on the remarkable efficacy of a mixture of kerosene and pyrethrum, or deobase oil and pyrethrum in the treatment of infestation with louse. It has certain definite advantages over other forms of treatment in that only one application is necessary and according to our experience eggs and adults are always destroyed.

As a rule louse infestation among hospital patients is not so common in this country, possibly owing to the free use of oil and practice of taking daily baths. However, a large number of the female patients, all evacuees from Burma, who were admitted into the hospital for treatment of other diseases, had lice in their hair and the infestation was as a rule heavy. This opportunity was made use of to test the usefulness of pyrethrum in louse infestation of the hair. Before, the actual tests were undertaken on man, preliminary tests carried out on monkeys had proved encouraging.

In all, 26 patients were treated, 24 being females. The method of treatment followed was the spraying of every part of the hair from the root to the tip with an extract of pyrethrum,

diluted with either kerosene or deobase oil, by means of a De Vilbiss atomizer No. 15. The extract used was Pyresect 25* which was diluted with 24 times its volume of kerosene or deobase oil immediately before use. The taking of a bath within 12 hours following the treatment was in the beginning forbidden, though later observations made it clear that as soon as pyrethrum entering through the operculum came into contact with the embryo inside the egg-shell, the latter was killed, and therefore it would be unnecessary to restrict bathing for more than an hour or so after the treatment. Only one application was required to effect complete cure of their pediculosis in every case. - Laboratory experiments clearly showed that the egg-shell is impermeable to kerosene and also to a mixture of kerosene and pyrethrum. On the other hand, application of a minute drop of pyrethrum in kerosene or deobase oil on the operculum of nits always destroys the embryo. This is in contrast to the application of kerosene alone in which case a very large proportion of nits so treated will hatch.

* Pyresect 25 was kindly placed at our disposal by the supplier, General Export Co., 1, British Indian Street, Calcutta.

It is clear that pyrethrum is not only toxic to adults but also to nits for which a direct contact is essential. The reason why kerosene acts on adults, though the action is uncertain, but fails to act on nits, is the fact that it cannot penetrate the operculum; this pyrethrum in kerosene or in deobase oil readily does. A marked alteration of the surface tension may be accepted as the explanation. Thus a drop of kerosene poured on water has the tendency to collect in one place, whereas kerosene-pyrethrum will quickly spread over a large area of the surface.

Patients treated with kerosene-pyrethrum mixture have not been known to complain of any irritation of the scalp even when superficial ulcerations were present. It is liked by them on account of its containing a drop or two of oil niroli, which is always added to the mixture in order to make the smell pleasant.

Those with long hair require from $\frac{1}{2}$ to $\frac{3}{4}$ oz. and those with short, less than $\frac{1}{2}$ oz. of the mixture.

A Mirror of Hospital Practice

GIARDIASIS—TWO CASE REPORTS

By D. N. SEN GUPTA, M.B., D.T.M.

Medical Officer, Nuddea Mills and Company, Naihati, 24-Parganas, Bengal

ON 20th October, 1941, I was called in to see a female patient, aged 30 years, who had been ailing for more than a year and was suffering from terminal broncho-pneumonia and I was given to understand that she was very seriously ill.

The condition on my first visit was as follows :—

She was very emaciated, toxic, prostrated and dyspnoic. Temperature—103°F. (axillary). Pulse—140, with low volume and tension. Respiration—60 per minute and shallow. Lungs showed signs of broncho-pneumonia. Cyanosis was present. Cough was incessant and hacking with muco-purulent sputum.

Previous history.—She was a mother of 5 children—last issue one and half years back. Complaints started as dysentery one year ago. The symptoms, especially diarrhoea and flatulence, persisted in spite of various treatment. During the whole period of illness she lost about 40 pounds in weight. She was kept on a very low diet.

Treatment and progress of the case.—I put her on M.&B. 693. The temperature was normal on the third day and the lung condition improved, but troublesome diarrhoea started—loose frothy evacuations with mucus about 6 times per hour. The stool was examined microscopically—*Giardia intestinalis* cysts and vegetative forms were found. M.&B. 693 was omitted on

account of diarrhoea and bismuth with opium was given to control it.

On the fifth day the temperature was 99°F. to 100°F., diarrhoea was checked and M.&B. 693 given again but diarrhoea recurred. The stool was again examined; it showed a heavy giardia infection.

Next morning the pneumonic condition having settled down and the patient being free from toxæmia, atebirin 0.3 gram daily was given after food. On the fourth day of atebirin, she passed firm stools twice. On the fifth day she developed atebirin psychopathy and was violently delirious. Peacock's bromide and adalin were prescribed that settled down the condition within 24 hours. She was given an acid mixture and high protein diet. She had no more flatulence and diarrhoea. She gained weight and developed a voracious appetite. Her stools were examined for three consecutive days and no giardia was found.

Some time later I had another similar case.

This case was a woman, aged 18 years, after the first childbirth had been suffering from chronic flatulent diarrhoea for one year. She was treated along various lines, on a very restricted diet, with no improvement.

On my first visit I examined the stool microscopically and found giardia, vegetative and cystic forms, in large numbers. No atebirin was available in the market, so she was put on acid mixture and stovarsol. She improved so long as stovarsol was continued, but diarrhoea recurred when the drug was discontinued.

With great difficulty one phial of atebirin was procured by the patient's relative at a fabulous price. She was cured with one course only. Stool was repeatedly examined but no giardia was found.

A CASE OF ACUTE BACILLARY DYSENTERY TREATED WITH M.&B. 693

By B. M. CHATTERJEE, M.B.

Assistant Surgeon, Tangail Subdivision and Hospital

ON Monday, the 16th March, 1942, at about 10 p.m. I was called in to see a boy, aged 12 years. According to the history given by the relatives, the boy was passing frequent loose motions with mucus and blood for the last few days. On the day when I was called, the boy passed about 40 stools.

On examination, I found the boy to be in a desperate condition. He was very restless, and complained of severe griping pain in the lower abdomen associated with tenesmus. Temperature was 101°F., pulse 120, and respiration 22 per minute. The tongue was coated and dry. Tenderness was present over the lower abdomen. Stools were passed every 10 to 15 minutes, alkaline in reaction and consisted of abundant mucus, blood and greenish sloughs. Faecal matter was entirely absent. For want of proper facilities microscopical and cultural examination of the stool could not be done. Clinically, the case was diagnosed to be acute bacillary dysentery.

M.&B. 693 was prescribed, and considering the desperate condition of the boy, a moderately heavy dose of 1.5 gramme of sulphapyridine was given by mouth in powdered form immediately. Along with general resuscitative measures the drug was repeated in the same dose once more, four hours afterwards in the night. Next morning, I came to know that after the first dose of M.&B. 693, the number of stools became less frequent and the boy slept for some time. The general outlook of the patient in the morning was much better. Griping pain and tenesmus diminished to a marked extent. Stools passed in the latter part of the night showed marked diminution in the amount of blood and greenish sloughs, and the M.&B. 693 powder was found to be present in the stools. Another 3 grammes of the drug were prescribed for the day, and stools completely stopped after 12 noon of the very day. There was absolute constipation for three subsequent days and afterwards the boy recovered uneventfully.

The miraculous efficacy of sulphapyridine in the treatment of acute bacillary dysentery has been recently reported by Bell (1941) and Lapping (1942). The presence of the sulphapyridine powder in the stool in the above-mentioned case shows that the drug acted locally on the large intestine. To decide whether the abatement of symptoms was due to the action of the drug on the dysentery group of organisms, or due to action on the associated streptococcal infection, requires further investigation.

I am thankful to Dr. P. R. Das Gupta, civil surgeon, Mymensingh, for kindly allowing me to publish the report of this case.

BACILLARY DYSENTERY TREATED WITH M.&B. 693

A CASE REPORT

By B. MUKHERJI, M.B., D.P.H.

Section of Epidemiology and Vital Statistics, All-India Institute of Hygiene and Public Health, Calcutta

BACILLARY dysentery is rife in India and the mortality is particularly high amongst the

younger age-groups. The public health measures adopted to control or eradicate the disease are far from being satisfactory even in cities and towns, not to speak of rural areas which constitute the major part of India. Taking these facts into consideration if a quick and radical treatment can be instituted at a cheap rate, it will be greatly welcomed from all quarters.

Reitler and Marberg (1941) successfully treated 20 cases of bacillary dysentery of various types with sulphapyridine with the result that all were cured within 48 to 72 hours after the drug treatment was started. Later on, Bell (1941) used it in an epidemic of bacillary dysentery at a colony in Southampton where all his fourteen cases recovered in the same space of time. Whereas in the former series there were no relapses, in the latter there were two relapses who were successfully tackled within 24 hours by the same drug.

A boy, aged 3½ years, was attacked with bacillary dysentery at Lucknow on 1st May, 1942, and was frequently passing dark green-coloured stool with plenty of mucus and fresh blood. He was put on homœopathic treatment on the same day. Fresh blood disappeared from the stool on the next day, but no other improvement regarding other symptoms followed within the subsequent two days. On 4th May he was put under the local medical practitioner who put him on castor oil and later on phage (intestinal and dysentery) at usual intervals. No improvement occurred till the 6th evening when the case was brought to my notice. The stool was at once sent for an examination and ordinary microscopic examination revealed it to be a case of bacillary dysentery (plenty of blood corpuscles with a few epithelial cells—no amoeba detected; reaction alkaline). He was put on M.&B. 693 receiving 1.25 gm. on the first day. With the administration of the second dose the character of the stool began to improve; yellow flakes appeared and the dark green colour was replaced by a lighter one. On the second day 1 gm. of sulphapyridine was administered and towards the evening he began to pass formed stools of yellow colour and with practically no mucus. Number of motions diminished from six on the 6th to two on the 7th, and the temperature which was never above 99.6°F. fell down to normal. On the third day only 0.5 gm. of the drug was administered and he passed a normal formed stool. Thereafter, he was observed for one week more but no relapse occurred.

Diet included milk and barley water for the first four days, with occasional substitution of whey for barley water, followed by light rice diet and a seer of barley water every day.

Further trials with this drug will be awaited with interest as no definite conclusion can be drawn from a single case like this.

My thanks are due to Dr. Gupta, Lucknow, for kindly examining the stool and giving the diagnosis.

[Note.—Our contributor has referred to foreign publications, but seems to have overlooked Dr. Lapping's report in the February number of this journal. Sulphapyridine has been used by several workers in this country, but so far not always with uniformly good results.—EDITOR, I. M. G.]

Indian Medical Gazette

AUGUST

THE TRANSMISSION OF KALA-AZAR

MALARIA has been recognized as a clinical entity for some thousands of years and as long ago as the Vth Century B.C. the most characteristic clinical signs were described accurately by Hippocrates.

Malaria takes many forms and it was looked upon by the physicians of the early days of the present era of scientific medicine as the standard fever of the tropics, on which main theme nature was capable of playing an infinite number of variations; but it was credited with a much more protean pathogenesis than it really possessed, and gradually certain clear-cut clinical types which appeared to have distinguishable epidemiologies emerged from the morass; amongst these were blackwater fever, about which our predecessors were—we now believe—wrong, and typhus, typhoid, yellow fever, relapsing fever, trypanosomiasis, and many other fevers, including kala-azar, about which they were right. This differentiation was aided by the introduction of the cinchona alkaloids in the treatment of malaria.

Then came Laveran and his discovery of the malaria parasite, and we have no doubt that many of the scientists of these days thought that all doubts regarding the relation of malaria to the other fevers of the tropics would soon be cleared away, but, although this discovery undoubtedly heralded a very great advance in our knowledge of tropical fevers, the immediate results were not all beneficial; a little knowledge once more proved a dangerous thing, for as malaria was so universally present in the tropics, malaria parasites were occasionally found in cases of typhus, typhoid, yellow fever, relapsing fever, trypanosomiasis, and kala-azar, and the issue was thereby confused. In the case of many of these diseases that had well-recognized syndromes, the syndrome survived and doubt was cast on the specificity of the malaria parasite; in the case of others, the malarial parasite won the day and the diseases temporarily lost their identity and were considered special forms of malaria. Amongst the latter was kala-azar.

By the middle of the XIXth Century and probably much earlier, kala-azar was recognized as a clinical entity—locally at least, for little about the disease had found its way into medical literature. An epidemic that started in Burdwan and spread throughout Bengal and the first recorded Assam epidemic of 1872 were recognized as being different from malaria. When the second Assam epidemic started and depopulated certain areas in that fertile country, officers were deputed from Bengal to investigate the cause. Many fell into the partial-correlation trap; for example, Giles in 1890 finding that a number

of patients with kala-azar had ancylostomes in their intestinal tracts—as indeed have nearly all the inhabitants of that country—described it as ‘undoubtedly ankylostomiasis’, and, even later, when the giants of medical research, Rogers (1897) and Ross (1899), were called in, they gave their considered opinions that it was a particularly resistant form of malaria. Thus, in the twenty years since Laveran’s discovery, matters had retrogressed.

In 1903, Leishman and Donovan independently discovered the causal organism of kala-azar. The method of demonstrating the parasites during life presented no difficulties and therefore a definite diagnosis could be made. It was now possible to separate kala-azar from malaria with greater accuracy, and further the disease which had hitherto only been recognized in India was found to occur in other countries, e.g., China and the Sudan; and other recognized clinical syndromes, e.g., *ponos* in Greece, were found to be caused by the same, or at least by a morphologically identical, parasite. So ended the first phase in the investigation of the aetiology of this disease.

The next question that naturally arose was—how is the disease transmitted to man? Investigations were started almost immediately, and Patton in Madras was one of the earliest investigators. He showed first that the causal parasite, *Leishmania donovani*, was always present in the peripheral blood and not demonstrable in the secreta or excreta (subsequent investigations showed that it is recoverable from the stools, urine and nasal secretions in special circumstances). One of the earliest insects with which he experimented was the bed-bug; he found that the parasite survived in this insect for a considerable time and multiplied if the bug did not take another blood meal, but that, if it did, the infection was likely to be killed. For some years, all work by experienced investigators such as Patton, Cornwall, Adie and Knowles was concentrated on the bed-bug, but little advance was made; the bug was at best a poor culture medium, only a very small percentage of bugs that took an infected blood meal became infected, and in them the infection was very light and often transient.

The 1914-18 war interfered with research work, but immediately after the war, when the School of Tropical Medicine in Calcutta was opened, a special kala-azar research department supported by the Indian Tea Association was included in the scheme; Napier was appointed to this post and with Knowles, a more senior member of the staff with previous experience of the subject acting in an advisory capacity, and the staff of the protozoological department, including B. M. Das Gupta, co-operating, a new attack was made on this problem. It was decided that an entirely fresh start had to be made and a thorough epidemiological study of the disease in Calcutta was carried out by Napier. Certain observations

made by him regarding the distribution of the disease seemed to indicate that it would be possible to narrow down the scope of any special investigations to one particular quarter of the town. The Calcutta inquiry was strengthened by the addition of Smith, appointed under the Indian Research Fund Association to act as medical entomologist, in May 1924. The earliest investigations showed that of those under suspicion, excluding the bed-bug on account of its ubiquity, the insects most constantly present in the endemic quarter in Calcutta were sandflies, *Phlebotomus minutus* and *Phlebotomus argentipes*. As the former was reputedly not a human-blood feeder, experiments were first carried out with the latter. No infected flies were found in nature at that time, but it was thought that clean laboratory-bred flies ought to be used, and after a short delay while the technique of breeding these was learnt, in the very first batch of these flies fed on kala-azar patients, 40 per cent were found to develop a heavy flagellate infection in their mid-guts (Knowles, Napier and Smith, 1924, *I.M.G.*, 59, 593).

In the same year the Indian Research Fund Association's Kala-azar Commission, with Christophers, Shortt and Barraud were starting work in Assam. They too had decided on a completely unprejudiced approach and were first exploring the possibilities of oral infection; when however the observations regarding the development of the parasite in *Phlebotomus argentipes* were made in Calcutta, they immediately switched over their full attention on to this sandfly and very soon were able to confirm the Calcutta findings. The Kala-azar Commission carried the matter much further and were able to show that the infection in the sandfly progressed forwards to its mouth parts, so that when the fly took another blood meal it must almost inevitably contaminate the wound with flagellates and thereby transmit the infection. At this stage, help was received from outside India by the discovery by Young, Smyly and Brown that the Chinese hamster was very susceptible to leishmania infection and a large consignment of these animals was received from Peiping. It was by this time felt that the problem was almost solved, but attempts to transmit the infection to hamsters by means of the sandfly's bite were singularly disappointing. However, Shortt, Smith, Krishnan and Swaminath (1931), and Napier, Smith and Krishnan (1933) succeeded in infecting one and two hamsters, respectively, in this manner. But all attempts to transmit kala-azar to volunteers failed, so that at the end of nearly ten years since the initial incrimination of the sandfly, *P. argentipes*, by Knowles, Napier and Smith, the final and conclusive proof was still wanting that this sandfly could actually transmit kala-azar to man.

However, despite the failure of the crucial experiment and certain confusing observations,

such as the finding of the parasite of kala-azar in nasal secretions, most protozoologists considered that the circumstantial evidence against the sandfly was sufficiently strong for this mode of transmission to be accepted as a working hypothesis, and means for controlling sandflies were therefore investigated. Most of the workers themselves felt certain that the sandfly was the transmitter, and that it was only a matter of time and the discovery of the particular 'trick' for experimental transmission to be effected at will. (The disease had been transmitted to three hamsters by sandflies, but it was the many failures that needed explaining.)

The general opinion at this time is well represented by Napier's summing up of the position in the *British Encyclopædia of Medical Practice* which reads as follows:—

'So far as India is concerned, every epidemiological observation fits in with the sandfly hypothesis of transmission. Further, this sandfly has actually been found in large numbers in every locality where kala-azar occurs; it is a persistent human-blood feeder; a large percentage of the flies that feed on an infected person acquire the infection; infected flies have been found repeatedly in nature; this is not true of other sandflies which are more prevalent in the non-endemic areas, nor in insects of any other genus so far experimented with; in this fly an anterior development of the flagellate infection occurs and is unlikely to be purposeless (in natural flagellate infections which pass from insect to insect the development is usually posterior); and it has been shown experimentally that the fly is capable of transmitting the infection to a mammalian host by its bite. All these facts make it almost certain that this insect is an important agent in the transmission of the disease from man to man in nature, although it may not be the only agent.'

The Kala-azar Commission was disbanded in 1931 and the main Calcutta inquiry three years later, and the principal workers turned their attentions to other matters. However, in 1939 work on kala-azar was resumed at the instance of the local governments in certain provinces where it was thought that the disease was showing signs of recrudescence. Smith was again appointed under the Indian Research Fund Association and the inquiry was located in Bihar. The work was primarily a bionomical and ecological investigation of the sandfly, with special reference both to the mechanics of transmission and to the possibilities of sandfly control.

Smith made some very important observations, namely (i) that after its primary blood-meal the sandfly could be kept alive for weeks by feeding on fruit juice, (ii) that, if after a primary infected feed the sandfly was given another blood meal, the flagellate infection was likely to be knocked out or at least its activity was reduced, but that if the sandfly was fed on raisins, the leishmania infection increased until the whole pharynx of the fly was blocked with

flagellates, and (iii) that flies thus 'blocked' with heavy leishmania infection, although they attempted to feed when given an opportunity, were unable to draw any blood, despite very violent efforts to do so; during these efforts it was certain that portions at least of the flagellate block became detached and entered the wound made by the proboscis.

Whilst it could truly be said that none of these observations was entirely new (e.g., the standard method of keeping mosquitoes alive is by feeding them on raisins and the method has been previously applied to sandflies, the observations that subsequent blood-meals knocked out the flagellate infection had been made by Patton, a quarter of a century ago in his bed-bug experiments, and the 'blocking' had already been observed histologically by the workers of the Kala-azar Commission with reference to this sandfly and has of course long been recognized in the flea in plague transmission), yet Smith's perfection of the technique was undoubtedly the most important step in providing the final proof that the sandfly *P. argentipes* can transmit the disease to man; the next two steps followed naturally when opportunity arose.

Smith, who was now able to produce these blocked flies more or less at will, first placed them to feed on hamsters, and obtained a very high infection rate amongst his experimental animals, and he would in the ordinary course of events have conducted the final experiments with human volunteers, but was recalled to military duty. This experiment was entrusted to Swaminath, one of the earliest and most constant workers on the kala-azar transmission problem, who, with the administrative assistance—and no doubt expert technical advice—of H. E. Shortt and L. A. P. Anderson, Inspector-General of Civil Hospitals and Director of the Pasteur Institute, respectively, in Assam where these experiments were being conducted, repeated Smith's experiments with human volunteers. Six volunteers, who lived in a hill district in Assam where kala-azar does not occur, were selected, and infected flies were fed on them; a paper that is at present in the press reports that at least three of these volunteers have contracted kala-azar. The hypercritical might say that this does not prove that this is the way kala-azar is *always* transmitted. It is true that this isolated experiment would mean nothing more than that it *can* be transmitted this way, but taken in conjunction with all the rest of the observations that have been made on this disease, every scientist will, we believe, agree that this experiment has removed the last objection to the already generally accepted conclusion that the *usual* method of transmission of kala-azar is by the agency of the sandfly, *P. argentipes* in India and other allied species in other countries.

An attempt has been made to give a consecutive account of the investigations that led to the final solution of one of the few outstanding problems regarding the transmission of the major

tropical diseases. A very fair criticism would be that only work in India has been mentioned. Very important and valuable work on this problem has been done by a number of foreign workers, for example, the Sargent brothers' very suggestive experiments with sandflies and oriental sore in North Africa in 1921, which were confirmed and developed by Adler and Theodor, the later work of Adler on kala-azar in Europe in which the *P. perniciosus* was incriminated as the vector, the collateral work in China by Young, Hertig, Meleney, Patton, Hindle, Faulkner, Zia, Yung Sun, and many others, which showed that *P. chinensis* of the *P. major* group of sandflies was an efficient carrier, and the more recent observations by Kirk and others in the Sudan; all this work has encouraged the Indian workers and led them to believe that they were working along the right lines, but it actually started no new lines of thought, and it bridged no gaps in the road to the final goal, as far as the transmission of kala-azar in India was concerned.

At least three of the active supporters of the sandfly hypothesis have not lived to see their beliefs justified; during the last ten years, Young, Knowles and Acton have died. Though the last-named took little active part in the work on kala-azar, his belief, based analogously on his observations on oriental sore in Iraq, that the sandfly was the transmitter inspired all these who were associated with him.

FILTERS AND FILTRATION

WITH SPECIAL REFERENCE TO THE FILTRATION OF BLOOD PLASMA AND SERUM FOR TRANSFUSION PURPOSES

By K. V. KRISHNAN

and

E. K. NARAYANAN

(From the Section of Microbiology)

All-India Institute of Hygiene and Public Health

Introduction

WITH the starting of blood banks in India certain commonplace laboratory procedures, such as filtration, have assumed considerable importance. Located as India is at present with her usual supplies from abroad cut off, workers in blood banks in this country are faced with the problem of obtaining suitable filters for their work. While drawing up proposals for the blood bank in Calcutta, it was found that use could not be made *in toto* of filtration procedures adopted by blood banks in the West for want of appropriate material. Various alternative methods and materials had to be thought of. In connection with that a review on filters and filtration was prepared and in the hope that persons interested in filtration will find it useful it was submitted for publication.

Definition

Filtration is the process by which solids suspended in liquids and in an extended sense solids or liquids suspended in gases, are separated from one another by means of a false partition. This partition is called a filter and it blocks the passage of suspended matter while allowing the fluid in which it is suspended to pass through.

Filters

It is common knowledge that there are many kinds of filters in the market prepared from a variety of material. Some are simple while others are slightly more complex, but each type has its own special use. In order to be able to choose correctly the type of filter required for any particular work one must know the different basic materials used in making the different types of filters, and their advantages and disadvantages.

The materials commonly used in making filters are cotton, paper, glass, asbestos, sand, clay or other forms of earth, plaster of paris, charcoal, collodion and gelatin. A brief description of these materials and of the filters made from them and their uses are given below :—

Cotton.—Cotton is the carbohydrate, cellulose. On account of its filamentous nature, it is used as filter in one of two forms—(i) as cotton-wool and (ii) as woven cloth.

Cotton-wool is prepared in two forms—absorbent and non-absorbent. While absorbent cotton is a useful clarifying agent for liquids both the absorbent and the non-absorbent types are useful for filtering gases. The familiar cotton-wool plugs in test-tubes containing media for bacterial growth in fact act as bacterial filters for the air that enters the tubes.

Cloth, lint and gauze are forms of woven cotton which are sometimes used as filters for clarification and under suitable conditions they yield filtrates which are quite clear.

Recently, Bushby and Whitby (1941) have employed a patent preparation called 'perfecta pulp' for clarifying blood plasma by removing the suspended fat globules. It is said to be made of pure cotton.

Paper.—Paper, like cotton, is a form of cellulose. Unsized paper, i.e., paper which has not been glazed, has a porous texture and is in principle filter paper. But good filter paper of constant porosity is prepared by more refined methods. Papers of graded porosities designated by numbers are on the market. The numbers are given by the makers and with each number its uses are also given. The number of paper chosen will depend upon the purpose for which it is needed.

Apart from the ordinary kind of filter paper, special forms are also available for special purposes. For example, ordinary filter paper is acted upon by strong acids and alkalies, and therefore a special kind of filter paper which is resistant to these has been manufactured. This is produced by changing cellulose into a

gelatinous form called 'amyloid' which is resistant to acids at ordinary temperature. It is however relatively less porous. Parchment paper is also prepared in a similar manner, but it is gelatinized to a larger extent. As yet there is no method of standardizing this gelatinizing process to obtain different porosities. If that could be done, excellent bacterial filters could be made out of gelatinized paper. There are also filter papers specially prepared for other types of work. For example, a fat-free form is prepared for use in fat estimations and an ashless form in gravimetric chemical analysis. Special types are also available for filtering oils called 'Postlip thick grey' and for colloidal material called 'Chardin'.

Paper pulp is also used in filtration. It is supplied in the form of compressed slabs. These are broken up in hot water and ground up until the mass is of an even soft consistency. For use, the pulp is placed into a Buchner funnel of which the holes are covered by ordinary filter paper and by gentle hand pressure and suction the pulp is made into a pad. Such a filter is efficient in clarifying protein solutions.

Glass.—Glass, a mixture of silicates of calcium and sodium, is used in filtration in the form of glass wool or sintered glass discs. The former is a very familiar form and is used for rough clarification. Its main advantage is that it can be used with impunity with acids and alkalies. Glass wool is not difficult to prepare. A process known as 'the bow and arrow process' is employed in making it. In this process heated glass in the plastic stage is shot through with a bow and arrow type of arrangement and the long thin filaments formed are wound round a drum. By keeping the drum rotating all the time a continuous stream of glass fibres is drawn out from the plastic glass.

Sintered glass filters are also available in the market. These filters are made by spreading powdered glass of uniform degree of fineness into a uniform layer over mica plates and then heating them in ovens to a high temperature to enable the pieces just to fuse into a porous plate. This process is known as sintering. The surfaces of these plates are ground rough with emery and cut into proper discs which are later fused into suitable holders. Filters of varying porosities are available and recently some bacterial filters have also been produced. These have an average pore diameter of 0.9μ which though very much larger than the smallest bacteria (0.2μ) serve well as bacterial filters in practice, probably due to the clogging of the pores during filtration. The firms employ a code designation for the porosity of these filters. On the filter is stamped one letter between two figures, as for example, 1G3. The first figure indicates the type and size of the filter, the capital letter the quality of the glass and the last figure refers to the porosity of the filter disc. Sometimes the letter 'P' is added to the designation of the filter. This means that the filter disc is ground

plane and polished. For bacteriological work the filter is designated G5 on 3 which means that 2 discs of porosities 5 and 3 are fused one over the other. These filters are easy to clean and sterilize and can withstand temperatures up to 120° and 150°C.

Asbestos.—Asbestos is a double silicate of calcium and magnesium. It occurs in the form of large sheets consisting of layers of long crystals. It has a filamentous texture and can be processed into a woolly consistency or ground into a pulp. This asbestos wool or pulp can be used as such or after being pressed into pads. Pads of asbestos incorporated with paper pulp are sold by the German firm of Seitz in two grades of porosities, K and EK; K for clarification and EK for bacterial filtration. They are available in different sizes—3 cm., 6 cm. and 14 cm. in diameter. There are also American and English equivalents of these pads. Suitable apparatus for mounting these pads for filtration are available in two types—(i) Manteufel and (ii) Uhlenhuth. These filters (particularly the latter) are becoming extremely popular in bacteriological work on account of their efficiency, cheapness and rapidity of action. They are also easy to handle and sterilize. It is this type of filter that is used in plasma and serum work both for clarification and sterilization. Further data regarding these filters are given later.

Sand.—Sand, the oxide of silicon, acts in nature as a filter when water percolates through the soil. It is used in the purification of community water supplies. The sand itself does not account for the whole of the filtering efficiency; it is the biological deposit of slime, that forms on the top of sand that acts as a true bacterial filter.

Clay.—Clay, the silicate of aluminium, when baked and unglazed as porcelain is much used in filtration. The popular form in which porcelain is used as a filter is a hollow tube, thimble or candle. Chamberland, a French worker, was the first to use them and later Pasteur, and hence the name, Pasteur-Chamberland filters. They are prepared in different porosities, designated in increasing order of fineness, as L_1 , L_1 bis, L_2 , L_3 , L_5 , L_7 , L_9 , L_{11} , L_{13} . The L_3 candle is the commonest in use for bacterial filtration. The English equivalent is known as the Doulton filter, the German as the Massen filter, and the American as the Allen filter. These are made in one porosity only, approximating to Chamberland L_3 . Recently porcelain discs held between rubber gaskets in a metal holder called Jenkin's filters have come on to the market.

Keiselguhr.—Keiselguhr is a siliceous earth of diatomaceous origin obtained from the Keiselguhr mines. The story of the value of this earth for filtration is interesting. It was first found that water from the Keiselguhr mines was of excellent quality and bacteria-free. Investigation revealed that the earthy bed

through which the water came was responsible for its bacterial purity. Use was made of this earth for the preparation of bacterial filters and these worked very efficiently. Filters made from this material were given the name of Berkefeld after the owner of the mines. They are shaped as hollow candles fitted to a metal nozzle and are sold in three grades of porosities, V, N and W. V or *viel* meaning coarse, N or normal, and W or *wenig* meaning fine. The English Berkefeld Company supplies filters of one grade only. These filters are extremely fragile and cleaning of the candles is a laborious and unsatisfactory procedure. There is also the danger of a leak developing at the junction of the candle with the metal nozzle. The American equivalent of these is known as Mandler filters, and the composition of these is slightly different. They are made of Keiselguhr, asbestos and plaster of paris. The proportions are varied to give three porosities which are graded according to the air pressure they withstand in water. They are called 'preliminary' (2 to 5 lbs.), 'regular' (6 to 9 lbs.) and 'fine' (10 to 16 lbs. per sq. inch). The Mandler filters are said to be stronger than Berkefeld.

Plaster of paris.—Plaster of paris, the semi-hydrate of calcium sulphate, becomes plastic on wetting with water and later sets. Recently, Kramer filters made of commercial plaster of paris either alone or combined with different quantities of magnesium oxide have come on to the market. They have been used for special purposes in which filters carrying a positive charge are required.

Charcoal.—Charcoal has been used in filtration, specially in connection with the clarification of sugar solutions and oils. In water purification for domestic purposes charcoal is, at times, employed.

Collodion.—The earlier filters made of collodion were those prepared by impregnating collodion on filter paper, but these filters were not of uniform porosities, nor could they be exactly reproduced when needed. The latest type of collodion filter is the Elford membrane. This is prepared from a solution of collodion in a mixture of absolute alcohol, anhydrous ether, acetone and amyl alcohol. The mixture is poured on to special plates and allowed to evaporate spontaneously under standard weather conditions and the film produced allowed to jelly by the addition of water. The resulting membrane is of uniform porosity and exactly similar membranes can be reproduced by employing the same identical procedure. The porosity of a membrane can be varied at will by the addition to the collodion solution of varying quantities of water to increase the pore, or acetic acid or ethylene glycol monomethyl ether, to decrease the pore. The actual pore size of any prepared membrane can be determined by noting the rate of flow of water through it and applying Poiseuille's equation. These membranes are sufficiently strong to stand

handling and pressure and are of great use in certain types of bacterial and ultra-filtration work.

Gelatin.—The use of gelatin as a filter material is now obsolete. But it is of historical interest in that many of the earlier investigations on ultra-filtration were carried out by depositing it on filter paper.

Purpose of filtration

It is common knowledge that filtration is widely employed for a variety of purposes in several branches of science. So far as bacteriology is concerned it is used at least for four purposes:—

(1) To obtain fluids free from bacteria as in the filtration of water for drinking purposes which is done with the object of removing bacteria and suspended matter.

(2) To obtain bacteria free from the fluid in which they are suspended as in the isolation of pathogenic bacteria from water samples where filtration is done with the object of concentrating the organisms in the filter as a preliminary to their isolation.

(3) To separate organisms of different types from one another as in the filtration through collodion membrane of fluids containing a mixture of bacteria and viruses for keeping back bacteria but allowing the viruses to pass through.

(4) To clarify material used in bacteriological work as in the filtration of culture media which is done with the object of removing gross particles and obtaining filtrates clear to the eye.

In serum and plasma filtration in which we are primarily interested, filtration is done with the object of 1 and 4, i.e., sterilization and clarification. No doubt, theoretically it should be possible to avoid filtration of serum and plasma by the adoption of a strict aseptic technique and a closed system of collection, pooling and bottling. In fact, Dr. Strumia of the Bryn Mawr Hospital, Pa., advocates the aseptic closed technique and does not find any necessity to filter the plasma or serum he prepares. But most others in the West, as well as ourselves here, feel that, despite the adoption of a closed system and all-care in technique, contaminative bacteria do get introduced at some stage or other, and that these have to be removed. Under the conditions prevailing in India and particularly during the summer months, we find filtration essential and cannot be avoided.

Equipment required

In order to carry out filtration, four main things are required as shown in figure 1. These are (1) the filter and its holder, (2) the vessel for holding the fluid to be filtered, (3) the receptacle for collecting the filtrate, and (4) a mechanical pressure system which will ensure proper rate of filtration.

Choice of equipment

The choice of equipment for any filtration work will depend upon two important considerations—(i) the purpose of filtration, and (ii) the quality of the filtrate required.

As our main interest lies in the filtration of blood serum and plasma it may be pointed out that it is done for the purpose of clarifying and sterilizing the serum. And as regards the quality of the filtrate the requirements are that it should be free from bacterial and chemical contaminants and also have a chemical composition as near to its original as possible. From these two points of view let us consider the choice of equipment.

Choice of filter

A suitable filter is the first requisite for conducting successful filtration. From the long list of filters already given it will be clear that we have a wide range of filters to choose from for the two purposes mentioned. For clarification we can choose cotton-wool, gauze, cloth, lint, filter paper, paper pulp, asbestos wool or pads, glass wool, sintered glass, charcoal or sand. And for sterilization we can choose special types of filters, such as, Pasteur-Chamberland, Doulton,

Fig. 1.

Massen, Berkefeld and Mandler, Seitz or Kramer filters. But before making the choice we will also have to take into consideration the chemical composition of the fluid to be filtered, its pH, its viscosity, and the nature of the filtrate we wish to obtain. English and American workers are using Perfeeta pulp for clarification and Seitz filter for sterilization. But in view of the fact that these are not available in India, it will not be out of place to say a few words as to what these are and what substitutes can be used in their place.

Perfeeta pulp is a patent article sold by Messrs. Beeker & Co., in cakes about 12 inches \times 12 inches \times $\frac{3}{4}$ inch, weighing $1\frac{1}{4}$ lb. each and priced at 1s. 6d. per cake. The exact method of manufacture of this pulp is not known, but from the description in the catalogue it seems to be made out of 'pure cotton without any admixture'. It should not at all be difficult to manufacture this locally. Further, for clarification purposes for which it is used, suitable substitutes can be improvised. It is a familiar practice in protein laboratories to use filter paper pulp for clarification. This pulp is made by kneading pieces of filter paper with water and then pressing a pad of them on Buehner funnels.

It would be worth while experimenting with such a substitute and determining its efficiency. Theoretically it should prove successful. Since writing this article experiments conducted at the A. I. I. H. have revealed that paper pulp made as above and sterilized by autoclaving is quite effective for clarification. In fact the Institute blood bank uses it regularly for clarification of serum.

Seitz Pilot filter.—The Seitz Pilot filters are special large types of Seitz filters which can take 20 cm. square filter pads. Into these 8 sets of paired pads (a clarifying Ford FCB pad followed by a bacterial Ford S.B. pad) can be fitted. Its advantages are: (i) that a large filtration surface is obtained and 140 litres of serum can be filtered in one day using a filtration pressure up to 12 lb. per sq. inch, and (ii) that both clarification and sterilization can be effected in one operation. These filters are not available in India and there is no knowing when they will arrive even if indents are placed. Although there are advantages in using these instead of the ordinary Seitz filters which are smaller, yet the latter will prove, if properly used, equally efficient. Another advantage in using a Pilot filter is that positive pressure can be employed in working it. Though the ordinary Seitz filters are meant for working with negative pressure, the Uhlenhuth models can be used for filtration both under negative and positive pressures. In fact it is this type that we have recommended for filtration of serum in the Institute.

The pads used in Seitz filters are of German manufacture. There are also English and American substitutes of these. India had a very poor stock of German pads when the war broke out. Since then all available pads have been sold out. Fortunately the Institute has stocked a fair quantity of the pads. But they may not last long, specially as large numbers of these will be used in serum filtration. Thus the problem of obtaining a large stock of pads still remains, specially as the English and American substitutes have not yet reached India. Under the circumstances it would be worth while considering the manufacture of these in India or at least attempting to renovate the used pads. Ordinarily the pads are rejected after being once used. A few preliminary experiments on renovating these pads, i.e. making new pads out of the cast off ones, have been conducted and there is every hope that it may prove successful. Provided the renovated pads are proved efficient for bacterial filtration, our temporary difficulty in obtaining these pads can be overcome.

In the choice of a filter the second factor to be considered is the quality of the filtrate to be obtained. Judging from the available reports on the use of serum and plasma filtered through Seitz Pilot filters, we find that there are two objections to the use of these filters. One is the adsorption by the filter of some of the important constituents of the plasma and the other is the presence of magnesium ions in the

filtrate due to contact with the Seitz pads. As regards the first objection, it may be pointed out that all filters, other than glass and collodion filters, will adsorb a certain amount of the constituents in the serum, but that is not a very serious objection. As regards the second objection, it is important specially as the presence of magnesium ions in the serum has been held responsible for certain types of post-transfusion complications. These objections naturally raise the question as to whether other types of filters cannot be used with equal efficiency for serum and plasma filtration. It seems worth while investigating the possibility of using collodion or glass filters which approach nearer to the mechanical sieve. At least on theoretical grounds these should prove more satisfactory. They will certainly overcome the two objections raised against Seitz filters to a large extent.

Choice of vessel for holding the fluid to be filtered

In serum work as large quantities need to be filtered, suitable vessels for holding the fluid and feeding it to the filter are required. The ideal vessel for this purpose is one made of glass. Even where positive pressure is used glass bottles that can withstand the pressure would be the best. While some English workers use special aspirator bottles of 10 litres capacity (Greaves *et al.*, 1939), others (Bushby and Whitby, 1941) use copper containers. It is generally agreed that as far as possible it is best not to use metal containers for fear of contaminating the serum. Tinning or enamelling of these containers have been resorted to, to reduce the risk of metallic contamination. In America, they use monel metal receptacles. The only objection to using glass is that it may break easily and may not be able to stand high pressures. If metal containers are used they must be properly tinned or enamelled. They must also be fitted with pressure gauges and air-tight covers which can be held down by wing nuts. All joints should be protected wherever necessary by rubber washers. The one in use at the Institute is made of copper and tinned inside.

Choice of receptacles for receiving and storing filtered serum

As regards the choice of receptacles for collecting the filtered serum here again glass bottles of good quality fitted with air-tight screw caps are the best and they should be carefully chosen. The bottles recommended by M.R.C. are 'U.G.B. medical flat bottles' of 12 ounces capacity, while the R.A.M.C. workers recommend 'pint blood-transfusion bottles'. If bottles of the above specifications are not available in India due to war conditions, suitable substitutes may be used after proper testing. In the Institute, bottles made by Scientific India Glass Co., Calcutta, according to army standard pattern are used. These are of non-alkaline glass, 540 c.cm. capacity and fitted with metal screw caps inlaid with

rubber and having wire suspension hooks to keep the bottles in an inverted position during transfusion.

Choice of mechanical pressure system

As regards a mechanical pressure system all types of filtration do not require this. The gravitational force of the column of fluid in contact with the filter is, in itself, sometimes sufficient to effect complete filtration. Even in such cases the application of pressure renders filtration easier and more rapid. In some cases, due to the high viscosity of the fluid to be filtered and due to the fineness of the pores of the filter, filtration is very slow or is impossible unless pressure is applied. In such cases either positive pressure on the input side of the filter or a negative pressure on the output side can be applied.

For obtaining positive pressure one or other type of air pumps is used. There are in the market several types of such pumps. Mention may be made of the following: (1) The ordinary cycle pump giving up to 5 to 10 lb. pressure. (2) The bigger types of hand pump giving up to 20 lb. pressure. (3) The various types of foot pumps giving up to 40 lb. (4) Gas cylinders containing compressed N_2 giving up to 80 lb. (5) The rotary compression pumps giving up to 100 lb. or 200 lb. To any of these can be fitted a metal drum with a pressure gauge and regulator and from these the desired pressure can be got from one pound upwards.

As for obtaining negative pressure there are various types of exhaust pumps and mention may be made of the following: (1) The ordinary filter pump which can give a vacuum of about 25 mm. of mercury. (2) The hand Geryk pump giving a vacuum of about 0.02 mm. of mercury. (3) Rotary pumps single stage giving a vacuum of about 0.005 mm. of mercury. (4) Rotary pumps double stage giving a vacuum of about 0.00001 mm. of mercury. (5) Diffusion pumps using mercury or oil giving a vacuum up to 0.0000001 mm. of mercury.

In ordinary routine bacteriological work negative pressure pumps of the Geryk type are generally used, but in the filtration of plasma and serum there are certain advantages in using positive pressure, the most important of which are (i) avoidance of frothing of the filtrate, (ii) lesser chance of aerial contamination, and (iii) greater facility for bottling of the filtered product. It is on account of these that positive pressure is used instead of negative pressure. Here it may, however, be pointed out that when positive pressure is used the filtered serum or plasma will contain a larger percentage of dissolved gases.

For obtaining positive pressure one of the compressor types of rotary pumps giving a pressure of 25 lb. or more is recommended. This pump should also be capable of being regulated at will and being maintained without large fluctuations at any required level of

pressure. With such a pump it has been found that rapid filtration of large volumes of plasma or serum can be effected by adopting the following procedure: The filter is started at 5 lb. pressure per sq. inch and the pressure is then gradually raised over a period of an hour to about 9 lb. per sq. inch. Filtration is allowed to proceed at this level until the speed begins to slacken (which is usual in less than 4 hours) and then the pressure is further raised by steps of $\frac{1}{2}$ to 1 lb. up to a maximum of 14 lb. per sq. inch in such a way as to keep the flow approximately constant. At the Institute a 'Kellog' compressor is available. The compressed air, before use, is passed through a bottle containing heavy machine oil and glass beads, then through a sterile filtration 'F' Pasteur-Chamberland candle and finally through a sterile cotton filter 12 inches long.

Filtration room

Apart from choosing the right type of apparatus required for filtration, it is also necessary to have a specially constructed dust- and draft-free room with a concrete floor, where filtration can be conducted under as sterile conditions as possible. This room should be so partitioned as to ensure a lobby, an outer room and an inner room. The lobby is to be kept as clean as possible but no attempt is made to sterilize it. But the outer and inner rooms have to be kept sterile. The lobby is used for changing into sterile garments, the outer sterile room for filtration and the inner sterile room for bottling and capping.

The question as to whether these rooms should be air-conditioned or not, has been raised, particularly in the tropics. In cold countries it is not done as it is not very uncomfortable to work in such closed draft-free rooms. But in the tropics, specially in summer, when 3 to 4 people have to work for a few hours inside these closed chambers, the question assumes a different colour. Although the process of filtration itself is not going to be greatly affected one way or another by air-conditioning, the comfort of the workers would certainly be affected. But it should be remembered that as these rooms have to be kept absolutely draft- and dust-free during filtration, either the air-conditioning will have to be stopped during the operation or the room in which the closed chambers are located will alone be air-conditioned or arrangements will have to be made for cooling the chambers without draft, or using cooled sterile air. At the Institute the air put in is 100 per cent. fresh air which is cooled and filtered through a 'replacement filter' and again through a 'Visco filter'.

Preparation of apparatus for filtration

This may be considered under three heads—(i) sterilization of the apparatus, (ii) sterilization of gowns and caps, and (iii) care of the filtration room.

1. Serum being an ideal medium for the growth of organisms it is imperative that all

apparatus coming in contact with it must be sterile. Sterilization of these is effected by steam at 15 lb. pressure for 40 minutes to one hour. Before sterilization they are properly cleaned and wrapped in muslin or cloth and packed in copper boxes to facilitate handling. During sterilization the cover of the box is raised slightly on one side to allow steam to enter, and it is closed when the autoclave is opened. The sterilization is done a day before filtration. If 48 hours or more elapse, the apparatus should be re-sterilized.

2. As sterile gowns and caps are worn by workers during filtration, these garments are placed in muslin bags and sterilized in the same way as the apparatus.

3. The room in which the serum is filtered must be kept clean and free from dust. It should always be subjected to a thorough preliminary cleaning on the day preceding filtration. Steam at 5 to 10 lb. pressure is blown in from a small autoclave for about 20 minutes to one hour. This produces a dense fog in the room which settles by the following morning. Immediately before filtration the table tops and other flat surfaces are wiped off gently with a sterile towel dampened in 1 per cent phenol or dettol solution. Check is kept on the efficiency of this sterilization by exposing a few blood-agar plates on the table while filtering and bottling are in progress.

Mechanism of filtration

It was stated previously that the chief function of a filter is to intercept particles in suspension or dispersion. Its action, therefore, from a theoretical point of view, may be considered as that of a mechanical sieve, but in reality it is not such a simple mechanical process. Due to the physico-chemical properties of the fluid undergoing filtration and of the material composing the filter the mechanism of filtration is a very complicated one. The theory of filtration may be explained briefly as follows :—

Imagine, as in figure 2, a filter AB with n straight pores, 1, 2, 3, 4, . . . n exposed to a

Fig. 2.

liquid standing above the filter at a height of 'h'. If the liquid is free from suspended particles, the rate of its passage through the filter is given by the classical formula of Poiseuille :—

$$V = \frac{\pi p r^4 t n}{8 L \eta}$$

where 'V' is the volume of liquid of viscosity

η flowing through ' n ' pores of average radius ' r ' and length ' L ' under a pressure head of ' p ' in time ' t '.

But since in a filtration the liquid contains suspended particles which are steadily being deposited on the filter and as a result the pores are steadily getting diminished in size, the above equation indicates the state of things at any given instant of time only.

Furthermore the filtration process in practice does not follow this simple rule because it is never true that the pores of a filter are straight and uniform and usually the form of the filter is such that it does not expose all filter pores to the filtration process to the same extent. Also the physico-chemical properties of the fluid including the suspended particles in it and of the material of which the filter is made influence the process; and particles much smaller in size than the pores of the filter are retained not by virtue of the impenetrability of the pores, but by electrical and other forces brought into action by virtue of the physico-chemical conditions prevailing. Thus, in certain cases even substances in solution may be retained by filters during filtration. It is on account of these reasons that when serum or plasma is filtered not only the bacteria and the suspended particles in it but also some of the important chemical constituents are removed from it.

Factors affecting filtration

From the discussion on the mechanism of filtration it will be clear that several factors other than the size of the filter pore determine whether in any particular instance filtration will be successful or not. The factors affecting filtration according to Rivers (1928) are :—

1. The electrical charge of the fluid undergoing filtration.
2. The electrical charge of the particles suspended in it.
3. The chemical nature of the substances present in the fluid.
4. The concentration in which they are present.
5. The pH of the fluid.
6. Presence or absence of electrolytes, oils, etc.
7. The temperature of the fluid.
8. The electrical charge of the filter.
9. The degree of pressure employed.
10. The duration of filtration.

In the filtration of biological fluids all these factors have got to be considered. In the case of plasma and serum many of the factors pertaining to the fluid to be filtered are known and are fairly constant. We need to be cautious only about (i) the choice of the filter, (ii) the pressure to be used in filtration, and (iii) the duration of filtration. Of these three factors the first two have already been dealt with and only the third remains to be discussed.

The period over which filtration can be allowed to proceed in any particular case is an important matter to decide. In filtration of protein solutions it is well known that the quality of the filtrate varies with time. It may improve with time in certain respects while deteriorating

in other respects. This is true particularly of bacterial filtration of serum and plasma. In the earlier stages due to adsorption by the filter of important constituents the quality is poorer with respect to some of them; but later as the filter gets saturated the quality improves. But in the case of plasma long-continued filtration may lead to early clotting of the filtrate. Again, from the bacteriological point of view, if a filter is used over a long period bacterial growth may take place in the filter and pass by contiguity into the filtrate. On account of these elating influences an optimum time period has to be fixed. In the case of serum and plasma 4 to 6 hours are the upper limit.

Conclusion

By way of conclusion it may be added that filtering is a process fraught with many possibilities of error and although filters of all varieties are guaranteed by the makers no filter can be called absolutely fool-proof. The process is by no means a simple matter and does not depend

entirely on the size of the pores and the amount of pressure applied. Various physico-chemical processes come into play and only through a proper appreciation of these, can successful results be achieved. As such there is need, specially in an important matter like serum filtration for transfusion purposes, for the filtration to be carefully controlled by one who understands the subject, and can avoid its many pitfalls.

SUGGESTIONS FOR FIGHTING LEPROSY IN INDIA

A COMPREHENSIVE report on the leprosy problem in this country has been made by the Committee appointed by the Central Advisory Board of Health to report on leprosy and its control in India.

The census figures, according to the report, give no true picture of the prevalence of leprosy. The 1931 census reported 150,000 cases, but leprosy surveys show the true incidence to be, on an average, about eight times this figure. In some highly infected areas the incidence may be from 5 to 10 per cent of the population surveyed.

While the problem of leprosy is primarily that of the disease in the general population, its presence amongst beggars causes much concern to the public. From the public health standpoint the problem of beggars with leprosy should not be ignored and the opinion that almost all such beggars are not infective is incorrect. The problem is most acute in Calcutta, Madras and Bombay.

The problem, it is suggested, needs to be tackled from several angles. Migration might be minimized by each province providing for its own leprosy cases. A profound change in public opinion is required to prevent the assembly of beggars with leprosy at festivals. There is a great need for a popular movement commanding the support of the public and of Indian religious and charitable organizations to work towards this end and for spending this money in constructive work, such as the provision of leprosy colonies, hospitals and clinics. A large increase in institutions for the isolation of infective patients is required.

An urgent need is the improvement of the teaching in leprosy given in medical schools and colleges; every doctor should know how to diagnose and treat leprosy and what precautionary measures should be taken against its spread. The report also gives a description

of a model provincial leprosy institution and recommends that, in every province where leprosy is common, such an institution should form the hub of anti-leprosy activities.

The Central Advisory Board of Health has commended the report to all Provincial and State Governments in the hope that the various recommendations will materially assist them in the formulation of a co-ordinated policy for anti-leprosy work, with special emphasis on the preventive aspect of the problem.

While emphasizing the need for public co-operation the Board considers that provincial and local authorities should aim at providing for the isolation of those persons who are in an infective stage of the disease. In anti-leprosy propaganda more use should be made of schools and teachers' training institutions. The Board also recommends the establishment of a 'Leprosy Institute of India', the appointment of provincial leprosy officers and amendment of existing legislation for the control of leprosy in the light of the principles recommended in the report.

BLOOD PLASMA FOR AIR-RAID VICTIMS

It is understood that technical difficulties in the preparation of blood plasma for air-raid purposes have been overcome. Equipment is being manufactured locally and what is wanted now is a good response from the public to blood donor services in the Provinces and Indian States.

In a number of centres in India blood plasma is already being prepared. Dry blood plasma manufactured abroad is also being supplied to India.

The manufacture of dry blood plasma requires an elaborate unit which has recently been perfected in the United Kingdom and the U. S. A. Two dry blood plasma plants are on order from abroad and an experimental one is under construction in India.

Public Health Section

PUBLIC HEALTH ORGANIZATION

II. ORGANIZATION OF A MATERNAL AND CHILD HEALTH DEPARTMENT

By JEAN M. ORKNEY, W.M.S.

Director, Maternity and Child Welfare Bureau, Indian Red Cross Society, Red Cross Building, New Delhi

IN the introductory article in this series, attention was called to the important rôle of the maternal and child health services in the general scheme of work of the health department. These services occupy in fact a key position.

In India almost 50 per cent of the total annual deaths occur amongst mothers during pregnancy and childbirth and amongst infants and pre-school children. Deaths are merely a measurable index of health, and the state of health in a community where so many deaths occur, and in the school-going and adult populations arising out of the community cannot but be a matter of grave concern to every health department whose objective is a healthy population. The most effective, and in the long run economical, way of reducing deaths and improving the national health is to concentrate the attack where the incidence of sickness and death is greatest, and in India that is during pregnancy, infancy and early childhood. A further reason for beginning the health campaign at this stage is that much of the work now done by health departments rests on an unsound basis. Epidemic and environmental control measures cannot produce the maximum potential benefit in a population physically unfit. But there is yet a more fundamental reason for establishing a maternal and child health department. The maintenance of health and the prevention of disease are personal matters and depend on the intelligent co-operation of the individual. Intelligent co-operation can only be secured by education, by getting across to the individual an understanding of the scientific principles on which health is based, and by persuading him to apply these principles to his daily life and to use all the services provided by the medical and health and other social departments which will help him to this end.

The most educable section of the community is the school population but because the health of the school child may already be impaired beyond complete recovery by parental ignorance and mismanagement the care must begin at an earlier stage by the concurrent education of the parents in the upbringing of their children. The best agent we know for this purpose is the public health nurse or health visitor, and because parents will often do for their children what they will not do for themselves the most effective method of gaining entry into the home, of making contacts and influencing the life of the family is a visit to a new-born baby.

Contact can also be made through the delivery service. Assistance at childbirth is something which the people understand and want, and confidence engendered by this means prepares the way for the building up of many other public health services for the control of tuberculosis, leprosy, venereal disease, domestic and environmental hygiene. The child cannot remain healthy if malaria or fly breeding is prevalent, if attention is not paid to nutrition and horticulture, if housing, domestic and community refuse disposal are bad, if milk and water supplies are infected and unless social, economic and family relationship problems are tackled. All these matters therefore come within the purview of the health visitor attached to the maternal and child health department. The maternal and child health services in fact touch on and influence every activity of the health department, hence their basic importance.

A multitude of nutritional defects and common disorders of the respiratory and digestive systems, blindness, deafness and other defects and diseases which crowd the dispensaries and hospital out-patients, have their origin in infancy and childhood and can only be controlled by educating the parents in the care of their children. School and adult health are of importance in education, industry and society. The maternal and child health services are one of the main contributory channels through which the work of all these departments can be facilitated and improved.

The question which has now to be considered is, what machinery is necessary for the effective carrying out of this education for life and health? The first essentials are the establishment of a maternal and child health section in the public health department and the appointment of a full-time medical officer to organize and direct the work. To some this may sound like putting the cart before the horse. If there are no services and no staff to direct, what is the use of a director? The answer is that where there is no agency to focus attention on the need for maternal and child health, to enlighten local authorities and stimulate them to establish schemes the work will either not develop or, if developed, the chances are that it will be haphazard, limited, inco-ordinated and unrelated to the most urgent needs of the community. Planning is essential and to be effective the planning must be intelligent, that is, it must be based on knowledge. The first duty of the maternal and child health department therefore is to collate all the available data regarding relevant vital statistics and the facilities and staff provided for pre-natal care, institutional and domiciliary midwifery, infant and child care including the hospital services for sick children, the various ancillary services such as crèches,

nursery schools, orphanages; the existing legislation and the facilities for training the necessary staff of doctors, health visitors and midwives. The data will provide an indication of the *extent* of the problem and the provision made but it will have to be supplemented by an evaluation of the *quality* of the services and this can only be done by personal investigation in the field. A detailed survey of a whole province on these lines is not a feasible proposition. A limited and superficial survey of selected areas can, however, provide sufficient basis for the formulation of principles and for the setting up of experimental schemes.

Several types of scheme must be tried out to suit varying local conditions, local and individual financial resources, the local facilities and staff available and special health problems. In urban areas a fairly complete scheme for maternal and child health should be possible; in the village in the first instance it may be possible to do nothing more than to train the local *dai* to recognize abnormalities in the pre-natal period and to teach her asepsis and non-interference. A further step would be to teach her the elementary principles of malaria or hookworm control if these are the most serious problems or to carry out an 'eat unpolished rice' or 'boil your water' campaign if this seems the most effective means of reducing sickness and deaths. The schemes may be carried out by local authorities, by voluntary agencies or by the combined effort of both.

Good work is never static and the maternal and child health department will find never-ending occupation in analysing and drawing deductions from statistical data, in studying the defects, failures and successes of the experimental schemes, in evaluating the quality and quantity of the work, in planning extensions and developments and in revising the training of the staff in the light of experience.

As soon as a policy has been formulated the next duty of the department is to translate it into action. To effect this, much propaganda work will have to be done amongst the general population and more particularly amongst local authorities and voluntary organizations who are responsible for or interested in health, and amongst the medical profession, whose interest and co-operation must be secured. Conferences may have to be held and post-graduate courses arranged for the doctors taking part in the scheme. The establishment of a technical advisory committee is a useful means of maintaining the support of the medical profession and of voluntary organizations while at the same time providing the local authorities with skilled advice. One of the most effective forms of propaganda is the demonstration of an actual piece of work, and at least one urban and one rural model unit should be established in each province to be used for the practical training of the staff of doctors, public health nurses, midwives and other workers and for the

enlightenment of local administrators and voluntary workers. A demonstration unit is also extremely valuable for research work and experimentation with new methods.

Local authorities have *power* to provide for maternal and child health services and when public health acts become universal provision may become a statutory obligation, but even this will be insufficient to secure development along sound lines. If the services are to be of a high standard and basically more or less uniform, central control is desirable. Control can be exercised by requiring local schemes to be submitted for approval to the maternal and child health department before any expenditure is incurred and by supervising and advising on the work after it is undertaken. But local resources are small and if headway is to be made the advice of the department must be backed up by grants-in-aid from the central revenues. The administration of these grants will be a function of the maternal and child health department.

Other functions of the department are indicated in the diagram on the next page.

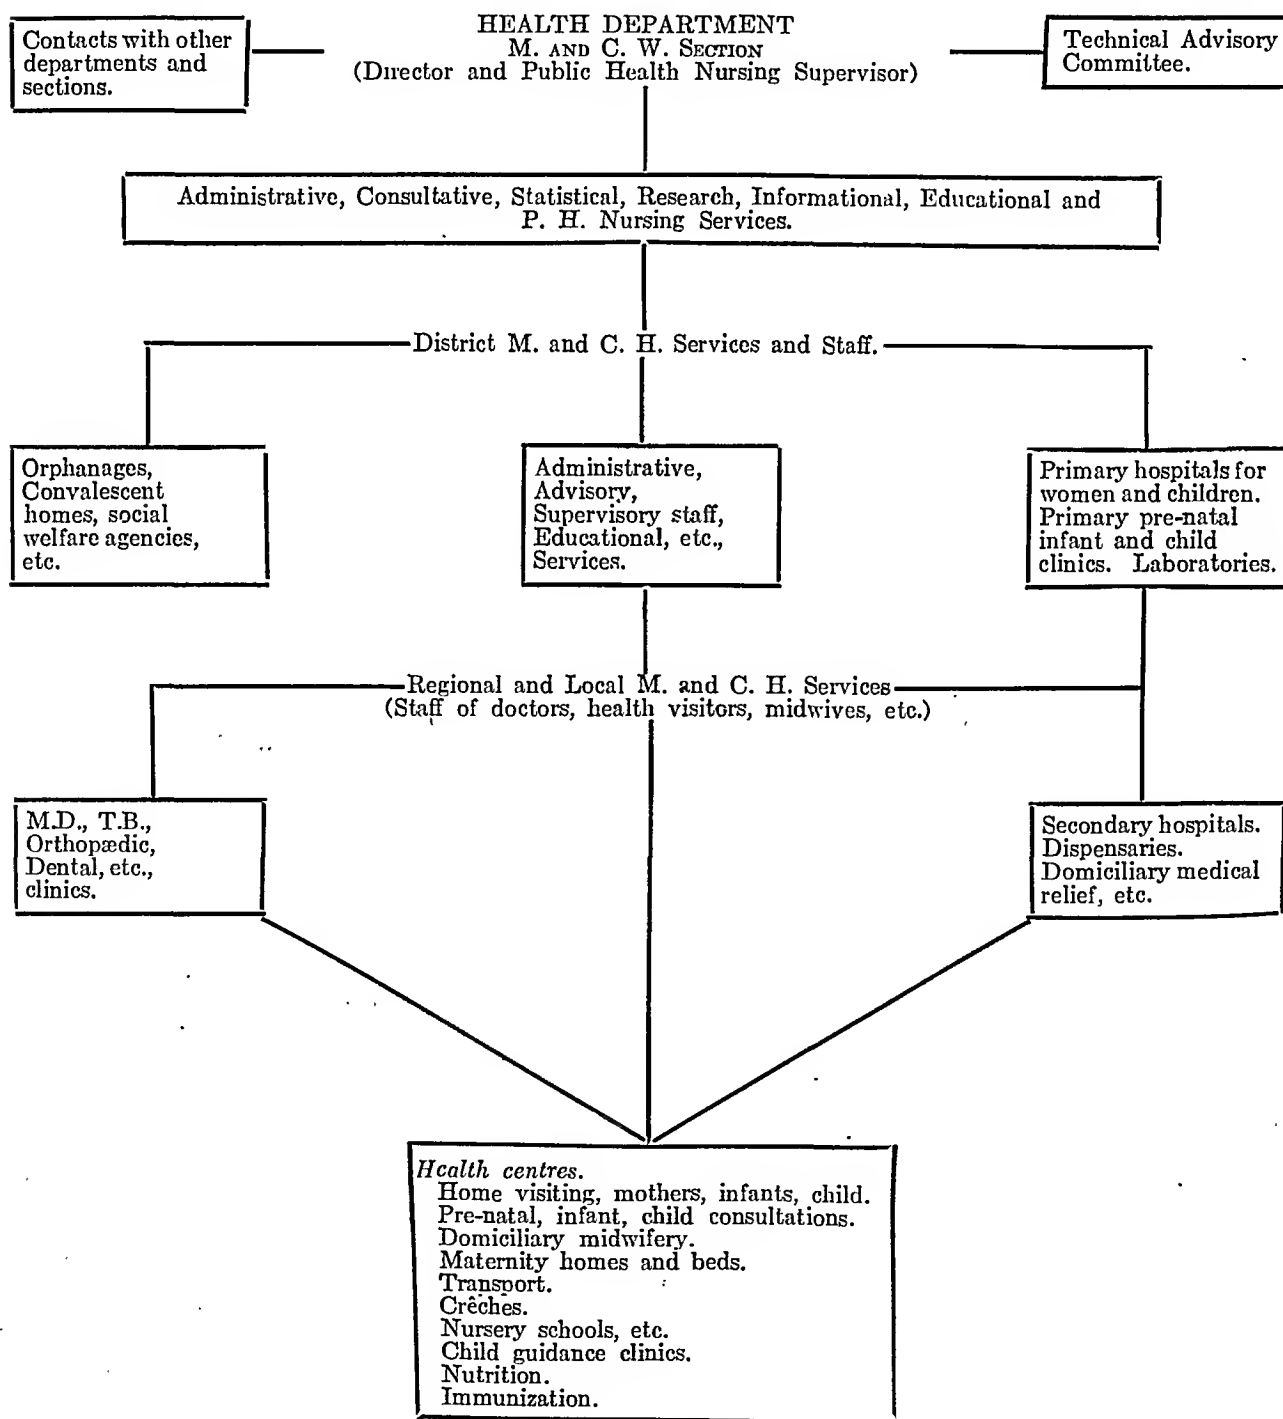

As the work develops additional administrative medical officers one to each district will be required for the adequate supervision and direction of the district maternal and child health services. These officers require to have special technical qualifications, high administrative and executive ability and a sound comprehension and experience of the work. To ensure the appointment of competent officers good conditions of service, security of tenure and opportunities for post-graduate study, these officers should be on the cadre of the provincial government. The functions of these officers are similar to those of the director.

In the maternal and child health field the divorce of curative and preventive medicine is disastrous. The expectant mother cannot be under one service while well and another if she develops any abnormality. Continuity of care is lost if her pre-natal care is given by one staff and for her confinement she enters an institution with which she had few if any contacts. The marasmic child who develops pneumonia cannot be under one service for instruction about feeding while another gives him medicine for his sickness, each in a water-tight compartment. Co-ordination between all the services must be secured and the district medical officer for maternal and child health should supervise not only the work done in and from health centres but preferably also in hospitals for women and children, in maternity homes, and by the domiciliary midwifery service, in fact all the health and medical services for women and children whether voluntary or official in the district. If unified control proves impracticable in the initial stages, close and harmonious contacts and co-operation between all the agencies and bodies concerned must be secured by the establishment of a district advisory committee representing all interests.

The district medical officer for maternal and child health should be responsible for planning, developing and supervising the district programme and for the proper co-ordination of all the services. It is not possible within the scope of this article to deal with the hospital, dispensary, maternity homes and health centre policy for a district. Further experimentation is necessary in this field before a definite policy can be laid down but the principle of planning on a regional basis is gaining wide acceptance as the soundest method of organization. In the maternal and child health field the smallest units, namely, welfare centres, women's dispensaries, the domiciliary medical and midwifery services,

maternity homes, anti-venereal and other special clinics, would be the individual or joint responsibility of one or more local health authorities according to the population and area; at a higher level and on a wider basis would come regional, general and maternity hospitals, and more elaborate health centres and laboratories; on a district basis well-equipped general and special hospitals and institutions; and at the centre the teaching hospitals, demonstration and research units and well-equipped laboratories.

The basic maternal and child health services to be provided by the local health authorities are: (1) Pre-natal—including home visiting, hospital and health centre clinics, pre-natal beds in

hospitals. (2) Natal—including institutional and domiciliary midwifery services. (3) Post-natal—including home visiting, infant, child and post-natal health clinics, hospital beds for sick children, crèches, and until these are taken over by the education department, nursery schools. The administrative details may vary from one locality to another. The consultation health clinics may be conducted by special full-time medical officers or staffed from a panel of general practitioners, or by buying the part-time services of obstetricians and pædiatricians from teaching or other hospitals. The actual organization is not so basically important as the technical qualifications, experience, ability and outlook of the officers employed. Apart from the medical officers who may be part time or full time, a full-time staff of midwives and health visitors is required and clerical assistance will be necessary in all but the smallest schemes.

The fundamental aim of the maternal and child health services is the education of the parents in the nature and nurture of their children and incidentally also for better citizenship and a fuller life. For reasons explained earlier the most vital factor in the attainment of the objective is the health visitor or public health nurse. The aspect of the maternal and child health services likely to have the greatest popular appeal is the delivery service, but it must be remembered that no matter how good this is it will fail to achieve success if the mother is not made physically fit beforehand, nor is it logical or economical to provide for the safe delivery of the infant if it is born in a debilitated condition or if it is allowed to die within the next few months or years from the accumulated effects of maternal mismanagement. The public health nurse is therefore an indispensable factor in the services, and an essential feature in the central maternal and child health department is a public health nursing section in charge of a director or supervisor of public health nurses and of midwives. District supervisors will become necessary as more health visitors and midwives are employed if the work is to be properly supervised, if the education of the staff in new techniques and for new duties is to be accomplished, and if conditions of service of the staff including freedom from exploitation are to be safeguarded and reasonable security of tenure of office secured.

A technical advisory committee at headquarters composed of qualified experts particularly in the field of obstetrics and pædiatrics, public health nursing and social work while not essential has considerable value. The medical profession is more likely to back any proposals known to be sponsored by leading technical experts. Further the expressed opinion of experts, viewing the services from a different angle and in the light of different experience, can be a valuable corrective to any tendency towards bias or narrowness of outlook, in the planning of policies, programmes and methods.

BENGAL PUBLIC HEALTH REPORT FOR THE YEAR 1940. PUBLIC HEALTH DEPARTMENT, GOVERNMENT OF BENGAL

Vital statistics.—There were 1,681,846 births registered in the year as against 1,597,651 in the preceding year. The birth rate was 33.7 per mille being 5.3 per cent above the rate of 1939. There were 1,111,082 deaths as compared with 1,090,530 in the previous year, the death rate being 22.3 per mille and 1.8 per cent above that of the preceding year. Calcutta was the solitary district in which deaths exceeded births.

Infantile and maternal mortality.—The total number of infantile deaths was 267,894 compared to 234,301 in 1939. It represented 24.1 per cent of the total mortality in the province. The number of maternal deaths was 15,758 as against 15,792 in the preceding year.

Three new maternity and child welfare centres were opened; altogether 18 such centres functioned during the year under review. The Model Health Unit established by Government at Singur 1939 provided *inter alia* facilities for institutional service both for pre-natal care and midwifery services. The annual grant for the training of indigenous *dais* was distributed among the different local bodies and other organizations as usual.

Cholera.—A remarkable feature was that the mortality from cholera was the lowest on record during the past fifty years. There were 21,743 deaths from this disease with a death rate of 0.4 per mille as against 33,221 deaths in 1939 with a death rate of 0.7 per mille—a decrease of 34.0 per cent over the figures of 1939. The usual preventive measures were taken in combating this disease.

Smallpox.—The mortality from this disease showed a marked decline, the total number of deaths being 5,608 against 7,029 in the preceding year, with a death rate of 0.11 and 0.14 per mille respectively. The mortality thus fell by 20 and 64 per cent compared with the year 1939 and the previous quinquennium respectively.

The number of persons vaccinated in 1940 was 8,476,920 against 7,925,382 in 1939. The increase is a happy sign which might have been due to the greater attention paid by the local authorities in the matter of vaccination than in the previous years.

Malaria.—51.5 per cent of the total mortality from fevers was due to malaria, which again accounted for 33.3 per cent of the total provincial mortality during the year, the corresponding percentages in 1939 being 49.6 and 31.3 respectively. There were 369,448 deaths from malaria in 1940 against 341,321 in 1939, representing an increase of 8.2 per cent. The death rate correspondingly went up from 6.8 to 7.4 per mille in the year under report.

Kala-azar.—This disease was responsible for 15,453 deaths with a death rate of 0.31 per mille as against 17,056 and 0.34 respectively in 1939. The highest mortality from the disease was recorded in the rural areas of Dinajpur. The special anti-kala-azar scheme, inaugurated in the district of Darjeeling in December 1937, continued to work satisfactorily during the year under review.

Special anti-malaria measures.—The survey and control measures in connection with the campaign against *Anopheles ludlowii* were carried out satisfactorily in the Salt Lake area, Budge-Budge and the suburban areas with the co-operation of the Corporation of Calcutta and other local authorities and interests concerned.

The special anti-malaria scheme for the town of Jessore and its surrounding rural areas undertaken in the year 1939 was continued.

Special investigation was taken by the transfer of the field malaria research laboratory to Netrakona (Mymensingh) and also to Kalimpong, Darjeeling district, in order to find out the local vectors and to investigate the various aetiological factors responsible for the spread of malaria.

Two anti-malaria schemes, viz., the Gopalganj drainage scheme in the district of Malda and the Nadana Khal re-excavation scheme in the district of

Noakhali, were sanctioned by Government during the year and a grant equivalent to half of the total estimated cost of these two schemes was made by Government, the other half being met by the district boards concerned.

A malaria engineer was appointed by Government in the public health department to assist local bodies in drawing up and executing anti-malaria schemes of an engineering type.

Pneumonia accounted for 44,967 deaths against 47,888 in the preceding year, showing a reduction of 6.1 per cent.

Pulmonary tuberculosis took a toll of 12,363 lives against 12,422 in 1939, the death rates being the same in both the years, viz., 0.25 per mille.

A comprehensive scheme for the prevention and control of tuberculosis in the province, in co-operation with local bodies and voluntary organizations, was formulated.

The Bengal tuberculosis association rendered valuable service by publicity and propaganda work in the province with the usual grant from Government and maintained six dispensaries in Calcutta and one in Howrah. The association also organized post-graduate training courses on tuberculosis in Calcutta and assisted in the training of the students for the diploma of public health and the health officers deputed by the Government of Bengal.

Enteric fever was responsible for 7,875 deaths as against 8,290 in 1939.

Influenza.—There were 2,127 deaths from influenza compared to 2,467 in the preceding year.

Cerebro-spinal fever accounted for 1,378 deaths against 1,721 in 1939, showing a marked decline in mortality from the disease.

Typhus fever.—The number of deaths from this disease further increased from 4,443 in 1939 to 5,183 in

the year under report. Calcutta was, however, entirely immune from the disease.

Dysentery and diarrhoea.—These diseases respectively took a toll of 24,730 and 20,692 lives as against 27,301 and 27,152 in 1939.

Leprosy.—The number of recorded deaths from leprosy was 1,304 against 1,517 in 1939, representing a reduction of 14 per cent. The largest number of deaths occurred in the district of Bankura. With a view to ascertaining the incidence of leprosy and suggesting measures for the control of the disease, a number of sample leprosy surveys were carried out by the British Empire Leprosy Relief Association.

Fairs and festivals.—The usual medical and sanitary arrangements were made for the welfare of the pilgrims and the prevention of outbreaks of infectious diseases in the chief *melas* in the province. The St. John Ambulance Corps rendered valuable assistance at the Ganga Sagar *mela*. It is gratifying to observe that no deaths from either cholera or smallpox occurred at the *melas* during the year.

School hygiene.—During the year 10,844 boys in 41 schools in Calcutta, 8,363 students in 125 schools in 26 municipalities and 1,750 boys and 72 girls in 54 schools in the rural areas were medically examined. The sanitary inspectors in charge of the rural public health circles also examined 207,988 pupils in 5,800 schools in the rural areas.

Health propaganda.—A weekly public health bulletin was published throughout the year and posters, charts, models, etc., relating to public health propaganda were prepared and distributed as usual.

Miscellaneous.—The normal activities of the department were maintained and their scope was widened in certain respects. Grants-in-aid were made to the local bodies as usual in order to enable them to make provision for health welfare services.

Current Topics

New Rules for Asepsis

(From the *British Medical Journal*, Vol. II, 15th November, 1941, p. 698)

It has become abundantly clear in recent times that 'hospital infection' is by no means a thing of the past. It must always have existed, although remaining mostly unrecognized, in 'septic' wards, but it has now become a major problem in hospitals dealing extensively with casualties. The detailed study of wound flora, and in particular the typing of hæmolytic streptococci, have made it possible to trace the spread of infection from case to case; that this is a frequent occurrence and may involve considerable numbers of patients was shown by the investigations of A. A. Miles and others published in this journal last year. The burden of their argument was that the many precautions taken in the operating theatre do not always extend to ward work, where various faults in technique may cause avoidable wound infections. Few surgeons know everything that goes on in their wards, and many details connected with the sterilization of various materials and the care of wounds are left to the discretion of the nursing staff. It is with no disrespect to the nursing profession that some of their methods have been condemned, since they may reasonably ask that instructions for the proper conduct of such work should be made available; nor are they, in fact, by any means wholly responsible for the defects in technique which have been brought to light. There is need, in fact, for a thorough review of aseptic technique in the light of modern knowledge. So far as it concerns ward work, and as the direct outcome of recent research, this need has been met by the publication of *The Prevention of Hospital Infection of Wounds*, a memorandum sponsored by the War Wounds Committee of the Medical Research

Council and the Committee of London Sector Pathologists. This furnishes in simple language, full instructions for the conduct of dressings, the sterilization of all ward apparatus and materials, and other precautions necessary to safeguard wounds from extraneous infection. It should be widely studied, and may well serve as the basis for generally accepted hospital rules or, indeed, be adopted *in toto* for that purpose.

The chief instructions for avoiding contamination by dust and by droplet infection are already widely observed. Apart from the oiling of floors, it is laid down that sweeping and bed-making should be finished an hour before dressings are begun, and that during the dressing itself bedclothes should be moved gently. Closed plasters are a prolific source of dangerously infected dust, and should be opened only in a special room. A pattern is given for a simple and effective mask, and masking of the staff and silence on the part of other patients are enjoined during the conduct of dressings. The method of doing dressings requires two people, and may be considered too elaborate for universal employment; on the other hand, it is carefully thought out, and every step has its reason. The operator is not required to 'scrub up', but merely to wash his hands; he works entirely with forceps, and should not touch the wound and the surrounding skin, the inner dressing, or any sterile material. It should be noted that this technique demands a generous supply of forceps and certain utensils; a shortage in this direction is the most easily remedied source of difficulty and consequently of danger. Some may wish to vary these instructions, but if so they will do well to bear in mind their underlying principle: that the hand should never touch either the wound or anything supposed to be sterile. The observation of this single rule would perhaps do more than anything else to prevent avoidable wound infections. It is also pointed out that

contamination of wounds may take place when they are handled by others than the ordinary surgical staff; precautions must therefore be taken when calling in the services of the radiologist, masseuse, or physio-therapist.

It is now notorious that infection has frequently been transmitted by utensils and other materials which are believed to have been sterilized but have not. Baths of various kinds have played a sinister part in this connection: a full-sized bath must be treated chemically, and rubbing over with strong lysol is recommended. Arm baths must, if necessary, be treated in the same way, but it is far better to boil them; another strong injunction given is that every ward should possess a sterilizer of such a size that it can contain all bowls, dishes, and other such utensils which require sterilization. Heat is preferable to chemical disinfection whenever it is feasible, and full instructions are given for the proper use of the autoclave; four alternative methods are offered for the sterilization of syringes by heat. There is nevertheless an appendix on chemical disinfectants, dealing only with the three principal types of coal-tar origin, with instructions for their specific uses, and the suggestion that some such instructions should be posted up in every ward. The intelligent co-operation of the nursing staff in all these matters can be secured by teaching them elementary bacteriology from this point of view, preferably with simple practical demonstrations. It is finally suggested that a large hospital needs a senior officer whose chief business it is to supervise the control of infection, both by teaching and by seeing that these rules continue to be observed. We commend this memorandum very strongly to surgical staffs, with the suggestion that they either adopt its rules or make better ones if they can.

Pleural Effusions

Their Causes, Diagnosis and Treatment

By R. ELLIS, M.D., M.R.C.P.

(From the *Medical Press and Circular*, Vol. CCV, 30th April, 1941, p. 356)

THE presence of fluid in the pleural cavity is always a cause for concern, if not actual anxiety, to the medical practitioner. The preceding history will often prove the correct guide to determining the nature of the effusion whether it be a transudate or an exudate.

Transudates, or passive effusions, are to be expected in the presence of heart failure, acute or chronic nephritis, intra-thoracic neoplasms, in the terminal stages of various debilitating diseases, and occasionally with suppuration below the diaphragm. Active effusions, or exudates, occur in the presence of acute inflammation. This may be in the lungs and pleura, as in pneumonia. The inflammation may spread to the thorax from without, as in subphrenic abscess and septicæmia, or the inflammation may be of a more generalized character as in acute rheumatism, though here the fluid is never purulent. Of chronic inflammatory lesions causing pleural effusion, tuberculosis is the one most commonly met with in this country.

PHYSICAL SIGNS OF PLEURAL EFFUSION

The characteristics of pleural effusion are the absence of tactile fremitus, wooden dullness on percussion, absent or diminished breath sounds, ægophony at the upper border of the fluid, and displacement of the apex beat of the heart. In the early stage, or in 'dry' pleurisy, a friction rub may be the only sign. With a moderate or large effusion the affected side of the chest appears to be flattened in full inspiration, whilst in expiration it appears to bulge.

The dullness is partly due to the fluid and partly to the compression of the lung. It is found earliest at the base posteriorly and may reach as high as the clavicle, and include or extend beyond the sternum. On the right it merges imperceptibly into the liver dullness.

On the left Traube's semilunar area of resonance is rarely obliterated except by very large effusions. Moveable dullness occurs only with pneumothorax. Ellis's S-shaped line, Grocco's triangle of paravertebral dullness, and Litten's diaphragm sign can also be demonstrated. A valuable sign is displacement of the heart towards the opposite side. In neoplasm of the lung and collapse of the lung without effusion the heart is drawn to the side of the lesion. Skodaic resonance is usually quoted as a sign of effusion, but it occurs also with pneumonia, though to a less marked degree.

Auscultation in the early stage of pleurisy reveals a friction rub, usually of a creaking or leathery type, occurring both with inspiration and expiration. It is unaffected by coughing, but disappears as effusion develops. Occasionally fine crepitations can be heard, as in pneumonia.

With effusion the breath sounds become weak or absent over the dull area. In children especially they may be bronchial in type. Above the dull area the sounds are harsh, loud and often tubular, and may be associated with râles.

Vocal resonance is usually absent or diminished.

Ægophony, the nasal twang or goat-like bleating of the transmitted voice sounds, is quite commonly heard at the upper level of dullness or at the angle of the scapula. The diminution of the breath sounds is not due to the fluid as such, but depends on compression of the bronchi, fluid being a good conductor of sound.

Radiography is often helpful as an aid to diagnosis, but it is as reliable in demonstrating the presence of fluid as in so many other pulmonary conditions. For instance, thickened pleura will give a shadow very like that of a thin layer of fluid.

Having decided, on the history and physical signs, that fluid is present, it is usually safe to explore the chest, though it is not always necessary to aspirate any great quantity immediately. The treatment to be adopted depends on the nature of the fluid, which may be clear or turbid, purulent, hæmorrhagic or opalescent. Hæmorrhagic effusions (not to be confused with hæmo-thorax) occur in tuberculosis, from the rupture of newly formed vessels in the inflamed pleura; in neoplasms of the lung, which is the commonest cause; and very rarely in association with chronic nephritis, cirrhosis of the liver and severe fevers. Any effusion which has been aspirated recently may be blood-stained from the rupture of vessels, either by the aspirating needle or as a result of too vigorous aspiration. When trauma results from introducing the needle, only the first sample of fluid will be heavily blood-stained and the amount of blood will decrease as the aspiration proceeds. Should a grossly enlarged *left* auricle be mistaken for an effusion in the *right* pleural sac and exploration or aspiration be attempted, then pure blood will be withdrawn easily, in contradistinction to the difficulty experienced when the needle enters lung and a little bloody fluid is obtained.

Opalescent exudates are found most frequently in nephritis. Sometimes they are found in association with neoplasms, or after repeated aspiration. The lipid which causes the opalescence is soluble in alcohol but not in ether. Such fluids are therefore pseudochylous. True chylous fluid is very rare, occurring only with lesions of the thoracic duct or infections with filaria. Pneumococcal fluids, at the time of exploration, are usually creamy pus, containing much fibrin, though clear, or only faintly turbid fluid containing pneumococci and a few polymorphonuclear leucocytes may be found earlier. Fœtid fluids are most likely to be found where there is a communication between a bronchus and the pleura, in bronchiectasis, gangrene of the lung and with infections of the colon group of organisms.

Cytology.—Unless one is very sure of the underlying pathology it is advisable to examine any fluid obtained on exploration. Small lymphocytes will be the prevailing cells in chronic inflammatory lesions. These are almost always tuberculous, and the fluid is sterile. Tubercle bacilli are rarely found. To prove the nature of the infection it is necessary to resort to animal inoculation.

Polymorphonuclear leucocytes will be found in acute infections with pyogenic organisms.

Endothelial cells are principally found in transudates, especially those due to neoplasms, when the cells may show mitosis. In transudates it frequently happens that there are no cells to be found.

Bacteriology.—Almost any pyogenic organism may be found in purulent exudates. The commonest is the pneumococcus and with it the prognosis is usually good. The next in order of frequency are the streptococci. Here the prognosis is less favourable, and the condition requires more careful handling. Staphylococci and other pyogenic organisms are less frequent causes of pleural exudates. Tubercle bacilli, although a common cause of pleural effusions, are rarely found in the fluid, whether it be serous or thick and caseous. Organisms are rarely found in serous effusions, except in the early stages of fluids which eventually become purulent.

Course.—The course of pleural effusions is variable, though on the whole they tend to be absorbed provided the effusion is not so large as to compress vessels. Absorption is fairly rapid in those cases of pleurisy following a 'chill', and in the so-called idiopathic types. The fever subsides by lysis in about seven to ten days, and the fluid level begins to decrease steadily after this. The actual time for absorption will depend on the amount of fluid present. With large effusions extending above the level of the fourth rib in front absorption is slow until some of the fluid is aspirated. Tuberculous effusions tend to persist unchanged for long periods. When an effusion recurs after aspiration it is probable that there is a neoplasm of the lung or pleura. With permanently collapsed or carnified lung, with tight adhesions or persistent pleural irritation, an effusion is likely to persist or recur after repeated aspiration. Two factors suggesting persistent effusion are densely thickened pleura and collapsed lung.

The earliest sign that absorption is taking place is the reduction in the degree of displacement of the heart. Later there is a return of breath sounds and tactile fremitus. It rarely happens that there is a return of a friction rub since adhesions form too quickly. When absorption is unusually rapid the chest wall falls in, returning only slowly or incompletely to the normal position owing to adhesions.

Treatment.—Treatment will depend on the cause of the effusion and its nature. Therefore, the preliminary to treatment is to withdraw a sample of the fluid for inspection. For this a 10 c.c. or 20 c.c. syringe is necessary, together with a needle suited to the development of the patient. In children and those with a thin chest wall a medium-bore hypodermic needle will suffice, otherwise a serum needle will be required. Should there be reason to suspect pus, a larger bore needle will be necessary if the exploration is to be successful. The use of the local anæsthetic is optional, but when a thick needle is used then an anæsthetic is preferable. The usual site for exploring is in the eighth or ninth interspace in the line of the inferior angle of the scapula though if the physical signs point to a loculated effusion the site will be determined by the position of the fluid. It is not advisable to withdraw the piston of the syringe until one is sure that the thickness of the chest wall has been penetrated, or blood may be obtained. An inter-lobe effusion may be reached by instructing the patient to place the hand of the affected side on the opposite shoulder. Then follow the line of the vertebral edge of the scapula to the axilla and explore in the eighth or ninth space in the mid-axillary line. This only applies to the space between the upper and lower lobes, not to the right middle lobe. Having found fluid, do not aspirate more than one syringe full with this apparatus or air will enter the pleural cavity. This may not be very important with a simple serous effusion, but should the fluid already be infected there is grave risk of a widespread empyema with unfortunate results.

Indications for aspiration.—Briefly, these are:—

Fluid large in amount (above the 4th rib in front).

Fluid increasing.

Embarrassment of respiration or pulse.

Fluid not absorbing after at least two weeks.
Fluid infected or already purulent.

Having decided that aspiration is necessary, the procedure is similar to that for exploration except that a local anæsthetic is essential. First infiltrate the skin freely, then inject all the tissues down to, and including, the pleura. If a really large bore needle is to be used, its passage will be greatly facilitated by first making a small incision through the skin. Whatever apparatus is used for aspiration, the fluid should be withdrawn slowly. There are several instruments available for the purpose. Large capacity syringes with two-way taps have the disadvantage of high resistance between the piston and barrel wall, and the effort necessary to pull out the piston often leads to displacement of the needle, either from the syringe itself or in the chest wall. There is still much to be said in favour of the old-established Potain's aspirator with its flexible rubber connections and locking joints. Care must be taken to be sure that the pump has lowered the pressure in the suction bottle and not raised it. Burell's bottle is perhaps the simplest and easiest aspirator to use since it has no moving parts to wear and the fluid cannot be withdrawn rapidly. However, the apparatus is one for personal choice. The operation must be carried out with the strictest regard to asepsis, and should be stopped if the aspiration causes much coughing, distress or signs of collapse. At the conclusion the needle track should be obliterated as far as possible by gently squeezing up the skin and moving the superficial tissues in several directions. Finally, seal the puncture with a collodion dressing. Where it is necessary to remove several pints of sterile fluid, air should be admitted, as in filling a pneumothorax, to replace the fluid withdrawn. Only in this way can a large volume be removed without causing serious discomfort to the patient or shifting the heart and mediastinum too rapidly. Since most serous effusions tend to be absorbed, it is rarely necessary to aspirate large quantities of fluid except as an aid to diagnosis, as, for example, in suspected bronchial or mediastinal neoplasm. In such circumstances the fluid obscures the main picture on x-ray examination. Not until the bulk of the fluid has been aspirated and replaced with air can a useful x-ray picture be taken.

Tuberculous effusions are best left alone unless by their bulk they are causing mechanical difficulties.

Transudates, as in congestive heart failure and nephritis, will only need aspiration when the effusion is large and a satisfactory diuresis cannot be obtained by the usual therapeutic measures. The effusions associated with pulmonary neoplasms often call for repeated aspiration since they are usually large, recur rapidly, and tend to cause mechanical embarrassment of the heart and opposite lung.

Empyema.—Aspiration in empyema is frequently an aid to recovery. In streptococcal empyema repeated aspiration is necessary before undertaking rib resection, since the pus is poor in fibrin and the cavity does not become shut off from the main pleura until the pus thickens. Open drainage before this takes place would result in pyo-pneumothorax with chronic empyema and an inexpandable lung bound down with dense layers of fibrin. Pneumococcal empyema is never made worse by aspiration. Rather the reverse, for it tends to reduce the ultimate size of the cavity. Occasionally repeated aspiration is the only treatment necessary. Of recent years there has been a tendency to treat empyema by continuous aspiration. In selected cases the results are excellent. At the worst, it will tide a very ill patient over the severe stages of toxæmia and allow a more radical operation to be performed later without risk. Sulphapyridine (M.&B. 693) will not prevent empyema, neither, in my experience, will it cure it. Great care should be taken in giving more of this potent drug to a patient who has already had the full course for his pneumonia. The risk of damage to the blood-forming tissues cannot be too strongly stressed.

Tuberculous empyema should always be treated by aspiration; never by open drainage.

After treatment.—Subsequent to aspiration or other form of drainage, whether the effusion be serous or purulent, the lung should be assisted to expand by breathing exercises. Patients who are too feeble to perform such exercises early in convalescence may be given frequent inhalations of carbon dioxide with oxygen for a few minutes at a time. This acts through the respiratory centre, causing full excursions of the diaphragm and chest wall. Later, blow bottles may be used and, finally, exercises in the gymnasium.

All cases in which the prevailing cell in the fluid is the small lymphocyte should be regarded as tuberculous and given the benefit of sanatorium treatment. Where there is no positive evidence of disease in the lungs, as shown by x-ray, the prognosis is good. Without sanatorium treatment, the prognosis is only fair or sometimes even bad.

Eye Injuries in Warfare

By L. H. SAVIN, M.D., M.S., M.R.C.P., F.R.C.S.

(From the *Medical Press and Circular*, Vol. CCIV, 16th October, 1940, p. 298)

THIS article is mainly based on observation of a series of ophthalmic war injuries treated at Horton Hospital. Although the incidence of various types of injury may probably alter with variable war conditions, general principles of treatment are not likely to change radically—in fact, they have been applied for years in peace time to industrial eye injuries.

Eye injuries seen have been mostly lacerations, injuries by small foreign bodies and missiles, contusion injuries by blunt objects and explosive blast, and burns. Sequelæ of injuries, such as contracted sockets, cicatricial ectropion and entropion, and symblepharon, are beginning to appear. Ophthalmic injuries from war gases have not yet been seen at Horton, nor, fortunately, have we yet had cases of sympathetic ophthalmia.

Lacerations have been chiefly of lids. There seems to be a tendency among general surgeons to treat these injuries too drastically. Blood supply in the lids is so good that the extensive wound excisions necessary elsewhere in the body are not necessary there. Lid lacerations can be cleaned up and resutured without sacrifice of injured tissue, and there will seldom be sloughing. It is important that the lid margins shall be sewn in proper alignment, as irregularities greatly distress a sensitive patient. 'To think that this should happen to the best-looking corporal in the regiment', as one patient sadly remarked. The fact that he was badly smashed up in many other parts of the body did not seem to worry him.

In suturing together lid margins care must also be taken that the lashes are not allowed to turn in towards the globe. One of our patients had had a cut at right angles to the lid margin, and suturing had been roughly performed so that the lashes rubbed the cornea over a length of about 3 mm. Electrolysis was not practicable, as too many lashes were involved, but the condition was readily rectified by a plastic operation. The lid was first split longitudinally by an incision along the inter-marginal grey line of the lid-edge. A wedge-shaped piece was excised from the anterior flap, the affected lashes being along the base of the wedge. A similar-shaped wedge of the tissue was excised from the posterior flap of lid farther along, so that the two wedges did not coincide antero-posteriorly. The lid was reconstructed by resuturing in layers. The trichiasis was rectified and there was no visible deformity.

Particular care must be taken if the laceration involves the inner end of the lower lid where it may involve the lower canaliculus. If this is faultily resutured the patient may have a permanently watering eye. If seen early, the condition is easily treated. A fine silk suture is used with a needle on each end. One needle is passed down the lumen of the lateral cut

half of the canaliculus, coming out through the punctum lacrimale. The other needle is made to enter the medial cut end of the canaliculus. After passing a little way along the lumen it is made to turn forward so that the point is brought out on the skin of the face. By tightening the suture the two cut ends of the canaliculus can be brought into apposition. Union readily occurs.

The greatest care should be taken to avoid adhesions of lacerated lids to the globe, as troublesome symblepharon may be caused. If the adhesion occupies the lid margin only, simple division of the adhesion and subsequent separation of the cut edges may suffice. The condition is not so simple if the adhesion obliterated the conjunctival fornix. Here it will infallibly reform if simple division is resorted to. In one case of such symblepharon posterior the soldier was completely incapacitated by diplopia from limitation of movement of the globe by the adhesion.

The surgical prognosis in such cases has been greatly improved by the plastic operation invented by Duverger and Velter. The principle of the operation avoids the division of the adhesion. The adherent portion of the lid is cut away from the rest of the lid and left in undisturbed adhesion to the globe. The lid is first split along the inter-marginal grey line opposite the adhesion. With scissors the adherent portion of the posterior flap is cut around, so that the lid is completely separated from the globe. A new lid is fashioned anteriorly by the sliding flap method. The raw surface on the globe is covered by pedunculated interdigitating conjunctival flaps swung down from above the globe.

In modern warfare actual lacerations of the globe usually are sufficiently serious to necessitate enucleation. A few eyes may be saved by covering the lacerations by conjunctival flaps; but this is, unfortunately, exceptional. Any prolapsed ocular tissues, such as iris, choroid, or ciliary body, should be excised. A prolapse replaced might form the start of an intra-ocular infection.

Enucleation of a badly lacerated eye may be a particularly difficult operation to carry out neatly. At Horton we have seen several badly contracted sockets from rough or infected enucleations. Inexperienced surgeons often get themselves into unnecessary difficulties in the enucleation of a perforated eye by omitting to sew up the perforation at the first stage of the operation. If this is done it is usually possible to enucleate the eye in the classical style as an operation deliberately performed in proper sequence of stages. Otherwise the operation is apt to resolve itself to much blind cutting with scissors in a mass of bleeding tissues. If an eye has collapsed like a squashed grape, identification of such structures as muscle, etc., becomes exceptionally difficult. It is better to hand on such an enucleation to an experienced ophthalmic surgeon rather than to rush the job at the casualty clearing hospital or advanced base.

Many injured eyes seem to be precipitately enucleated for fear of the possible destruction of the second eye by sympathetic ophthalmia. This, if it occurs, is a terrible tragedy, and it is much better to sacrifice a badly injured eye rather than incur the danger. There is, however, no usual necessity to make the decision immediately. An injured eye can usually be safely left for 14 days without incurring the risk of sympathetic ophthalmia. It will usually be possible to refer the patient during this comparatively safe period to a trained ophthalmic surgeon. Such a person will be less likely to obtain a contracted socket if he decides that an enucleation is necessary.

Rough enucleation is not the only cause of a contracted socket. Another cause is prolonged sepsis, particularly sepsis involving the accessory nasal sinuses or the bony orbital margin. While sepsis is present, something can be done to prevent contraction of the socket by separating adhesions and by the use of a glass 'shell' to prevent the in-turned lashes from irritating the socket. Operative treatment must usually await the disappearance of the sepsis. In cases of

accessory sinus or bony involvement, the early co-operation of a rhinologist is desirable.

The operative treatment of a contracted socket varies according to the degree.

In some of the minor degrees a specially made artificial eye may sometimes be fitted after the division of one or more band-like adhesions in the socket.

In the next stage of severity the socket appears roomy and capacious; but there is a poorly defined lower conjunctival fornix. The artificial eye looks for a few moments as if it will stay in position; but it is then extruded, the lower edge over-riding the lower lid margin. To keep the prosthesis in position, a new lower fornix must be constructed. Most surgeons have their own favourite operations for this purpose. One successful method is to employ small mattress sutures of fascialate from the ilio-tibial band. By means of these sutures the lower sulcus of the socket is sewn into apposition with the lower lid, the free ends of the sutures being brought out on the skin surface. Fascial sutures need never be removed. The groove of the fornix is permanent, and the artificial eye stays readily in position.

In the most severe grades of contracted socket it is impossible to insert a prosthesis. For these cases the operation of Esser or one of its modifications can be employed. All the mucous membrane of the contracted socket is excised. A stent mould of the future socket is wrapped round with a large skin graft and buried in a bed cut in the soft tissues. The lids are sewn together over the mould, which is not removed until the skin graft is firmly attached to the new bed.

A large proportion of war injuries are inflicted by large and small flying foreign bodies. Many such injuries will be obviated when the Cruise visor is generally adopted.

The skin of the lids is frequently tattooed by flying carbon particles. These carbon particles require no treatment and are gradually extruded from the skin surface. Similar carbon particles are often found on the cornea. They can readily be removed with a sharp dissection needle from the cocaineized cornea.

From bursting bombs most of the injuries seem to be due to tiny flying fragments of white metal. Analysis of some of the pieces has shown the metal to be an alloy containing aluminium and magnesium. After a few days' exposure to the ocular fluids the metal is crusted over with a white crumbly powder.

Such fragments can easily be picked out from the cornea with a sharp dissection needle. This was found possible even in one case where the tip of a small metallic flake was protruding into the anterior chamber. The flake was soft metal, which was impaled on the dissection needle and withdrawn. A gush of aqueous followed from the corneal perforation.

Surprising momentum is imparted to such fragments by a bomb explosion. We have often been surprised to note the distance penetrated by pieces so small as to require a slit-lamp for their inspection. In one case a piece of very small size passed completely through the cornea and the crystalline lens, its tip entering the retro-lental space. The patient's other eye had completely lost its sight. Like most of the bomb fragments, this particular piece of metal was non-magnetic. Active surgical intervention seemed out of the question, and the patient was simply kept under observation. A localized opacity formed around the track of the fragment through the lens. The piece itself gradually became covered with a crumbly, powdery coat, presumably of hydroxide. Polychromatic lustre made its appearance on the posterior lens capsule. So far the deterioration of vision is only what would be accounted for by the localized lens opacity. Another patient had the vitreous filled with shining metallic fragments, looking very similar to a synchysis scintillans.

Larger pieces of metal, such as shrapnel, usually destroy the eyes they hit. In certain instances, however, the pieces have passed close to the eye without penetration. In such instances the eye frequently sustains a concussion injury. The anterior chamber is

filled with blood which later clears, allowing a view of the interior of the eye. In most of these cases there is some serious internal injury, such as a detached retina or ruptured choroid.

There have been a large number of injuries by blunt objects or by blast. In two cases the optic nerve has been ruptured by a blow on the outer side of the orbit. In these cases vision is lost immediately after the blow. The pupil of the affected side loses its direct light reflex, though the consensual contraction to light on the other eye is retained, as also the reaction to accommodation. Later on the affected disc becomes atrophic.

The sixth nerve is often paralyzed after contusion injuries. Many of these paralyses are temporary in nature, so that it is worth waiting for some months before seeking remedies by surgery. The operation of choice is that of Temple Smith, in which the action of the external rectus is taken over by slips of muscle transplanted from the superior and inferior recti. A recession of the internal rectus is undertaken at the same time.

The superior oblique is often affected by injuries involving the trochlea. In these cases much relief from the troublesome diplopia can be obtained by a recession of the superior rectus of the same eye.

The eye is often injured by blast. In several of these cases a Vossius ring has been visible, a dark imprint of the pupillary outline on the anterior lens capsule. These rings slowly disappear. It is not infrequent for the crystalline lens to be dislocated or partially subluxated. In one case the patient had monocular diplopia, as he had one image through the aphakic part of the pupil, another through the lens. The sclera has been several times ruptured by blast, usually but not invariably subconjunctivally. Lens, iris, ciliary body, choroid or vitreous may be seen forced out through the rupture. The choroid is frequently ruptured or detached. In the cases where the retina has been detached by blast injury, there have been too many tears in it to render surgical interference practicable. In two cases retina have been detached by ordinary strains and stresses. In one case a myopic soldier gave his rifle a sharp upward cant when he saw a bright flash in his left eye. He had a large detachment with an obvious disinsertion, which was easily closed by operation. Another man detached his retina when he flung himself quickly down on the ground to take cover. He had three small round holes, which corresponded in the detached retina to old patches of choroidal scarring. The retina was replaced by operation.

Electric and thermal burns have been fairly common. Those seen in the first instance have not been particularly severe in character, and have been simply treated by antiseptics. The areas involved have not been large enough for the tannic acid treatment to seem necessary. There have been several cases of cicatricial ectropion after burns. These have been treated by performing a tarsorrhaphy after dissecting out the contracted scar tissue: the raw area has been covered by a whole-thickness Wolff skin-graft, usually taken from the hairless skin behind the ear. These Wolff grafts take readily and have the advantage that they do not contract after transplantation. Later on the tarsorrhaphy is undone.

So far we have seen no ocular injuries from the war gases, and only one case in which a piece of shrapnel injured the higher visual centre in the occipital lobe.

It will be seen that most of the eye injuries of war time are similar to the ordinary peace time industrial eye injuries.

Pleurisy

By J. MAXWELL, M.D., F.R.C.P.

(From the *Practitioner*, Vol. CXLVI, April 1941, p. 223)

THE treatment of pleurisy can be considered under two headings, the immediate treatment of the presenting symptoms, and treatment of the underlying lung

condition. From the point of view of the patient palliative treatment is perhaps the more important of the two, for pain is the most common symptom and the relief of pain is the most pressing need in acute cases. The cause of the pleurisy is of more remote importance, as the view taken concerning the aetiology of the condition to a large extent determines the advice which must be given concerning convalescence and after-care.

ACUTE PLEURISY

Acute pleurisy is nearly always of the fibrinous type, and many cases do not progress beyond this stage. When 'primary', it is commonly due to tuberculosis, and the underlying lung may be affected to a greater or less extent. In some cases the disease appears to be entirely confined to the pleura, whereas in others an acute pleurisy may be merely an event in the course of established pulmonary tuberculosis. In all cases in which acute pleurisy appears to be 'primary' it is as well to assume that the cause is tuberculosis unless definite proof of some other cause is forthcoming.

The chief symptom of dry pleurisy is *pain* in the chest, worse on inspiration, and often attended by a dry cough which increases the pain. It follows that in the treatment of dry pleurisy the most important measures to be adopted will be those designed for the relief of pain and cough. The patient will naturally be in bed and will adopt the position of least discomfort. In many cases he lies on the affected side in order to minimize respiratory movement, and this object can be assisted by strapping the affected side of the chest. For this purpose it is necessary to obtain wide strips of elastoplast, or other strapping, which should be applied firmly from below upwards with at least half an inch of overlap. Strapping the chest contributes greatly to the comfort of the patient, but the removal of the plaster may be so unpleasant as almost to counteract its advantages, especially if there is much hair on the chest; the best way to remove strapping is to wipe it off gently with antihæsin on cotton-wool, being careful not to attempt to hurry the procedure.

When there is extensive change in the lung substance, as occurs with lobar pneumonia, it is unwise to strap the chest and other measures must be employed for the relief of pain.

Of these, the most usual method is to apply a poultice to the chest, the favourite at the present-day being a kaolin compound, although it is doubtful if this retains the heat as well as the old-fashioned linseed poultice. Kaolin is also apt to leave the surface of the skin sticky and it is inconvenient when the chest has to be examined. It is simple to prepare and to apply, however—hence its popularity. If a poultice fails to relieve the pain it may be necessary to employ some form of counter-irritant. A mustard plaster is a simple and fairly effective remedy, and blisters and leeches have their uses in the more severe cases. Should the pain still fail to respond, it may be justifiable to introduce 300 or 400 c.cm. of air into the pleural cavity, a method of treatment which is most effective and almost devoid of risk; the pneumothorax thus obtained is kept up for as long as may be desired, but it is usually safe to abandon it in the course of a week or ten days, except in cases in which the pleurisy is due to tuberculosis, in which event it may be kept going on standard lines as a method of treatment of the underlying lung condition.

Drugs, with the exception of morphine, are not of great value in the treatment of acute pleural pain, and it is better to trust to the measures already outlined. The usual course of the illness is one of fairly rapid subsidence of symptoms, and the chief question is then one of convalescence. An apparent primary dry pleurisy, for which no cause can be found, either on examination of the chest or on the x-ray film, should not be dismissed as a minor complaint. The ideal advice is that the patient should have at least three months' convalescence in the country. He should subsequently be kept under observation at gradually increasing intervals for two or three years, and serial

x-rays should be taken in order to keep a check on any subsequent development in the lung. Sometimes, for economic reasons it is not possible to carry out this programme in full, but a convalescence which falls short of this is incomplete, and an even more careful watch must be kept in order to forestall subsequent developments. Cough is rarely a troublesome symptom and it is usually sufficient to prescribe Gee's linctus. A more severe cough might be treated with heroin.

CHRONIC PLEURISY

Chronic dry pleurisy is a somewhat unusual condition and may be the result of a previous acute attack, or it may be detected in the absence of any history of acute pleurisy. In the former case it is likely to be tuberculous, and it is then due to recurrence of sub-acute inflammation in a pleura which is to some extent adherent. It may be due to tuberculosis, even when it appears as a chronic condition from the onset, but in such cases it may also be due to nodules of malignant growth in the pleura. It is therefore most important to investigate such cases carefully before forming an opinion. It is noteworthy that in some cases of malignant disease the pleurisy may be so gross that friction can be felt, and yet the patient may not complain of pain. A symptomless chronic pleurisy of this sort does not need symptomatic treatment and, if the cause be irremediable, there may be no treatment at all. In chronic pleural tuberculosis, if there be evidence that the disease is active, general treatment on the usual lines should be advised. Sometimes, however, pain may be intense and this applies particularly to a case in which growth involves intercostal nerves. It is quite likely that the measures suggested for acute pleurisy will not succeed in some of these cases, and it may then be necessary to inject a 1 per cent solution of novocain into the affected region of the pleura. A still more radical method of dealing with pain, especially when it is certain that it is due to involvement of intercostal nerves, is an alcohol injection to the nerves affected, together with the nerves immediately above and below. Good results are sometimes obtained by this method in cases of cancer of the lung and pleura.

PLEURAL EFFUSION

Pleural effusion may complicate a simple dry pleurisy or it may arise as an apparently primary event. In most cases the symptoms vary directly with the rate of accumulation of the fluid. A rapidly forming effusion may cause marked shortness of breath and an ache in the chest, whereas an effusion which has formed slowly, yet which completely fills the pleural cavity, may be detected on routine physical examination without any of the characteristic symptoms having been present. The detection of fluid in the pleura should be a comparatively simple matter. In the first instance it is noted that the affected side of the chest is moving poorly, or not at all, and inspection in a good light may show that the intercostal spaces on that side are not drawn in on inspiration (Litten's sign). On palpation it is found that the heart and trachea are shifted towards the sound side and the vocal vibrations are absent; the absence of vocal vibrations is a particularly important sign in the distinction between effusion and consolidation for, in the case of lobar pneumonia for instance, the vocal vibrations are often actually increased. On percussion the note is dull, and the shape of the dullness is of some diagnostic help. In a medium-sized effusion the upper border rises from the spine towards the axilla and then sinks as it approaches the sternum, whereas consolidation of a lower lobe gives an upper border which falls steadily from the spine of the scapula towards the lower part of the sternum. On auscultation breath sounds are not usually heard when an effusion is considerable, but this sign is often misleading and it is possible to hear bronchial breathing when there is a moderate amount of fluid present in the chest. Failure to recognize this fact is a not uncommon cause of failure to detect an empyema until it has already been present for some considerable time, but this mistake should not occur if

careful attention is paid to the other physical signs in the chest.

The *management* of pleural effusion depends to a large extent upon the cause. In this article it is proposed to deal entirely with clear effusions, and not to consider empyema as a complication of pleurisy. It may be accepted that most cases of primary pleural effusion, in young patients at least, are due to tuberculosis and every effort must be made to determine whether the damage is confined to the pleural membrane or whether the underlying lung is also diseased. The patient must be kept in bed until the temperature has been normal for at least a fortnight; this means that the duration of confinement to bed will be about six or eight weeks in the average case. While the patient is in bed a determined effort should be made to discover tubercle bacilli in the sputum, if available, or in the stomach washings. If the evidence points to absence of involvement of the lung it is usually sufficient to keep the patient in bed for the stated period of time, and further measures may not be necessary. It is, however, an excellent plan to withdraw some of the fluid for examination, bearing in mind that culture on Lowenstein's medium is a good method of detecting the presence of tubercle bacilli. A guinea-pig should be inoculated as a routine. There is another reason why a routine chest puncture should be performed, namely, that in this way a diagnosis is firmly established beyond all possibility of doubt. It is not uncommon to find a patient who complains of respiratory symptoms and who gives a history of 'pleurisy' months or years previously. In such cases the patient rarely knows whether the pleurisy was wet or dry, and the physician may even be in doubt whether the condition was a pleurisy at all. A simple statement by a patient that the chest was punctured and a sample of fluid removed is sufficient to clarify the situation at once.

Aspiration.—An important decision which has frequently to be made is whether or not the fluid should be removed. It may be stated that, as a general rule, the average effusion will be absorbed spontaneously in about six weeks, and therefore it is clear that routine aspiration is unnecessary. When the fluid is allowed to be absorbed at its own pace it is found that there is little irritation of the pleura, and the membrane may return to its normal state; the fact that patients are seen who have had a recurrence of an effusion on more than one occasion in the same part of the chest is proof that it can be absorbed without leaving gross pleural adhesions. There are some cases, however, in which aspiration must be performed. The chief indication is shortness of breath, which accompanies a rapidly developing effusion. Another indication is to prevent thickening of the visceral pleura in cases in which absorption of the fluid is unduly slow.

Pneumothorax.—Replacement of the aspirated fluid by air is necessary in certain cases. Effusions which recur rapidly after removal can be controlled to a considerable extent by air replacement; as much fluid as possible is withdrawn and about two-thirds of the amount of air is injected; the procedure is carried out at one sitting, using a special two-way cannula. This type of air replacement is of special value in cases of recurrent effusion due to malignant disease. Finally, air replacement may be done in order to secure a satisfactory x-ray film showing the state of the underlying lung and pleura, which are of course obscured by the fluid in a plain film. Growth may thus be disclosed in the lung or on the pleural membrane, or cavities may become visible. When the condition is proved to be tuberculous it may be decided to continue with injections of air, thus constituting an artificial pneumothorax, which can be kept up for as long as may be necessary.

Drugs are not of much value in assisting in the absorption of fluid. It is said that the intravenous injection of a 5 per cent solution of calcium chloride is of value in promoting resolution. Sometimes an aching pain is felt in the lower part of the chest

for some considerable time after an effusion has been absorbed: usually a mustard leaf or a blister will control the symptom.

The after-care of a case of tuberculous pleurisy is a most important matter. It is not usually necessary to advise sanatorium treatment in cases the lung is not involved, as these patients are better kept carefully away from contact with tubercle bacilli. It is best to send them to the country or to the sea to live a quiet life on sanatorium lines for between three and six months. Sun-bathing and sea-bathing must be expressly prohibited. A generous diet and carefully regulated exercise should result in a moderate increase in weight. An unduly rapid gain usually means that the patient is not taking sufficient exercise, and an unhealthy fatness with flabbiness is the result.

Anaemia in Pregnancy in Calcutta An Analysis of Haematological and other Data from 529 Pregnant Women

By L. EVERARD NAPIER, C.I.E., F.R.C.P. (Lond.)
and

M. I. NEAL EDWARDS, M.D., W.M.S.
(From the *Indian Medical Research Memoir* No. 33.
December 1941)

Summary of observations

Blood examinations were carried out and an analysis is made of the blood picture in 128 'normal' non-pregnant women, in 64 'normal' pregnant women and in 467 pregnant women clinically chosen as anæmic; of these women of the last group, 386 were first examined before parturition and 81 after parturition.

For the purpose of analysis the anæmic women were divided into three classes, A—markedly anæmic, 50 per cent or less (Hellige), B—moderately anæmic over 50 per cent but under 68 per cent, and C—68 per cent or over; this last class acted as additional controls. The cases were further divided into three haematological groups, microcytic, normocytic and macrocytic, so that there were altogether nine sub-groups. Epidemiological, pathological and clinical data were analysed with reference to these classes, groups, and sub-groups. From this analysis the following conclusions were arrived at:—

1. The 'normal' pregnant women show a distinctly lower hæmoglobin level than the normal non-pregnant women (reported elsewhere), but no evidence of the progressive reduction of hæmoglobin percentage throughout pregnancy that has been reported by other workers; there is, however, evidence of a tendency to increase in cell size as pregnancy progresses.

2. Amongst the anæmic patients the same tendency towards increase in size of the red cell throughout pregnancy is apparent, but otherwise there is no constant change in the size of the red cell; macrocytic and microcytic anæmias usually maintain their own characteristics until cure is effected.

3. There is evidence that the removal of the fœtus, naturally, at term, or prematurely, was a more potent factor than any treatment that may have been given in bringing about improvement in the blood picture, in the macrocytic and normocytic cases, but less so in the microcytic.

4. There is evidence that there is an iron deficiency in the large majority of the cases under investigation. This iron deficiency was most evident in the class that showed the least anæmia, this anæmia-producing factor probably being overshadowed by other factors in the more anæmic classes, and, though it is more prominent in the microcytic groups, there is evidence of some degree of iron deficiency in the other groups.

5. Liver injections appeared to be effective in some individual cases, but, in the analysis of the cases as groups, there was no evidence of this effect, perhaps because a negligible number of injections were given in many cases.

6. Macrocytic anæmia is more common amongst primigravidae; this association is independent of age, for otherwise there is less anæmia amongst young women. Microcytic anæmia is commonest amongst older women.

7. Of the severe cases coming under observation early in pregnancy, the majority were macrocytic.

8. A distinctly larger number of macrocytic cases come under observation during the second half of the year.

9. There is a very marked association between poverty and anæmia, and some correlation between macrocytosis and poverty. In the richer classes, vegetarianism appears to be correlated with macrocytic anæmia.

10. There is a significant correlation between Mohammedanism and microcytic anæmia, and also therefore with purdah.

11. There is a negative association between excessive hæmorrhage at parturition and both ante-partum anæmia and macrocytosis.

12. There is no correlation between sore-mouth and the degree of anæmia, but there is a suggestion of association between macrocytosis and sore-mouth.

13. There is a significant association between diarrhoea and to a less extent vomiting, and macrocytosis.

14. There is a significant association between both severe anæmia and macrocytosis, and œdema.

15. There is a significant association between severe macrocytic anæmia, and both spleen and liver enlargement.

16. Albumin in the urine is significantly more frequent in the severe anæmia class.

17. Hyperbilirubinæmia is definitely correlated with severe anæmia and macrocytosis.

18. There is a positive correlation between reticulocytosis and both the degree of anæmia and macrocytosis.

19. In the severe macrocytic anæmia group hyperbilirubinæmia is correlated significantly with liver enlargement and spleen enlargement, but in the rest of the cases in the severe anæmia group it is correlated only with splenic enlargement.

20. There is considerable evidence of an ætiological association of syphilis or some other Wassermann-positive-producing factor, in the severe anæmia groups, for a positive Wassermann reaction was obtained in over 20 per cent, and in over 25 per cent of the 'poor' patients of this group; in the case of the latter the difference between the macrocytic groups and the rest is significant. There is also a strong suggestion that a positive Wassermann is particularly associated with macrocytosis.

21. The maternal deaths recorded were mostly amongst the macrocytic and normocytic cases.

22. Prematurity and early death of the child both show a high correlation with severe anæmia and macrocytosis. The neo-natal death rate in the anæmic classes is over 36 per cent amongst infants of mothers with macrocytic anæmia, 20 per cent amongst those with normocytic, and was *nil* amongst those in our series with microcytic anæmia. This is also evident amongst those cases first seen post-partum, for the neo-natal death rate was over 30 per cent in the combined macrocytic and normocytic groups and again *nil* in the microcytic.

23. In the post-partum cases there was evidence of a rapid decline in the influence of the macrocytic-anæmia-producing factor.

Conclusions

Ætiology.—One of the objects in carrying out this inquiry was to obtain evidence of the important ætiological factors in the development of severe anæmia in pregnant women in Calcutta, and thus provide a rational basis for a campaign against the high anæmia mortality.

Considerable evidence was found in the whole series of cases of an iron deficiency. The hookworm infection rate was negligible amongst the patients whose stools

were investigated, and, as it is not usually high amongst women of the class from which the patients were drawn, it seems probable that the origin of this iron-deficiency anæmia is dietary, i.e., the iron intake is insufficient for the extra requirements of the pregnant woman. The higher incidence of anæmia in the lower economic groups supports this suggestion and the fact that this 'poverty' anæmia is not predominantly microcytic is not necessarily against it, for it is probable that the microcytic picture of the anæmia is overshadowed by other influences.

A relative iron deficiency occurring in the child-bearing period of life with a tendency to exacerbations during pregnancy and lactation is well recognized in other countries and is especially common amongst the poor whose iron intake is near or below the borderline of the body's requirements. In our series the pure microcytic anæmias occurred mainly in multiparæ and older age groups suggesting that iron depletion during earlier pregnancies may have been the cause.

Microcytic anæmia appeared to be associated with the observance of purdah. The pallor and debility which results from close confinement to the house and lack of fresh air and sunlight is probably similar to the chlorosis of a previous generation in England, which quickly responded to iron therapy.

This iron deficiency, however, though widespread, is of secondary importance in this series of cases of anæmia, for the majority, as well as most of the worst cases, were macrocytic. The far greater frequency of very severe anæmia amongst the macrocytic group may be evidence that the macrocytic-anæmia-producing factor is the dominant one.

The production of macrocytic anæmia appears to be influenced by several factors. In the first place, it appears to be connected in some way with the presence of the fetus; the anæmia and the macrocytic tendency show a progressive increase throughout pregnancy, both in the anæmic patients and in the controls, and they tend to decrease immediately after parturition. Secondly, that this anæmia is nutritional in origin, is suggested, not only by the higher incidence in the lower economic classes, but by the fact that it is the macrocytic type that is more closely correlated with low economic status and that in the richer classes, vegetarianism, with its lower protein intake, is correlated positively with macrocytic anæmia. It is possible that the higher incidence of anæmia and macrocytosis in the second half of the year is connected with the less varied dietary, and with a lack of fish and vegetables, that is taken during the hot weather and monsoon months. Further, the common association of macrocytic anæmia with sore-mouth, another deficiency condition, still further suggests a nutritional defect.

Thirdly, the association of severe macrocytic anæmia with primigravidity, independent of age, its occurrence relatively early in pregnancy, and its association with premature delivery and a high neo-natal death rate, suggest comparison with the toxæmias of pregnancy. This is further supported by the common association of macrocytic anæmia with œdema and albumin in the urine.

The significant positive correlation of severe macrocytic anæmia with enlarged spleen and liver, hyperbilirubinæmia and reticulocytosis all point to some hæmolytic condition and are especially suggestive of chronic malaria. Malarial parasites were recorded in only a few cases, but this is beside the point as it is not suggested that acute recently-acquired malaria is the cause, but chronic, or 'latent', malaria with hyperreticulo-endotheliosis.

Another suggestion for an ætiologically associated infection is provided by the high correlation with a positive Wassermann reaction (with the possible proviso that this positive Wassermann reaction may be another manifestation of an association with malaria).

Finally, the occurrence of diarrhoea or a history of dysentery, often accompanied by prolonged adherence to a limited and unbalanced diet, suggest a state of gastro-intestinal dysfunction. This raises other ætiological possibilities for which added evidence is

provided by the similarity of this type of anæmia to the macrocytic anæmia which occurs in association with sprue and celiac disease.

To summarize, findings seem to suggest that the macrocytic anæmia of pregnancy is a 'conditioned' toxæmia, that is, a toxæmia associated with the presence of the fetus and conditioned by a low dietary intake, or deficient absorption, of certain essential blood-forming and protecting substances, the syndrome being aggravated by (or perhaps only operative in the presence of) a chronic malarial infection, with the associated hyper-reticulo-endotheliosis and excessive blood destruction which causes an extra demand for these blood-forming essentials, by chronic intestinal infections and diarrhœa with consequent exaggeration of mal-absorption, and/or by syphilis with its hæmopoietic depressing action.

Such a conditioned toxæmia is not purely hypothetical and has been shown to occur in connection with both lead and selenium poisoning and with sulphanilamide administration; in the former case it is recognized that people on a rich diet may escape the effects of lead poisoning, whilst others on a poor diet suffer, and recently Smith *et al.* have shown that in animals a high protein diet will counteract the effect of chronic selenium poisoning and the hæmopoietic depressing action of sulphanilamide.

The fact that a macrocytic anæmia similar in many respects to the macrocytic anæmia of pregnancy occurs, although less commonly, in men in Calcutta, suggests that, as in the case of the iron-deficiency anæmia, the fetus is the last straw that breaks the camel's back.

Clinical picture.—A further object in mind in carrying out this inquiry was to correlate clinical syndromes with different hæmatological groups, so that treatment in the absence of complete blood examination might be more rational. The findings of the inquiry have, however, in the first place impressed on the workers the complexity of the problem of the anæmias met with in Calcutta and the absence of any clearly-defined clinical types which can be correlated with the hæmatological groups according to which the cases were analysed. It is probable that one reason for this is, as has already been suggested, that an iron-deficiency condition may underlie other superimposed types of anæmia, leading in many instances to a confused hæmatological picture. Our findings do, however, emphasize the existence of marked clinical differences between cases of moderate anæmia (class B) as compared with severe anæmia (class A), and further, certain clinical distinctions can be drawn between the severe macrocytic anæmias and the severe microcytic anæmias in class A.

The main differences between moderate and severe anæmias in general can be summarized as follows:—

In moderate anæmia (class B) the patient usually makes no complaints and the condition is found on routine examination. On inquiry she may admit to feeling tired, but many women expect this in pregnancy and think nothing of it. On examination some pallor of the mucous membranes of the mouth (and of the vagina, if the pelvis is healthy) is a more reliable guide to the degree of anæmia than the conjunctivæ or nails. The heart may be normal, but in the borderline cases will probably show a hæmic murmur or slight dilatation.

Post-partum hæmorrhage is rather more likely to occur in these moderate cases than in very severe anæmia.

In severe anæmia there may or may not be presenting symptoms. The degree of anæmia which may develop without complaints is a striking testimony to the low standard of well-being with which so many women seem satisfied. It is not uncommon to find a hæmoglobin of 30 to 40 per cent on routine examination. In more severe cases in this group, questioning will, however, elicit symptoms of shortness of breath, palpitations and often swelling of the feet and face. Diarrhœa is sometimes the presenting symptom. On examination, marked pallor is seen, and the skin often has an 'alabaster' appearance, due to

a combination of pallor and œdema; according to the degree of severity, the following signs will be found: œdema of feet, face or of the whole body; a degree of dilatation of the heart, a systolic murmur localized in the pulmonary area or audible all over the præcordium; the spleen may or may not be palpable.

Premature delivery, stillbirth and neo-natal deaths are common in this group. Tendency to post-partum hæmorrhage is not marked; sepsis in the puerperium is a danger.

The differences between the macrocytic and the microcytic cases in class A (severe anæmia) can be summarized as follows, but it must again be emphasized that the types are not by any means clear cut.

Macrocytic anæmia has a seasonal incidence and cases tend to occur in the second half of the year. It is found on the whole rather more often in the first and second pregnancies irrespective of the age of the patient. These cases come under observation earlier in the course of pregnancy than the microcytic type and show a greater tendency to spontaneous recovery after parturition. They respond little, if at all, to iron therapy. Symptoms include a larger proportion of cases with a history of diarrhœa or dysentery than in the microcytic type. A yellowish tinge of the conjunctivæ and skin is often noticeable, corresponding to the large number in this group who show evidence of hyperbilirubinæmia. The mouth may be sore and the tongue be seen to have a shiny smooth appearance with red sore patches. It is usual to find enlargement of the spleen and liver. Labour is often premature, generally easy, and these cases do not often suffer from post-partum hæmorrhage, although delay in delivery of the placenta is not uncommon. The added strain of labour may be more than the enfeebled circulatory system can stand, and in extreme cases death occurs from heart failure during or soon after delivery. The neo-natal death rate is very high. A positive Wassermann reaction was more common in macrocytic than in microcytic cases in our series.

The severe *microcytic anæmias* show a positive correlation between Mohammedanism and purdah, the influence of the one perhaps overshadowing the other. Cases of this type of anæmia tend to come under observation later in the course of pregnancy than the previous type. Cases occur at a later age period and in the later pregnancies. The tendency for spontaneous recovery after delivery is less marked, but the reaction to iron both during pregnancy and afterwards is good. The conjunctivæ and mucous membranes of cases in this group are dead white rather than yellowish white, and signs of enlarged liver and spleen, sore-mouth and intestinal complaints are less common, although by no means always absent. Heart failure in severe cases is equally possible, although in the series under investigation no microcytic case died; the explanation of this may be that severe microcytic cases were uncommon, for the very severe cases both factors were probably operating and the macrocytic picture predominated.

The neo-natal death rate is low, and was actually *nil* in this series, for the infant has the first call on the available iron.

Recommendations regarding prophylaxis and treatment

It was no part of the programme of this investigation to assess the value of any particular form of treatment, and in fact we had very little opportunity to do so, for in the severe cases usually many different forms of treatment were given in quick succession or at the same time; our recommendations are therefore based on deductions from our hæmatological observations combined with other experience on our part and on that of others.

Prophylaxis.—It is encouraging to consider that no other fatal complication of pregnancy can, in theory, be so easily prevented if taken in time, as severe anæmia.

Pre-natal care must include constant watchfulness for any signs of development of anæmic states. Regular examination of the woman for pallor of face and mucous membranes, and the rough estimation of the hæmoglobin by the Tallqvist method, are a matter

of a few moments' work, are within the capacity of any trained midwife to carry out, and will serve to detect all the grosser cases. The medical examination which should be undertaken in the early months of pregnancy should include a careful inquiry into the history of hæmorrhages, especially with reference to their frequency, of malaria, dysentery and syphilis, and of anæmia and œdema in previous pregnancies. The diet should be inquired into and any deficiency adjusted. Physical examination should be directed especially towards the colour of the mucous membranes, the presence of a hæmic murmur or dilatation of the heart, the condition of the spleen and liver, œdema of feet and the examination of the urine and blood pressure.

The pregnant woman's diet should ordinarily be the diet to which she is accustomed, with any necessary additions to make it 'balanced'. A pint of milk should be considered a minimum requirement, and this is more especially important in a vegetarian diet. Some substance rich in vitamin-B complex (sprouting gram, rice polishings, Marmite) should be taken, and articles containing a plentiful supply of salts including iron should be encouraged. Sunshine and fresh air should be insisted upon, and women who observe purdah should take extra vitamin D.

All pregnant women of the classes from which we drew our cases should be given iron by mouth as a prophylaxis during pregnancy. It is suggested that the first course should be given in the 3rd or 4th month and the second between the 6th and 8th month.

If a patient has an enlarged spleen or gives a history of malaria, a course of quinine may be advisable. This should be given after the 3rd month is completed, and not at the time when menstruation would have occurred, and the patient should rest during the administration. The quinine should be given in 5-grain doses, three times a day combined with bromide. The chances of quinine causing abortion is exaggerated; the dangers to which the foetus is subjected are far greater if quinine is withheld than if it is administered in moderate doses, but the time for its use should be carefully chosen, unless active malaria is present when in any circumstances thorough treatment must be given.

A Wassermann reaction should form part of a pre-natal examination and, if it is positive, treatment should be instituted.

If a history is obtained of severe anæmia in a previous pregnancy, a prophylactic course of iron by mouth, and liver by mouth or injection should be given early in pregnancy and blood examinations made at intervals throughout.

Diagnosis and treatment.—The first essential is accurate diagnosis and the detection of underlying and associated diseases. When anæmia is found, a full hæmatological examination should be carried out to discover the type of anæmia present, the stools and the urine should be examined, the blood pressure taken and a Wassermann test carried out.

The earlier treatment is instituted the more likely is the patient to respond.

Treatment in pregnancy.—The diet should be inquired into and suitably supplemented.

Sunlight and fresh air should be insisted upon.

If the anæmia is microcytic hypochromic, iron should be given in full doses, e.g., ferrous sulphate tablets, 6 grains twice a day after food, iron and ammonium citrate, 40 grains three times a day, or better still ferrous ammonium sulphate, 20 grains with glucose twice daily. All iron preparations should be given after food with a glass of water. Full doses of iron are not constipating, but diarrhoea and indigestion are sometimes complained of, and the pregnant woman is more particularly sensitive in this respect. The tablets and pills are more irritating than mixtures but the former keep better and are easier to administer. Iron 'plastules', a proprietary preparation that contains peppermint, are also convenient and will be found

useful in cases in which the ordinary ferrous iron tablets cause gastric irritation.

If the anæmia is macrocytic and hyperchromic, liver extract should be given by mouth or injection. In pregnancy the time factor is important and injection is to be preferred.

If the anæmia is normocytic and orthochromic both liver and iron are indicated.

When there is failure to respond to treatment, the question of blood transfusion arises. Large transfusions are generally contra-indicated by the state of the circulatory system (œdema, etc.) but small transfusions may be given, or better still transfusions of moderate size by the drip-feed method. It is, however, doubtful whether evidence has been produced to show that these are any more effective than intramuscular injection of whole blood, which obviates grouping, is much easier to obtain, less distressing to give, and does not contain the risk of severe reactions, which seem particularly liable to occur in very anæmic women given intravenous transfusion.

Intramuscular injections, 20 c.cm. on alternate days, should certainly be tried in cases that fail to respond to other treatment.

A reticulocytosis should be observed in about a week. It should be remembered that anæmia will not respond to treatment in the presence of active sepsis.

(In milder cases of anæmia when facilities for blood examinations are not available, it is a good working rule to give a course of iron and observe the result; if there is no improvement, liver injections should be given in addition. If the skin shows a yellowish tinge, liver should be given from the first and a careful inquiry for underlying conditions, e.g., malaria, syphilis, dysentery, carried out.)

During labour.—Many cases of severe anæmia come under observation for the first time when labour has begun.

In very severe cases the patient is suffering from a degree of heart failure and anoxæmia, and the strain of labour through which she has to pass may well be too much for her cardiac reserve. Labour in these cases is, however, often premature and generally easy (cf. labour in cardiac disease, with which these cases have much in common), and it is surprising how women with red cell counts of a million, or even just under a million, may survive.

A minimum of excitement and disturbance of the patient is necessary, and delivery should be allowed to take place in a quiet room, preferably on a bed, with the patient half sitting, well propped up on pillows, or with a back rest. Frequent small feeds with plenty of glucose should be given. Sedatives usually helpful are paraldehyde, bromide and chloral. Morphine may be needed, and has the added advantage of preventing the tendency to restlessness which is induced by the cardiac distress and anoxæmia. It may have to be combined with atropine, if there is œdema of the lungs.

The œdema and disturbance of the circulatory system contra-indicate the use of large transfusions of blood or subcutaneous injections of fluid, but small intravenous injections of glucose may be used to tide the patient over a critical period.

We have observed no good results from hypodermic injections of strychnine and digitalin, but camphor and coramine sometimes seem to help. On the whole, sedatives are indicated rather than stimulants.

The third stage should never be hurried. Efforts to express the placenta are particularly exhausting to the patient and should never be made. Post-partum hæmorrhage is rare in severe anæmia but particularly dangerous if it does occur. Spontaneous expulsion of the placenta nearly always occurs unless death is imminent.

Treatment in the puerperium.—If the patient with very severe anæmia survives the first 3 days after delivery she nearly always recovers, unless sepsis supervenes. The danger of puerperal infection is however very great, and, in some conditions of practice, it is probably true that as many very anæmic women

dic later from puerperal sepsis as die from the effects of anæmia and the strain of labour. When sepsis occurs the difficult question arises of the use of the sulphonamides with their depressant effect on the hæmopoietic system. But as the anæmia will not

improve in the presence of the marked sepsis, there is no alternative but to give them combined with iron, liver and intramuscular injections of whole blood, or continuous blood transfusion when circumstance permits, at the same time.

Reviews

TROPICAL MEDICINE.—By Sir Leonard Rogers, K.C.S.I., C.I.E., LL.D., M.D., B.S., F.R.C.P., F.R.C.S., F.R.S., and Sir John W. D. Megaw, K.C.I.E., B.A., M.B., Hon.D.Sc. (Queen's University, Belfast). Fourth Edition. 1942. J. and A. Churchill, Limited, London. Pp. xii plus 536 with 2 coloured plates and 87 text-figures. Price, 21s.

A NEW edition of this well-known book will be particularly welcome at this time when many people unfamiliar with the tropics are being sent out for service abroad. There is probably no more readable book on tropical medicine than that of Rogers and Megaw. It is of convenient size and reasonably comprehensive. Although there are not very many extensive changes in this edition, the subject has been brought more or less up to date, and the authors have kept themselves well abreast of the times, in spite of the fact that they have been divorced from practice in the tropics for a number of years.

Among the additions, we notice that sulphonamides have been advocated in plague, oriental sore, granuloma inguinale, tropical ulcer, and undulant fever, chiniofon in amœbiasis, and nicotinic acid in sprue; Boyle's classification of the dysentery bacilli is now included; the new diseases dealt with include Bornholm's disease (incidentally however this new addition has not found place in the index) and Colorado tick fever.

There are naturally some matters for criticism: Beri-beri is still included under diseases of doubtful ætiology; vitamin-B₂ deficiency has been given as the cause of pernicious anæmia; atebirin is said to be toxic to infants; and very minute doses of atebirin are advocated in blackwater fever. There is one mistake which was possibly only an unfortunately expressed sentence, but which might lead to serious misunderstanding; under the heading 'yellow fever' is the following sentence: 'The viscerotome should be used in all areas where the disease is expected to exist; by the use of this instrument early cases can be detected'. The viscerotome is of course only used for making a post-mortem diagnosis, so that 'early cases' in which one attempted to make a diagnosis by its use would, I am afraid, shortly be referred to as 'the late'.

We believe this new edition will maintain the popularity of the previous editions.

SURGERY. (CATECHISM SERIES.) Fifth Edition. Parts I and II. E. and S. Livingstone, Edinburgh. Pp. 70 with 8 x-ray plates in Part I and from 71 to 140 with 8 x-ray plates in Part II. Price, 1s. 6d.; postage 3d. for each part

A NEW edition of surgery in Livingstone's excellent catechism series has appeared. There must be few students in the British Isles who are not familiar with these valuable books. There are in this edition many helpful skiagrams which some of the earlier editions did not have. They are all relevant, show what they are meant to show, and are well reproduced.

One is tempted to say that they are almost an essential to a student about to take his surgery finals.

THE M.B., B.S. FINALS. A COLLECTION OF THE PAPERS SET AT THE LONDON M.B., B.S. EXAMINATION FOR THE YEARS 1925 TO 1940, CLASSIFIED AND ARRANGED IN SUITABLE SUBDIVISIONS.—By F. Mitchell-Heggs, M.B., B.S. (Lond.), F.R.C.S. (Edin.), Major, R.A.M.C. Second Edition. 1941. J. and A. Churchill Limited, London. Pp. xvi plus 96. Price, 7s. 6d.

THIS book can be recommended to the student and also to his examiner. Examiners in this country do not always set their questions in a form readily understood by the student. The setting of questions is an art, to achieve which nobody need be ashamed of seeking help from others; the examiners in the London M.B. are experienced, and useful guidance may be obtained from them.

If the student can answer all the questions that are found in this book he knows his subject and can face his examiners with confidence.

ESSENTIALS FOR FINAL EXAMINATIONS IN MEDICINE.—By John De Swiet, M.D. (Lond.), M.R.C.P. 1941. J. and A. Churchill Limited, London. Pp. viii plus 168. Price, 7s. 6d.

THIS is not a cram book, but it is a book that will be very useful for the purpose for which it was designed, namely, for rapid revision just before taking the medical finals.

Its usefulness will not end there as it will still form a very valuable small book of reference. It is not comprehensive but it covers a wide field.

The few tropical diseases that are included are treated in an orthodox way, though the reviewer doubts if a 1 in 50 agglutination is diagnostic of Shiga infection. A few lines lower, the dosage of Shiga antiserum '6 to 10,000 units' is a little startling, though the meaning 'six to ten thousands units' is obvious.

This little book is a very valuable pocketful at a very reasonable price, and we can recommend it to the physician and would-be physician alike.

ARCHITECTURAL PRINCIPLES IN ARTHRODESIS.—By H. A. Brittain, M.A., M.Ch., F.R.C.S. 1942. E. and S. Livingstone, Edinburgh. Pp. xi plus 132. Illustrated. Price, 21s.; postage, 7d.

ARE the modern methods of joint arthrodesis as good in technique and as successful in results as they might be?

The author of this monograph was disappointed with the results of orthodox methods of arthrodesis and set out to improve them by working on architectural principles.

Briefly, these principles are that the bone graft used should be placed in compression, not in tension, that its breadth should be in position of maximum stress; where possible two grafts, crossing, should be used, and that the graft should be properly protected. The author then goes on to explain his technique and operative steps when using bone grafts on these principles. He explains how best they may be cut and how adapted to the fusion of the various joints, ankle, knee, hip, thumb, wrist, elbow, shoulder and spine.

Clear, easily-understandable and useful illustrations, some in colour, are a feature of this small book, and photos of x-ray films illustrate end results.

This is an interesting and instructive monograph for orthopaedic and general surgeons.

K. S. F.

Abstracts from Reports

THE ELEVENTH ANNUAL REPORT OF THE ASSOCIATION FOR THE PREVENTION OF BLINDNESS, BENGAL, 1940-41

THE association has now completed the eleventh year and as will be seen from the results obtained in this report, it has justified its existence as one of the most popular and active utility services in Bengal. As the work grows more each year and its activities extend to more remote villages, it is encouraging to find how eager the people are to take advantage of the benefits it provides in dealing with the problem of prevention of blindness and cure of eye diseases. Prevention of blindness is not the problem of only one agency, government, municipalities, district and union boards, the medical profession, parents, guardians and teachers must do their share in tackling the problem. The association tries to co-ordinate the work and educate the lay public in the importance of the movement of prevention of blindness.

Within its limited resources, the committee have been able to carry out the greater part of their programme. One of the long cherished hopes and chief aims of the association has been realized this year, viz, to have five travelling eye dispensaries for the five divisions of Bengal. The fifth travelling eye dispensary started its work in the Murshidabad district on the 12th March, 1941.

The committee have so far not been able to do much in the way of legislation against couchers, quacks and other unauthorized practitioners. These charlatans do a tremendous amount of damage in Bengal. We once again appeal to the government and members of the legislature in the province to take up the matter which is of vital public importance and thereby earn the gratitude of thousands of persons.

Enumeration of the blind.—In the Bengal census for 1931, amongst other counts of disabilities, the enumeration of the blind was undertaken. A person is considered blind who is unable to count the fingers of an out-stretched hand when placed close up to the eyes. This enumeration of Bengal revealed a figure of 73 persons blind per 100,000 which may be taken as a rough figure.

With the starting of the first travelling eye dispensary in Bengal by this association in 1936 an attempt was made to estimate the number of blind persons in the villages of Bengal. At first, progress was very slow but as other travelling eye dispensaries came into existence and there are now five working, we have been able to carry out counts in 500 villages and have obtained a figure of 148 blind persons per 100,000 which is about double the figure ascertained by the 1931 census.

Rural reconstruction.—During the year many comprehensive schemes have been launched for rural uplift and natural constructive work to improve the conditions of the life of the villagers. Large sums of money are being spent to provide good water supplies, improved methods in the breeding of cattle, union board dispensaries, village schools, libraries and playing grounds. The Travancore State in matters of rural reconstruction and village uplift has set an example. The Government of the Punjab is also doing much in this connection.

The work of the five travelling eye dispensaries in the districts and the eye examination and lecture unit in and around Calcutta has been most gratifying.

Propaganda.—The propaganda work of the association has been still further increased by the activities of the eye examination and lecture unit commonly called the 'E.E.L.U.' which was started two years ago.

A special syllabus of lectures for the teachers and students of schools in Bengal has been drawn up by the association and lectures are being delivered in

accordance therewith. This is financed out of a special grant made by the Bengal provincial branch of the Indian Red Cross Society, Calcutta, to the association. These lectures were greatly appreciated by the various schools in which they were delivered.

During the year a new set of magic lantern slides depicting the work of the travelling eye dispensaries in mofussil areas has been prepared from actual snapshots and photographs taken by these dispensaries.

In addition to our work of prevention during the year 106,485 cases have been treated in the mofussil by the five travelling eye dispensaries.

Funds are most urgently required and the committee are always anxious that the activities should not be curtailed by insufficiency of money.

REPORT OF THE SCIENTIFIC ADVISORY BOARD FOR THE YEAR 1ST JANUARY TO 31ST DECEMBER, 1941

In connection with the cholera field enquiry in Bengal under Dr. S. R. Pandit, the percentage of positive isolations was 81 and at the height of the epidemic 92 per cent were positive. The Ogawa sub-type prevailed. Non-agglutinable vibrios were not encountered in higher proportion in negative cases than in association with the agglutinable vibrios in positive cases. Direct plating gave a higher proportion of positive results than enrichment methods. A further study was made of vibrio hemolysis and it was found that strains could be divided into two groups: (a) 'early hemolytic' corresponding to Greig-positive strains and (b) 'late hemolytic' corresponding to Greig-negative strains.

Two outbreaks were investigated in different areas by the Director, King Institute, Guindy.

The examination of a large number of tank waters near Negapatam showed the presence of agglutinable vibrios of the Ogawa hemolytic type. The method of filtration in the field and the use of buffered KCl-boric acid saline with transmission by post to the laboratory for subsequent culture in modified Wilson and Blair medium proved successful.

Cholera bacteriological enquiry was carried out at the School of Tropical Medicine, Calcutta, under Dr. G. Panja. A few cases were treated with human plasma and no opinion can be given on the value of the method.

Brilliant green in 1 in 5,000 dilution was given by mouth in half-ounce doses every 2 hours. Clinical improvement was noticed.

Histological examinations were carried out by Dr. D. N. Banerjee. The vibrio was found in the wall of the small intestine but rarely in the wall of the large intestine. Vibrios were present in the mucosa, the sub-mucosa and at the base of Lieberkühn's follicles but only in rare instances in the sub-serous layer. Histological examination showed evidence of reaction of inflammatory nature with necrosis and desquamation of epithelium. The Peyer's patches and solitary follicles and mesenteric glands showed hyperplasia and necrosis.

Clinical trials were carried out on the value of transfusion with concentrated saline solution (20 per cent) in cases of collapse with high specific gravity of the blood and encouraging results were obtained.

The observations made in India by all enquiries made so far have not shown the existence of any direct association of the El-Tor type of vibrio with a cholera case although strains of this type have been isolated from water in Bengal, Madras, Bihar and Sind. The El-Tor type of vibrio has not been isolated from stools of either healthy persons or of cholera cases. The studies made in the last year have shown that although hemolysis may be produced under certain conditions by vibrios which can be classified as true *V. cholerae* there are differences in the type of hemolysis as compared with that produced by El-Tor strains which enable the two to be differentiated.

The research activities of the Malaria Institute have necessarily been greatly curtailed owing to the

abnormal conditions brought about by the war. The post of malaria research officer remains vacant and several of the most experienced members of the staff are serving overseas. In addition to the annual malaria courses for medical officers and engineers respectively, three special courses for military personnel have been held during the year, and the total number of those who have received training at the Delhi field station since the outbreak of war is 122.

Much work has been done in regard to the testing of insecticides and mosquito repellents. Pyrethrum insecticides have continued to give the best results for spray-killing adult mosquitoes. The repellent value of pyrethrum extract has also been demonstrated, as a result this now forms the chief ingredient of the anti-mosquito cream supplied to the army overseas.

Many tests have been carried out on sprayers, both for spray-killing of adult mosquitoes and for the application of larvicides. An improved hand sprayer and a knapsack oil sprayer, from which rubber diaphragms and washers have been eliminated, have been designed, and are now being supplied to the army.

Little progress has been made in the study of the schizogony cycle of *Plasmodium heroni* and the course of the disease in the host (paddy birds). This, according to the author (Dr. B. C. Basu), was due to his undertaking the preparation of the Malaria Transmission Memoir which has since been compiled.

A filariasis survey was carried out by Dr. Sundar Rao in 9 villages in Cachar district, where the infection is said to have been introduced in recent years from Bihar. Night blood smears from 2,445 persons showed a gross infection rate of 4.7 per cent. Out of 115 carriers, 5 were *Mf. bancrofti* and the remainder *Mf. malayi*. The percentage showing clinical signs of the disease was 4.5.

Pharmacological enquiry under Dr. B. B. Dikshit, Bombay, has shown that sulphathiazole has little action on the cardio-vascular, gastro-intestinal, genito-urinary and central nervous systems when given intravenously, but exerts a stimulant action when applied directly to the central nervous system by ventricular or cisternal puncture. It is rapidly absorbed and excreted when given orally, the channel of excretion being the kidneys. It permeates the placental barrier fairly easily, and is found in measurable quantities in the cerebro-spinal fluid. It is superior in the local treatment of wounds to the other sulphanilamide derivatives tested. A suspension of the drug in cod-liver oil gave promising results in the treatment of burns.

Experiments with the cross circulation technique in the study of immunity in monkey malaria yielded the following results:—

(i) An immune monkey retains its immunity to *P. knowlesi* even when nearly 80 per cent of its blood is replaced by that of a normal monkey.

(ii) A normal monkey acquires immunity when 75 per cent of its blood is replaced by that of an immune monkey; if the replacement is 50 per cent, immunity may or may not be acquired; if it is 33 per cent or less, immunity is not acquired.

(iii) If 70 per cent of blood from a freshly infected monkey is replaced by immune blood, the animal passes into a stage of chronic infection.

The experiments show that both cellular humoral agencies play a part in conferring immunity in malaria infections.

Malaria surveys were carried out by Dr. D. K. Viswanathan in two collieries, two tea estates and in Sadiya, the headquarters of the Sadiya Frontier Tract, and in two urban areas.

The nutritive value of soya bean has been studied by experiments on animals and also by controlled experiments on school children. The general conclusion is that soya bean, considered as a supplement to typical Indian diets, is not of outstanding value; it does not appear to have any advantage over various

common pulses which have long formed part of the diet of the Indian people.

Shark-liver oil is now being produced in the Madras Presidency (Calicut), Bombay, Travancore and Baroda, total production amounting to considerable quantities. Rapid progress has been made in this newly created industry and it appears that the lack of cod-liver oil resulting from cessation of imports can easily be made good, as far as vitamin A is concerned, by developing indigenous supplies of fish-liver oil rich in vitamin A.

A satisfactory fluorometric method of testing for riboflavin has been worked out by Dr. W. R. Aykroyd.

Superficial keratitis due to riboflavin deficiency has been described in India for the first time. Numerous cases were observed in the Government Ophthalmic Hospital, Madras. Typical cases show superficial opacities in the cornea and circumcorneal injection, and complain of a burning sensation in the eyes, photophobia, lacrymation and dimness of vision. The ophthalmic condition is usually accompanied by angular stomatitis and fissuring of the tongue. In males a rough scaly condition of the skin of the scrotum is often observed. The effect of injections of pure riboflavin on the eye lesions is immediate and striking, improvement being often observed within 48 hours or less. A suitable initial dose is 4 milligrammes of riboflavin. Oral administration is less immediately effective than parenteral injection. While relief on treatment with the pure vitamin is usually rapid, there is a tendency towards recurrence when treatment is stopped and the patient returns to his customary riboflavin-deficient diet.

Investigations have been carried out by Dr. N. C. Datta at the Grant Medical College, Bombay, in about 300 clinical cases in order to study the range of changes usually observed in the proteins of the plasma in various pathological conditions and their significance.

Eight cases of nutritional oedema showed that the total protein was much below the normal average, being only 4.7 per cent. The deficiency was entirely due to the albumin fraction, a value of 2.5 per cent based on 15 determinations being obtained. In a few cases of oedema of a severe type in children the globulin was found below to be normal. The oedema of malnutrition in children was found to be successfully eliminated by dietetic treatment, while that in adults appeared to be more resistant to treatment.

More than 50 cases of different types of anaemia showed a general reduction of total protein from its normal average of 7.0 to 5.5 per cent, the albumin fraction being subject to reduction. Twenty cases of anaemia with oedema had an average albumin content of 3.0 per cent. In 5 out of 50 cases the plasma protein was found to be within normal limits.

In connection with leprosy enquiry under Dr. John Lowe at the School of Tropical Medicine, Calcutta, a method has been evolved for obtaining from leprosy material the leprosy bacillus free from tissue. By a combination of physical and chemical methods it has been found possible to isolate the different chemical fractions of the bacilli. Tests with these fractions have shown that protein is the only antigenic fraction, and that it produces an early reaction only. On the basis of this work a test has been evolved using as antigen the acid-precipitated protein of the bacillus. The test with this antigen is at least as sensitive as the Mitsuda test, and has great advantages over it.

It is believed that this new test is of importance. The Mitsuda test takes a month to read and, if positive, causes nodulation and sometimes ulceration. The new test is read in 24 hours, the reaction does not persist, and causes no ill effects. The new test has explained some of the anomalies of the Mitsuda test and with further work may explain more. The new test should do much to facilitate further studies of the immunology of leprosy.

Plague enquiry was carried out under the Director, Haffkine Institute, Bombay. He obtained a large reduction in case mortality by the use of sulphathiazole

and sulphapyridine in comparison with mortality under ordinary treatment. With sulphathiazole case mortality was 22.4 per cent and sulphapyridine 30 per cent; a control series relating to previous experiments had a case mortality of 53.6 per cent. The respective figures in septicæmic cases were 41.9 per cent, 57.5 per cent and 90.6 per cent. Sulphathiazole appeared to give the best results. The optimal dosage was ascertained.

Dr. A. C. Ukil at the All-India Institute of Hygiene and Public Health, Calcutta, studied tuberculosis in relation to industry. A large number of contact cases were examined.

Enquiry into the incidence of positive Mantoux reactions and latent tuberculosis as judged by skiagrams in medical students and nurses was carried out by Major G. F. Taylor, I.M.S., at the King Edward Medical College, Lahore.

From the results it is obvious there is a high rate of latent tuberculosis in medical students at the time they begin their medical work. As these students come from the same classes as officers and others, recruited in the army, it is suggested that the Indian Research Fund Association should take up with the army authorities the need for miniature radiography of all recruits to the army.

The study of the following problems in connection with indigenous drugs enquiry under Bt.-Col. Sir Ram Nath Chopra, I.M.S. (Retd.), at the School of Tropical Medicine, Calcutta, has almost been completed and will shortly be communicated:— (1) hypnotic effects of Rauwolfia alkaloids, (2) pharmacological action of stilbene, (3) cataphoretic velocity of red blood corpuscles and the influence of their environment, (4) rôle of the reticulo-endothelial system in explaining drug action in certain tropical diseases, and (5) sodium and diethyl salts of p-aminophenyl stibinic acid.

The work on the enquiry into anæmia of women in Assam was carried out by Dr. L. E. Napier at the School of Tropical Medicine, Calcutta. Animal experiments in relation to the problem of anæmia were conducted mainly along two different lines. In the first type of experiments, the object was to study the effect of sulphapyridine on the hæmopoietic system; for which purpose 10 monkeys living on the ordinary stock diet of the animal room were used. In all these cases there was evidence of a toxie depression of hæmopoietic function, the intensity of which depended not only on the dosage of the drug but also in some way on the individual susceptibility of the animals as there were considerable variations in the results.

The other line of work was designed to produce anæmia artificially in monkeys by injection of serum containing a specific hæmolysin. The result obtained so far shows that it is possible to produce a condition of micro-spherocytosis, attended with increased fragility and positive indirect van den Bergh as well as a condition of pseudo-macrocytosis during the period of regeneration from anæmia.

More recently experiments have been undertaken in monkeys to produce a state of chronic anæmia, resulting from chronic malarial infection, artificially induced in these animals.

Since January, 77 complete blood counts on monkeys, 69 on 'normals' in Shillong and 362 on anæmic patients have been done under the auspices of the enquiry.

There were two valuable publications:—

(i) *Indian Medical Research Memoir No. 33* on 'Anæmia of Pregnancy in Calcutta' [see p. 503, this issue.]

(ii) *Indian Research Fund Association Memorandum* on 'Anæmia of Pregnancy in India'.

[For reports of other researches carried out during the year and recommendations of the advisory committees one should refer to the original volume.]

Correspondence

PELLAGRA IN THE UNITED PROVINCES

SIR,—Dr. S. K. Ghosh Dastidar in the May issue of the *Gazette*, page 319, writing from Patna on 3rd April, 1942, wishes to draw my attention to the review of Dr. T. K. Raman (1940) and his case report (1941) published in the *Patna Journal of Medicine* and asserts that my statement that 'no cases have yet been reported from Bihar' does not hold good. I am surprised because, (1) he does not appear to have noted the first few lines of my article where I clearly mention that I am reviewing the cases reported during 1928-40—his case was reported in 1941, (2) he appears to have missed or forgotten my statement made at Patna in January 1941 during a lecture-demonstration of my pellagra cases of Bihar and the U. P., at which he was present on the front benches, that the photographs of the U. P. cases were part of my article 'Pellagra in the United Provinces' already sent to the *Indian Medical Gazette* for publication—the article was sent to I. M. G. in September 1940, though published in March 1942, (3) he appears not to have noted my reference to his case in my article, 'Pellagra in Bihar', published in *Patna Journal of Medicine*, January 1942, where on page 1 is mentioned 'in the same year and month Dr. Dastidar reported a definite case of pellagra in Bihar'. Had Dr. Dastidar been careful to note the above facts before raising the points I am sure he would not have felt the necessity of drawing my attention in April 1942 to Dr. Raman's review of 1940, nor to his own case report of 1941 regarding which I knew everything before it was published. It will thus be seen that my statement regarding Bihar as it stands in my article does hold good and is absolutely correct. However, it is gratifying to note that our efforts are bearing fruits,

interest is being created, and other cases are now being, and more will be, detected in Bihar.

N. AHMED,

Divisional Medical Officer,
East Indian Railway.

JAMALPUR,
8th June, 1942.

[Note.—Dr. Ahmed's paper was received for publication on 2nd September, 1940, but for lack of space we had to hold it over until March 1942.—EDITOR, I. M. G.]

LEPROSY INSTITUTIONS IN INDIA

SIR,—Your May 1942 number includes an abstract of the Triennial Report of the Civil Hospitals and Dispensaries in the Central Provinces and Berar for the period ending December 1940. This abstract contains the following sentence:—'The real problem in the attack on leprosy is the occupation of space in leper homes by burnt-out cases to the detriment of cases requiring treatment and hospitalization'. It is not clear whether this sentence appears in the original report or merely represents the opinions expressed in that report, but in any case the statement appears to me to be rather misleading and to display a wrong attitude to the question, an attitude, not confined to this particular province, and not infrequently expressed in public.

Most, if not all, of the leprosy institutions in the province in question were founded by private bodies, usually Christian Missions, and are still run by these bodies with aid from government which meets about half the cost, the rest being met by private contributions (chiefly from abroad). The institutions aim

at providing for persons who, as the result of their leprosy, are in need. Often, in fact usually, on admission the cases are infectious and require treatment and isolation and when not infectious they frequently are disabled from earning their living either by their physical condition or by the social stigma of leprosy. Even 'burnt-out' cases frequently require treatment, surgical and otherwise, which they cannot get elsewhere since for inadequate reasons most hospitals, including government hospitals, will refuse to admit them. Moreover, the cases which were infectious on admission, even when they become non-infectious may find return to their homes difficult or impossible. In providing for these people, the leper homes are doing an excellent work at relatively little public expense, the cost of maintenance being kept far lower than any government organization could keep it, and only a part of this low expense being met by the government.

The control of infectious diseases in a province is or should be the responsibility of the provincial or local administration. The International Congress on Leprosy, Cairo, 1938, stated that the control of leprosy is the inescapable responsibility of the government concerned. The only effective control measure against leprosy is the isolation of infectious cases, particularly those who live and/or work in contact with others, particularly children and young people.

What have most provincial and local administrations in India done towards this end? With a few notable exceptions, little or nothing. It has been left to voluntary bodies to do most of what little has been done, aided it is true by government grants, sometimes rather meagre ones. Such bodies are already assuming a good deal of the responsibility which should normally be borne by provincial governments. It is unjust that they should be blamed because they cannot more completely do the government's work for them.

In the province in question I do not know of a single leprosy hospital, colony or institution which has been established and is maintained by the government, and no real attempt has yet been made to establish government anti-leprosy work on a sound basis. I happen to know that the officers now responsible for the medical and public health work in this province are keen to improve this state of things, and wish to try to apply in their province some of the recommendations of the Report on Leprosy and its Control in India published by the Central Advisory Board of Health. This is a move in the right direction, and I have no doubt that the voluntary institutions in the province will welcome it and will do all they can to help in the work. It is hoped that other provinces in India will adopt a similar policy.

In the meantime non-government agencies should not be criticized for refusing to do what they have never set out to do, namely, to act purely as public health institutions, to confine admission to infectious cases, and to discharge cases as soon as they become non-infectious. Leprosy is a disease with both public health and social aspects and there will always be ample scope for the work of official and non-official agencies to attack the problem from both these aspects. At present the work of non-official agencies is usually greatest in quantity and best in quality. The great need is an improvement in the quality and in the quantity of work of official agencies with a view to making anti-leprosy work an integral part of the medical and public health work of provincial administrations.

JOHN LOWE.

LEPROSY RESEARCH DEPARTMENT,
SCHOOL OF TROPICAL MEDICINE,
CALCUTTA,
24th June, 1942.

[Note.—The sentence in question is a quotation from the report, word for word, except that we corrected an obvious misprint; 'the attack of leprosy' was the actual phrase printed in the report.—*EDITOR, I. M. G.J*

A CASE OF GIARDIASIS

SIR,—I have read with great interest the article, 'A Case of Giardiasis' by H. S. Andleigh, in the June 1942 number of the *Indian Medical Gazette*.

The author reports the striking results of treating a case of giardiasis with atabrin but does not offer any explanation for this, at first sight, surprising result. As this article may lead to further experiments with this method I may perhaps be permitted to suggest that the result obtained might be due to the acridine radical of the atabrin. We know that other acridine derivatives, such as Rivanol, have a very marked effect upon intestinal protozoa.

I consider the point rather important as the use of a highly complex and expensive derivate, such as atabrin, is an unjustifiable waste when equally satisfactory results might be obtained with cheaper and simpler preparations.

CAMP HOSPITAL, SATARA,
28th June, 1942.

A PLEA FOR SMALLER DOSAGE OF SULPHAPYRIDINE IN THE TREATMENT OF PNEUMONIA

SIR,—In the directions enclosed in the packages of sulphapyridine, especially Dagenan (M.&B. 693), the dosage recommended for treatment of acute pneumococcal infection is: two grammes initially, followed by same dose 4 hours later; thereafter one gramme to be given at 4 hourly interval for next 36 hours, then the dose is still reduced or interval prolonged. At any rate, one has to administer at least 14 grammes of the drug within first two days, which, in our opinion, is hardly necessary for an average case of pneumonia in an Indian subject.

Since the introduction of the drug in the treatment of pneumonia, we have extensively used it both in railway hospitals and private practice and it appears to us that in place of the recommended dosage as set forth above, the following dosage is as effective even in a case of moderate severity—when the patient is admitted 1 to 2 grammes according to severity. Thereafter one gramme (two tablets) three times a day till the temperature comes to normal, which usually happens on the third day, then the dose is still reduced according to patient's general condition. This dosage is virtually half of that recommended by the manufacturer, thereby a considerable amount of the drug is saved which is a prime necessity in these days of scarcity, inasmuch as the chance of toxic reactions (such as methæmoglobinæmia, sulphæmoglobinæmia, agranulocytosis and hæmaturia due to formation of insoluble acetyl salts), which are presumably due to a high dosage, administered in an attempt to maintain the maximum concentration in blood, is minimized. It is further possible that by employing the minimum effective dose, the patient's defence mechanism, that is, the cells of the reticulo-endothelial system, gets a chance to rise to the occasion.

Service Notes

APPOINTMENTS AND TRANSFERS

COLONEL G. R. LYNN, C.B.E., D.S.O., I.M.S. (Retd.), is appointed Additional Deputy Director-General, Indian Medical Service (Stores), with effect from the afternoon of the 9th May, 1942.

Lieutenant-Colonel F. H. Whyte is appointed Civil Surgeon, Simla West, with effect from the forenoon of the 11th May, 1942.

Lieutenant-Colonel W. M. Will is appointed Deputy Assistant Director-General (Medical Stores), Medical Store Depot, Bombay, with effect from 18th May, 1942, vice Major W. T. Taylor appointed as Additional Officer, Medical Store Depot, Bombay.

Major W. T. Taylor is appointed Additional Officer, Medical Store Depot, Bombay, with effect from 18th May, 1942, until further orders.

Major G. B. W. Fisher, Civil Surgeon, Dacca, is appointed to act temporarily as Surgeon Superintendent, Presidency General Hospital, Calcutta.

(Emergency Commissions)

To be Lieutenants

John Cameron. Dated 10th January, 1942.
Eric James Currant. Dated 4th February, 1942, with seniority from 3rd May, 1936.

Marraduke Ayscough Fawkes. Dated 4th February, 1942, with seniority from 20th December, 1940.

Anthony Maples. Dated 4th February, 1942, with seniority from 16th December, 1940.

Horace Williams. Dated 4th February, 1942, with seniority from 17th May, 1941.

Gerald Barwell. Dated 14th March, 1942, with seniority from 15th July, 1936.

LAND FORCES

To be Lieutenants (on probation)

Richard Augustine Johnson. Dated 16th March, 1941.

5th March, 1942

Francis Howard McCay.

Alexander Malcolm Kerr.

James Denis Clinton Currie. Dated 6th April, 1942.

(Emergency Commissions)

To be Lieutenants (on probation) for service in the Indian Air Force

6th March, 1942

Nariman Hormusji Oonvala.

Dossabhoy Bomanji Parakh.

Simadri Prasun Chatterjee. Dated 8th March, 1942.

Mihir Kumar Mitra. Dated 27th April, 1942.

INDIAN LAND FORCES

(Emergency Commissions)

To be Lieutenants (on probation)

Rustam Ardeshir Dayar. Dated 19th May, 1942.

Mallimadugula Venkata Ramanamurti. Dated 13th May, 1942.

LEAVE

Lieutenant-Colonel W. J. Webster, M.C., Assistant Director, Central Research Institute, Kasauli, is granted leave on medical certificate for 5 months, with effect from the 4th March, 1942.

PROMOTIONS

Captain to be Major

V. M. Albuquerque, M.B.E. Dated 5th June, 1942.

The undermentioned Captains (on probation) are confirmed in their rank, with effect from the date specified.

24th August, 1941

R. U. Qureshi.

W. A. C. Nason.

INDIAN LAND FORCES

(Emergency Commissions)

Lieutenants to be Captains

A. R. Biswas. Dated 25th March, 1941.

E. A. Ram. Dated 15th October, 1941.

M. C. Nath. Dated 24th August, 1941, with seniority from 14th June, 1941.

The undermentioned Lieutenants (on probation) are confirmed in their rank, with effect from the date specified:—

27th February, 1941

F. J. Bilimoria.

RETIREMENTS

Lieutenant-Colonel N. S. Jatar, C.I.E., D.S.O., Inspector-General of Prisons, C. P. and Berar, has been placed on the retired list with effect from 26th May, 1942, and re-employed by the Provincial Government as Inspector-General of Prisons, C. P. and Berar, with effect from that date for a period of 2 years or until the end of the war whichever is earlier.

Lieutenant-Colonel M. A. Nicholson, C.I.E. Dated 10th June, 1942.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to The Editor, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

QUININE DIURESIS IN MALARIAL CONDITIONS

By ROBERT HEILIG, M.D.

First Physician, Kriahmarajendra Hospital, and
Professor of Medicine

and

VISWESWAR, M.D., B.S.

Research Scholar

Medical College, University of Mysore

SINCE the occurrence of malarial nephritis in India was reported and the excellent diuretic action of quinine in this condition was established (Heilig, 1941), ten more cases came under our observation, where quinine proved to be the only effective diuretic. As very little is known about the diuretic effect of quinine up to now, two different cases of this group may be described in some detail.

Case 1.—K. Gowda, a Vokaligar boy of 5 years, was admitted to the hospital because of a rapidly progressing swelling of the face, legs and abdomen, which had started some three weeks previously. Urine was said to be very scanty and high coloured. The father stated that the boy had suffered from attacks of rigor and fever at irregular intervals of two to three months for the past half a year; each attack lasted eight to ten days.

On examination the most striking features were œdema of the face, with swelling of the eye lids, severe œdema of penis, scrotum, abdominal wall and legs, pitting on pressure; the abdomen was protruberant due to a huge ascites, which everted the umbilicus. Clinically and radiologically the heart and lungs did not show any pathological signs, except for those due to the very elevated diaphragm. Pulse rate 120, blood pressure 110/70 mm. Hg. The liver was apparently not enlarged; the spleen seemed to be floating in the ascites, but the œdema of the abdominal wall prevented one from feeling it distinctly. Neurological signs were not elicited. The temperature was intermittent febrile, reaching 102° to 103° daily for three days, afebrile for one to two days, and rose again as before. A purulent discharge was noticed from the left nostril; the subsequent removal of the rhinolith had no influence on the fever.

Fundal examination : nothing abnormal.

Laboratory findings :

Urine :

Specific gravity	..	1032
Albumin	..	+++
Sugar	..	absent
Urobilinogen	..	increased

Microscopic :

Red blood cells	..	++
Leucocytes	..	+
Hyaline casts	..	++
Granular casts	..	+++

Culture : No growth.

Motion : Among six examinations (within two weeks), once a few hookworm ova were found.

Blood : Hæmoglobin 37 per cent (Sahli); urea—40 mg. per cent.; Wassermann, Kahn and Kline reactions—negative; malarial parasites—not found; malaria flocculation test—positive.

The patient was put on diuretic mixture, one ounce thrice a day. The diet consisted of milk and bread. After one week's treatment, the weight remained

unaltered, the general condition unchanged. Diuretic mixture was replaced by ammonium chloride, potassium acetate, gr. 10 each, three times a day; the latter was increased to gr. 15, thrice a day, the following morning. The weight was not reduced after five days of this medication; thyroid, gr. $\frac{1}{2}$, thrice a day, was added. In spite of all these efforts to diminish œdema and ascites by using all possible diuretics, the weight was 41½ pounds after two weeks of treatment—½ pound less than on admission. The general condition became unbearable; the boy could neither sit nor lie down; the general anasarca made every movement and every position equally impossible. An irregular, intermittent fever persisted. Albuminuria, hæmaturia and cylindruria increased.

The positive malaria flocculation test, the fever and the lack of response to any diuretic treatment, together with previous experiences in similar cases (Heilig, *loc. cit.*), induced us to start antimalarial treatment and to stop every other medication. The boy was put on quinine sulphate, gr. xv a day; the temperature became normal overnight and remained so for at least six weeks, the duration of observation. After three days, for the first time, the weight dropped to 39 pounds; the urine quantity increased slowly, the specific gravity diminished from 1030 to 1012. To speed up and to intensify the effect of the oral quinine medication one quinarsol injection (1 c.cm.) was given every day intramuscularly. The urine quantity increased from 300–600 to 1200 c.cm., the specific gravity varied between 1010 and 1014; within sixteen days of this treatment, the patient lost 15½ pounds = 35 per cent. of his body-weight, which was reduced from 41½ to 25½ pounds. Ascites and œdema disappeared entirely. The spleen became distinctly palpable, three-finger breaths below the left costal margin; subsequently its size diminished to one finger below the costal margin. The girth width diminished by 8 inches from 27.5 to 19.5 (table I). Hæmoglobin remained 38 per cent (Sahli); blood urea diminished slightly to 36 mg. per cent. The child which had refused to take any food before the antimalarial treatment, could not get enough to eat; it became bright and active. Three weeks after complete elimination of all the retained fluid and stopping of antimalarial treatment, carbon tetrachloride was given; two hookworms were passed. Subsequent examination of five motions on alternate days did not show any hookworm ova.

The observation in the hospital was continued for another week; during these four weeks after quinine treatment was stopped, the clinical improvement was fully maintained. The urine showed on repeated examination no pathological deposit; red blood cells and the very numerous casts had disappeared but albuminuria remained; this fact shows that, in spite of all the surprising success of the quinine treatment, a complete cure of the nephritis was not achieved.

Case 2.—Ch., a Hindu coolie, 28 years of age, was suffering from attacks of fever, preceded by rigors, for many months; each of those febrile periods lasted for 10 to 15 days and was separated from the next attack by an afebrile interval of two to three months. About

two months before admission, patient noticed swelling of the legs, which gradually increased; later on, the size of the abdomen increased to such an extent that he was hardly able to bind his dhoti. The fairly well built young man was moderately anæmic; the heart (clinically and radiologically) slightly enlarged; apex beat just inside the mid-clavicular line; a faint systolic

Motion: Hookworm ova present (a few).
Blood: Hæmoglobin 23 per cent (Sahli); red blood cells—2.2 millions; urea—28 mg. per cent; van den Bergh—negative; Wassermann, Kahn, Kline reaction—negative; malaria parasites—not found; malaria flocculation test—positive; sedimentation rate—25/55.

murmur was audible in the mitral and pulmonary auscultatory area; no accentuation of the heart sounds was present. Pulse rate 80; blood pressure 108/70 mm. Hg. Respiratory system did not show any pathological signs.

The abdomen was prominently protuberant; all signs of a large amount of free fluid were elicited. The liver was not palpable. The spleen reached one and a half hand breadths below the left costal margin and floated in the ascites. The pitting œdema of the legs extended from the ankles up to the thighs. Patient was afebrile during his whole stay at the hospital. Body-weight on admission 139 pounds.

Laboratory findings:

Urine:

Specific gravity	..	1031
Albumin	..	slightly positive
Sugar	..	absent
Urobilinogen	..	highly positive
Bilirubin	..	absent
Microscopically	..	nothing abnormal
Bacteriologically	..	no growth

To see whether the general anasarca could be reduced by rest and bread-and-milk diet the patient was kept under these conditions for six days; the only remedy which we gave were Bland's pills, gr. 90 per day; the weight was diminished only by 1½ pounds (139–137½). Diuretic treatment was started on the seventh day by giving, apart from the iron medication, ammonium chloride, gr. 45, and urea, drachms 15 per day; the diet consisted of milk and bread as before. Under this medication the patient's weight was reduced by 20 pounds, from 137½ to 117½, in thirteen days; in spite of the continuation of this treatment, the weight remained now constant for five days; neptal was injected; patient lost ten pounds in 24 hours and gained eight again (115 lb.) in the following five days, though the dosage of ammonium chloride was

increased to 75 grains and 2 ounces of urea were still given every day.

Meanwhile a hæmoglobin level of 45 per cent (Sahli) was reached; carbon tetrachloride was given; the patient passed some forty hookworms and none of the subsequent stool examinations showed any worm ova.

perature and the absence of a malarial nephritis; even the slight albuminuria had meanwhile subsided.

Patient received ten quinine injections intravenously (gr. 5, 7 and eight times gr. 10) on ten consecutive days, along with quinine sulphate orally, gr. 10 per day; the oral quinine

Four weeks after admission, after three weeks of ammonium chloride-urea treatment, which had reduced the weight by twenty pounds but failed to reduce it further, even in spite of the use of neptal, the œdema of the legs had disappeared, but a marked ascites was still present. Because of the long history of previous fever attacks of apparently malarial origin, the large spleen and the positive malaria flocculation test, we decided to try quinine medication as diuretic treatment, in spite of normal tem-

perature and the absence of a malarial nephritis; during this treatment the urine quantity did not increase appreciably, as far as we could persuade the patient to collect the urine; but the specific gravity which was never lower than 1023 and mostly near 1030 during the previous diuretic treatment, dropped to 1015; the weight diminished by another sixteen pounds and was 99½ the last day of quinine treatment. The following week it varied between 98 and 100 pounds (table II).

The ascites vanished to the last drop; the contour of the spleen could be seen through the abdominal wall, though its size was slightly diminished. The hæmoglobin which was 45 per cent before the antimalarial treatment was started, increased to 50 per cent (Sahli) on its termination.

Discussion

To ascertain the diagnosis 'malarial nephritis' in case 1, we have only to exclude the hookworm infection as a cause of the general anasarca. It is beyond doubt that two hookworms do not produce any pathological signs, and certainly not such a marked fluid retention; hookworm disease never causes nephritis among our patients. A hæmoglobin content of 37 per cent (Sahli) never causes anasarca, even when such a hæmoglobin level is due to a hookworm infestation. Further, all the retained fluid was eliminated without any increase of hæmoglobin and before deworming; the anthelmintic treatment was performed three weeks after the antimalarial treatment was stopped and the presence of the hookworms did not prevent the achievement and the maintenance of the full clinical improvement. The absence of any other detectable ætiology of the subacute glomerulo-nephritis of the wet (or nephrotic) type, the excellent response to quinine treatment as far as fever, urine sediment and the total elimination of anasarca is concerned, taken together with the refractory response to any other diuretic treatment, make certain that malarial nephritis is the correct diagnosis.

The analysis of case 2 shows that the general anasarca in this case was due to two different factors. The one responded to ammonium chloride *plus* urea, given simultaneously in large doses; this medication was found to be the most effective diuretic treatment in anasarca due to hookworm disease (Heilig, *loc. cit.*). Twenty pints of œdema fluid were eliminated by those diuretic remedies. Was this part of the general anasarca due to the hookworm infestation? It is possible. The hæmoglobin value on admission was 23 per cent (Sahli) and increased to 45 per cent along with the reduction of the œdema; but in spite of the normalized blood condition, almost one-half of the retained fluid remained uneliminated; the ascites hardly diminished, in spite of the most intensive use of diuretics, mercurials included. And finally, the result of deworming proved that the hookworm population was very scanty, hardly sufficient to cause such a hypoproteinæmia that general anasarca should be its consequence. Whether we call the œdema producing factor, which yielded to ammonium chloride *plus* urea, ancylostomiasis or an unspecified toxin which increased the permeability of the capillaries and was responsible for the appearance of œdema in the legs, the other factor was related to chronic malaria and

maintained the ascites practically undiminished. The weight chart shows that but for the use of large doses of quinine, applied by intravenous and oral routes, the peritoneal effusion of this man seemed refractory to any treatment; he would have been one more of those unfortunate cases, frequently found in this part of the country, for whom tapping of the abdomen in shorter and shorter intervals brought the only possible relief. It is impossible, at present, to state definitely how the antimalarial treatment caused the elimination of the ascitic fluid. The fact that fever attacks of definite malarial origin occurred up to two months before the patient came to the hospital, shows that the irreversible fibrotic changes which develop in the spleen of chronic malaria cases had not much time to develop. The reduction of the size of the spleen which was noticed under the course of quinine is a further proof that the malarial changes were partly reversible. It is not far-fetched to assume that with the reduced volume of the spleen, the intra-abdominal pressure and especially the impairment of the portal circulation diminished to such an extent that a resorption of the effusion became possible. Considering the frequent incidence of cases with ascites, collateral circulation and large spleen among our patients, cases which do not belong to Banti's disease as no hæmatemesis ever occurs, it is of the greatest importance to stress their malarial origin, as early anti-malarial treatment saves them; whereas later on, when the enlargement of the spleen has become permanent due to the development of the firm connective tissue, spreading to and obstructing the portal branches, no treatment is of any avail.

The literature on malarial nephritis was ably surveyed by Giglioli (1930). Working in British Guiana, he found that kidney complications in malaria are almost specifically connected with *Plasmodium malariae*; that is also the experience of Clark (1912), regarding nephritis in Malaya, and the opinion held by Manson-Bahr who with Maybury (1927) reported two cases of nephritis, accompanying quartan malaria. In India, malarial nephritis was apparently not observed prior to the report from Mysore (Heilig, *loc. cit.*), though temporary albuminuria was noticed, 'especially towards the end of febrile paroxysms' (James, 1922) and ascribed partly to the use of quinine and alkaline mixtures (Sinton and Lal, 1924). However, the opinion that malarial kidney affections are practically confined to areas where quartan malaria is predominant is definitely at variance with our local experience; quartan malaria is a rarity among our patients and apart from one case, mentioned previously (Heilig, *loc. cit.*), no suspicion of *Plasmodium malariae* infection was substantiated from the history of our patients; when malarial parasites were actually found, they were *Plasmodium vivax*. The same

fundamental difference as between the ætiological factors is found in the therapeutic response. Manson-Bahr and Maybury and Giglioli seem to be the only modern authors who treated malarial nephritis with quinine; they are agreed upon the excellent effect of it on the nephritis and its manifestations (blood urea); but regarding the œdema in acute and subacute cases of wet type, Giglioli recommends the use of urca; he does not mention the diuretic effect of quinine anywhere. In chronic cases he found antimalarial treatment useless. We, on the other hand, emphasize that quinine is not only indicated in every renal affection, acute or subacute, which accompanies acute or subacute malarial conditions, the latter characterized by an occasional fever attack with long afebrile periods, but also where there was no sign of activity of the malarial process detectable. In cases where nothing but the large spleen and mostly, though by no means always, a positive malaria flocculation test point towards the malarial origin of ascites or general anasarca, a course of intensive quinine treatment with maximal doses should be started immediately. Case 2, reported above, is one of eight where not the slightest rise of temperature was noticed during weeks of observation; to base on afebrility the assumption that antimalarial treatment should not be tried is wrong; the same case shows also that quinine might act as a most potent diuretic in apparently chronic malarial affections with ascites and without any sign of nephritis, cases which are usually labelled as malarial cachexia or malarial cirrhosis (?) and which are hardly ever treated as malaria.

Conclusion

Under local conditions malarial nephritis occurs as a manifestation of benign tertian malaria; it is in no way bound on the distribution of *Plasmodium malariae*. It is encountered as an acute or subacute glomerulo-nephritis, wet or nephrotic type. Apart from these renal forms or complications of malaria, cases are seen of apparently inactive (chronic) malaria, characterized by a very considerable enlargement of the spleen, malaria flocculation test frequently positive and a huge ascites or general anasarca without signs of renal damage. In all these manifestations of malaria, quinine in full doses (preferably as an intravenous injection) is clearly indicated; it acts in most of these cases as a powerful diuretic, superior to all other diuretic remedies, which we had tried prior to its application; in some of these conditions of malarial dropsy it is the only effective diuretic. Though we do not assert that the cases of subacute nephritis or those of a late malarial ascites are cured by this treatment, the clinical improvement is so considerable that every patient of this kind should be given this chance.

DIAGNOSIS AND PATHOLOGY OF TRACHOMA IN INDIA

By R. E. R. MITTON, D.O., F.R.C.S.

and

M. K. BEATTIE, M.D.

Lady Hardinge Medical College, New Delhi

THE following investigation was done as a preliminary measure in an attempt at assessing the percentage of trachoma in Delhi's school population by the rapid examination of school children. It is now published in the hope that the information gained may be of use in the rapid estimation of trachoma in the examination of recruits. The routine practised in the schools was simply examination of the cornea and the lid conjunctiva after eversion of the lids in good daylight, or artificial light, with the aid of a binocular loupe or prismospheres. In the thirteen cases which were fully investigated, naked-eye examination was followed by examination of the conjunctiva and cornea with the slit lamp and corneal microscope. This in turn was followed by examination of an epithelial scraping from the upper fornix. Finally, biopsy was done on a specimen of conjunctiva snipped off the outer third of the upper fornix. This

(Continued from previous column)

Summary

One case of malarial subacute glomerulo-nephritis, nephrotic type, and one of general anasarca in an old afebrile malaria are reported in some detail. In both of them quinine, given in massive doses, was found to exert a diuretic action, superior to all other diuretic remedies administered in these cases.

These experiences are compared with those previously published.

Our thanks are due to Dr. J. F. Robinson, B.A., M.D., F.A.C.S., F.R.C.S.E., Medical Officer, Krishnarajendra Hospital, and Principal, Medical College, University of Mysore. Experience of many years in this country taught him that quinine treatment may yield most unexpected success in nephritis, whenever a malarial infection—even without any obvious sign of activity—is present; this experience gained by him stimulated our investigations.

site was chosen as one of the writers (R. E. R. M.) has come to the conclusion, after many slit-lamp examinations of trachomatous eyes, that trachoma remains active longest in the outer third of the upper fornix. Examination of these sections of conjunctiva led to the desire to follow the disease into the tarsal plate, and in part II of this paper one of us (M. K. B.) has described the findings in trachomatous conjunctiva and also in deformed tarsi removed in cases of advanced cicatrization.

appearance may look like 'roughening' of the conjunctiva before this stretching test is applied. A positive result on stretching is tabulated in column IV as 'granules on compression'. In column V the presence of fibrotic network, stars, and Arlt's line are classified as 'fibrosis'. The last step in the naked-eye examination was to investigate the cornea after the lids had been replaced and the upper lid drawn up by thumb pressure upwards on the eyebrow. These findings are noted under three headings: (a)

PART I

TABLE I

Number	CONJUNCTIVA OF UPPER LID					CORNEA			SLIT-LAMP EXAMINATIONS	
	Congestion	Hypertrophy	Projecting granules	Granules on compression	Fibrosis	Broadening	Vessels	Herbert's pits	Conjunctiva	Cornea
1	+	+	-	+	+	+	-	+	Gelatinous area and granules. Patches of oedematous network. Much fibrosis.	Long vessels. Infiltration. Pits.
2	-	+	-	?+	-	?+	-	-	Snowy honey-comb. Occasional large granules.	Superficial infiltration and pigmentation. Vessels not lengthened.
3	-	+	-	+	+	+	-	+	Gelatinous areas and much fibrosis.	Long vessels. Infiltration. Pits.
4	+	+	-	-	-	+	-	-	Gelatinous honey-comb.	Long vessels. Round maculae. Pigmentation.
5	+	+	-	-	?+	-	-	-	Gelatinous thickening. Oedematous network.	Short vessels. Pigmentation.
6	+	+	-	+	-	+	-	-	Honey-comb, ill-marked fibrotic stars. Occasional gelatinous granule.	Much infiltration. Long vessels. One limbal granule.
7	+	++	+	+	-	+	+	+	Large granules with yellow infarcts (fatty degeneration). No fibrosis.	Long full vessels. Infiltration. Pits.
8	+	+	+	+	-	?+	-	-	Large translucent granule. Very congested honey-comb.	Long vessels and much infiltration.
9	-	+	-	+	-	?+	-	-	Mainly snow-white honey-comb. Outer third red and oedematous.	Vessels and infiltration but not extensive.
10	-	+	-	+	+	+	-	+	Honey-comb with large tufts—oedematous papillary in outer third. Occasional gelatinous granule.	Long vessels. Superficial infiltration. Pits.
11	-	+	-	?+	-	-	-	-	Oedematous papillary appearance with white honey-comb in centre. A few gelatinous granules.	Long vessels. Infiltration in form of many maculae.
12	+	+	+	+	-	?+	-	-	Honey-comb with fading tufts. Raised amyloid network.	Long vessels. Superficial and gelatinous looking infiltration.
13	-	+	-	+	+	?+	-	-	Honey-comb still vascular. Oedematous in outer third. Occasional gelatinous granule, well-marked fibrotic bands.	Long full vessels. Infiltration.

In table I the first two columns show the findings on naked-eye examination after eversion of the lids. The presence of obvious granules is noted in column III. With the upper lid still everted the thumb was placed behind the everted tarsus which was then stretched on the thumb nail. Small granules otherwise invisible were demonstrated in this way, also fine fibrotic markings between the granules. To the naked eye this

broadening of the limbus, (b) vascularization, (c) presence of Herbert's pits or actual granules.

The terminology used in recording slit-lamp findings is probably rather personal to the author (R. E. R. M.) and so requires elucidation. Granules or follicles are easily recognized, their colour varying from grey to amber translucency and occasionally a fatty yellow. In earlier cases each future follicle is represented by a

TABLE II

Number	Presence of inclusion bodies in epithelial scraping	Report on section
	Giemsa	
1	Green granules and plasma cells.	Epithelial hyperplasia. Sub-epithelial lymphocytic infiltration. No follicles.
2	..	Epithelial hyperplasia only.
3	..	Papillary epithelial hyperplasia. Mast cells ++. Epithelial cysts. Fibrotic nodule.
4	Green granules.	A few accumulations of lymphocytes. Fibrotic nodule.
5	..	Epithelial hyperplasia. No follicles. Scanty new fibrous tissue.
6	..	Irregular hyperplasia of epithelium. Much fibrosis. Mast cells numerous. Large follicles.
7	..	Irregular hyperplasia of epithelium. Generalizes sub-epithelial infiltration. A few follicles. Early fibrosis. Epithelial cysts.
8	..	Papillary hyperplasia of epithelium. Large follicles. Mast cells in fibrous cone of nodule. Tendency for formation of fibroblasts at periphery of nodules.
9	..	Papillary hyperplasia of epithelium. Sub-epithelial lymphocytic infiltration. Deep fibrous tissue. One fibrous nodule.
10	..	Papillary hyperplasia of epithelium. Sub-epithelial lymphocytic infiltration. Lymphoid follicles. Tendency to epithelial cysts. Fibrous tissue present.
11	? initial body.	Irregular hyperplasia of epithelium. Polymorphs in epithelium. Sub-epithelial infiltration. Small epithelial cysts.
12	..	Hyperplasia of epithelium. Sub-epithelial lymphocytic infiltration. Loose fibrosis.
13	..	Hyperplasia of epithelium with slight degree of papillary hypertrophy. Sub-epithelial lymphocytic infiltration. No follicles. Early fibrosis. Many mast cells.

'tuft', a small vertical plume of vessels. In comparison, the infiltrated conjunctiva between the tufts appears as a paler honey-comb. Fresh tufts are pink, succulent, very definitely raised, and close together. They are difficult to isolate as separate eminences and are here put under the name of 'œdematous network'. The tissue between the tufts in other cases becomes whiter and more opaque, and in this form may be called 'amyloid honey-comb'. Later still, when the tufts atrophy the honey-comb becomes denser and whiter, 'snowy honey-comb'. Last of all cicatrization is seen as a condensation of this network, in other cases as star formations of fibrous tissue which appear to be superficially placed and are probably in the conjunctiva rather than the tarsus.

TABLE III

Out of 13 cases :

- (a) 7 have congestion of the lid conjunctiva.
- (b) All 13 show hypertrophy.
- (c) 3 have obvious granules.
- (d) 9 have granules on compression.
2 are doubtful as to the presence of granules on compression.
2 have no granules on compression.
- (e) 12 have elongation of limbal vessels.
- (f) 12 have pathological changes which may be accepted as characteristic of trachoma.

Of the two cases which have no granules on compression, one (case 4 in table I) shows congestion and hypertrophy of the upper fornix and broadening of the limbus. In the slit-lamp report on this case, only gelatinous honey-comb and long vessels on the cornea are visible. However, these vessels may be accounted for by the presence of a macula. The pathological report, a few accumulations of lymphocytes and one fibrous nodule, is also not conclusive regarding the presence of trachoma. In the second of these two cases, case 5 in the table, there are no corneal signs in either the naked-eye and slit-lamp reports, and there is doubt also in the pathological report where no mention is made of sub-epithelial hypertrophy or nodules. If the combination of pannus, epithelial hypertrophy, and sub-epithelial lymphocytic infiltration of the conjunctiva is taken as positive proof of the presence of trachoma, then in this series of thirteen cases of hypertrophy of the fornix twelve are definitely trachomatous. Three only of these thirteen have obvious granules visible on ordinary eversion of the upper lid, while eleven show granules by compression.

Conclusion

Stretching of the everted upper lid is of help in the routine diagnosis of trachoma.

PART II

That different types of trachoma may exist in different parts of the world has been suggested. It has been stated, for example, that in American Indians the predominating cell in the trachoma follicle is an epithelioid cell, whereas in Europe and Egypt the lymphocyte and plasma cell predominate, with a few epithelioid cells in old cases (May, 1928). It has also been said that in some countries a form of trachoma may occur in which lymph follicles are never observed, but instead a generalized sub-epithelial infiltration with lymphocytes (MacCallan, 1936).

As there is no record of the histopathology of trachoma as seen in this country, it was decided to study a number of consecutive cases, in order to ascertain what were the predominating features and to note what difference, if any, existed in the histology of trachoma as seen in the north of India and that described by workers in other parts of the world.

The most easily available material for the investigation was the upper tarsal plate, excised at operation for the correction of entropion and trichiasis, and specimens of lacrimal sac, removed for dacryo-cystitis associated with trachoma. More recently biopsies from the conjunctiva have been examined in order to ascertain the earlier changes.

Material.—Thirteen tarsi, classified clinically according to MacCallan's classification as trachoma III and IV, were examined, as well as eight specimens of lacrimal sac.

Methods.—The specimens were fixed in 5 per cent formal saline, embedded in paraffin and stained with hæmatoxylin and eosin for general structure, with van Gieson's stain for fibrous tissue, with a modification of Giemsa's method for inclusion bodies and mast cells. In a few cases carbol thionin (modified technique) was employed for rickettsia, and toluidin blue for the heparin granules of mast cells.

The tarsi were cut parallel with the lid margin and included the conjunctiva. The upper eyelid of a still-born infant was removed and sectioned in the same way, in order to compare the normal tarsus, before changes secondary to outside stimuli of mechanical or infective nature might occur. A tarsus was also removed *post mortem* from an adult in whom no disease of the eye was manifest. This served as a comparison of a normal tarsus which had come into contact with the usual irritation and infections to which the conjunctiva is exposed during life. Photomicrographs of these two tarsi and a trachomatous tarsus were taken, in order to illustrate the gross changes in the tarsus.

Gross changes.—The marked increase in thickness due to hyperplasia of the conjunctiva epithelium, infiltration with chronic inflammatory cells and the formation of new fibrous tissue is well illustrated in photo 1. The presence of a lymphoid follicle seen on the right would seem to indicate that the disease is still active in this case. The distortion of the tarsus due to cicatricial contraction is evident. Photo 2 is a section of a lacrimal sac, showing a large lymphoid follicle projecting into the cavity of the sac. A generalized thickening of the wall of the sac can be seen in this photograph.

Detailed histology.—In all the specimens examined profound changes were noted and will be described in detail under separate headings.

1. Epithelial layer.
2. Sub-epithelial layer.
3. Tarsus proper including Meibomian glands.
4. Blood vessels.

1. **Epithelial layer.**—Obvious disturbance of the tarsal conjunctiva was found in all cases. Some specimens showed a marked epithelial hyperplasia, with a stratified arrangement, and flattening of the surface layer, others showed a flattened epithelium with only a few layers, and in some cases only one layer in thickness, while yet another variety was a papillary formation

with strands of epithelium penetrating deep into the sub-epithelial layer and the formation of epithelial cysts. All of these changes might be found in one and the same tarsus representing no doubt different stages of the disease. The changes correspond on the whole with the description given by Lamb (1935). The lining epithelium in the specimens of lacrimal sac showed a similar type of change. In these, however, the cells were columnar, much mucoid degeneration was present and many goblet cells were seen. Cysts formed by down growths of epithelium and the glueing together of the opposing surfaces of epithelium could be clearly made out (see photos 3 and 4). These epithelial cysts were very numerous in some specimens of tarsus and were relatively large; the lining epithelium was often several layers thick, but sometimes was composed of a single flattened layer. In some cases these cysts could be seen quite deep in the tarsus with no apparent connection with the surface and often showing degenerative changes. They were, however, always situated superficial to the Meibomian glands, i.e., nearer the conjunctiva, and were quite different in appearance from retention cysts of those glands. The latter were more discrete and showed no encircling inflammatory reaction, while the epithelial cysts were generally surrounded by a dense small round cell infiltration (see photos 5 and 6). These are what Michail describes as intra-tarsal epithelial cysts.

2. **Sub-epithelial layer.**—In all cases a generalized sub-epithelial infiltration with lymphocytes and plasma cells was present. This varied in intensity from specimen to specimen and from one part of a specimen to another. Such cells were found to aggregate around epithelial cysts, to form dense clumps or definite lymphoid follicles. The follicles were composed of large cells with pale nuclei (lymphoblasts) in the centre and, towards the periphery, small lymphocytes and plasma cells. A few phagocytic giant cells (Leber cells) could usually be detected in the centre (photo 7). In many cases numerous fibroblasts were present, and a gradual replacement of inflammatory cells by fibrous tissue was apparent. These changes are essentially the same as those described by Wilson (1932) in Egypt and by Michail and others.

3. **The tarsus proper.**—Acini of Meibomian glands unaffected by any inflammatory change were seen in some parts of most tarsi. Scanty lymphocytic infiltration was seen in connection with these glands. The chief change was hyperplasia of the lining epithelium of the ducts and glandular acini. It was obvious in some specimens that the changes first appeared in the ducts, as the ducts showed early hyperplasia while the glands were still normal. In advanced cases ducts were seen obliterated by these cells and glandular acini entirely replaced by them, often with central cystic degeneration (photos 8 and 9). The end results appeared to be either

Fig. 11.

Fig. 1.—Electrocardiogram taken during an attack of paroxysmal tachycardia. Rate of heart : 200 per minute. The individual complexes display notching and a diphasic character. (Date of tracing : 14-4-40.)

Fig. 2.—Electrocardiogram, showing apparent bundle branch block with short P-R interval, wide QRS complexes and shurred and notched S deflections. (Date of tracing : 15-4-40.)

Fig. 4.—4-lead electrocardiogram taken a few hours before death, showing monophasic downward deflections in leads 2, 3 and 4 with 'doming' of S-T and flattening and inversion of the T waves. The duration of P-R has increased to 0.22 sec. (Date of tracing : 31-7-40.)

Fig. 3.—Electrocardiogram, showing apparent bundle branch block (right-sided) and ventricular extra-systoles. The short duration of P-R and the widening of the QRS complexes are characteristic. (Date of tracing : 22-4-40.)

retention cysts (photo 10) or obliteration of the glands, the new cells having been gradually replaced by fibrous tissue. In a few cases calcification of acini was seen to have occurred. This epithelioid infiltration of acini and ducts has not been described elsewhere. MacCallan (1936) states that the inflammation of the sub-epithelial tissue leads to blockage of the ducts of sebaceous or Meibomian glands; either by cell pressure or by cicatrization, but it would appear in this series that the ducts are blocked more often by a proliferation from inside the duct than from outside pressure or contraction.

4. *Blood vessels.*—The condition of the blood vessels varied considerably according to the stage of reaction present. In some cases numerous large dilated vessels were seen, in or deep to the sub-epithelial layer, in some numerous fine capillaries, close to the conjunctiva and in association with the follicles predominated. When much infiltration with small round cells was present the vessels were noted to have a hyperplastic endothelium, while in the cicatricial areas an obliterated process appeared to be occurring.

Further points of note.—In the Giemsa-stained sections, degenerative changes in the cytoplasm of the epithelial cells, and the cells in the lymph follicles, with much scattered cellular debris forming irregular granules of varying sizes between and inside cells, were a prominent feature. The enormous number of tissue mast cells present was also noteworthy. These were present where fibrous tissue was abundant and in approximation to the walls of blood vessels. Few were seen in follicles, and practically none in the epithelial layers or in the glands (photo 11). The presence of these cells in chronic inflammatory conditions including trachoma, and to a lesser degree in connective tissue generally, has been noted by various observers. J. E. Jorpes (1939), in discussing the chemistry and physiology of heparin, produces evidence to show that the basophil granules of mast cells constitute the anti-coagulant heparin, and can be stained specifically by toluidin blue. For this reason some of the sections were stained with toluidin blue and it was found that the mast cell granules, which were so prominent when stained by Giemsa, were also stained by toluidin blue and presumably therefore represent heparin. In tissues where cell disintegration is so notable a feature, the presence of large amounts of available heparin suggests that its function may be that of neutralizing the kinase liberated by cell disintegration, and the consequent prevention of coagulation of tissue fluids.

No Halberstaeder-Prowaczek bodies were detected in these sections; and no rickettsia.

Summary

The histology of specimens of tarsus and lacrymal sac, infected with trachoma, is described.

(Concluded at foot of next column)

A CASE OF MITRAL STENOSIS WITH APPARENT BUNDLE BRANCH BLOCK, SHORT P-R INTERVALS AND ATTACKS OF PAROXYSMAL TACHYCARDIA

(THE WOLFF, PARKINSON AND WHITE SYNDROME)

By RUSTOM J. VAKIL, M.D. (Lond.), M.R.C.P. (Lond.),
D.T.M. & H. (Lond.), F.R.F.P.S.G.

Honorary Assistant Physician, J. J. Hospital, and Tutor,
Grant Medical College, Bombay; sometime First
Assistant, Heart Hospital, Liverpool

THE following case is presented because of its apparent rarity and for the unusual electrocardiographic pictures it presents.

(Continued from previous column)

The main features are :—

1. Epithelial hyperplasia with formation of epithelial cysts.
2. Sub-epithelial lymphocytic infiltration both diffuse and aggregated into follicles, often with definite germinal centres.
3. Epithelioid hyperplasia in Meibomian glands and cyst formation.
4. Cellular degeneration and the presence of large numbers of tissue mast cells.
5. No Halberstaeder-Prowaczek bodies were detected.

Case Report

Mrs. D., a Khoja lady, aged 39, was first seen on 14th April, 1940, with a history of severe palpitation and shortness of breath of five days' duration. She had been in perfect health till 1935, when she had a similar attack of palpitation and dyspnoea lasting for two days. After the attack in 1935, she had an electrocardiogram taken; this showed widened QRS complexes with broadening and slurring of the S waves and frequent ventricular extra-systoles; in fact, the old electrocardiogram was identical with the recent tracing taken on 22nd April, 1940. A teloradiogram taken in 1935 showed a normal sized heart with some prominence of the pulmonary conus. Though she had suffered from vague aches and pains in childhood, there was no history of rheumatism.

She developed her second attack of palpitation quite suddenly on the 9th April, 1940, while attending to her household duties and in apparently the best of health. Besides severe palpitation and a feeling of 'fluttering' in the chest, there was throbbing in the neck, a feeling of faintness and exhaustion, profuse sweating and difficulty in breathing. Two days later, she developed abdominal discomfort with pain in the right hypochondrium. She was given large doses of digitalis by her attending physician.

When seen by me for the first time on 14th April, 1940, the patient was intensely dyspnoeic and lay supported in the semi-recumbent position with pillows. The face was drawn and pale, while large beads of perspiration were visible on her forehead and face. Cyanosis was apparent in the ears, lips and nose. There was slight oedema of the ankles and definite puffiness of the lower eyelids. In the neck, prominent and obviously distended jugular veins were pulsating vigorously. The pulse rate was too rapid to count.

The cardiac impulse was diffuse and foreible, the apex beat being in the 5th space, $4\frac{1}{2}$ inches from the mid-line. The heart rate determined at the apex was about 200 per minute (?). The heart sounds were almost 'tic-tac'. The liver was palpable and tender and crepitations were audible at both lung-bases.

An electrocardiogram (figure 1) taken during the attack was suggestive of paroxysmal ventricular tachycardia, with a heart rate of 198 per minute.

She was given 25 c.c. of 25 per cent glucose intravenously and 6 grains of quinidine sulphate. Within two hours, the rate had fallen to 120 per minute. The quinidine was continued in 3-grain doses for a week or more. The paroxysm had lasted exactly six days.

Next morning, the patient's general condition was found to be considerably improved. The heart was 96 per minute and regular. There was a short rough presystolic murmur just inside the apex, and a soft blowing systolic murmur over the left half of the præcordium; the second sound at the base was duplicated.

An electrocardiogram (figure 2) taken one day after the termination of the attack showed the following features: (1) A heart rate of 97 per minute, quite regular; (2) large P waves with a short P-R interval, duration of P-R being 0.10 to 0.12 secs.; (3) wide QRS complexes, duration of QRS being 0.14 sec.; (4) prominent and wide S deflections with marked notching and slurring; the S wave duration in lead 2 was 0.09 sec. The R waves were small in all leads.

Another electrocardiogram (figure 3) taken a week later showed the same sort of picture except for the frequent occurrence of ventricular extra-systoles. The latter showed a tendency to occur alternately with normal beats for two to four cycles and then to disappear completely for five to seven cycles.

The patient was soon on her legs again and carried on with her usual household duties. She could walk about with little or no dyspnoea and the oedema had practically disappeared.

On the evening of 25th July, 1940 (that is, three months after the attack of paroxysmal tachycardia), the patient while in the bathroom suddenly experienced

an attack of intense dyspnoea, palpitation and faintness. When seen by me two days later, she was intensely breathless and tossing about in bed, literally gasping for breath. She complained bitterly of nausea and vomiting. The urinary output had fallen to about 2 or 3 oz. a day. The extremities were cold and clammy, the face had a 'cadaveric appearance' and the pulse could not be felt. No sounds were audible to auscultation during blood pressure estimation, and since also the pulse was not palpable, the blood pressure could not be obtained. The veins were engorged while the venous pressure was found to be 29 cm. of water. There was moderate oedema of the ankles and face, the liver was markedly enlarged (to the level of the umbilicus) and tender, and the spleen was just palpable.

There was considerable enlargement of the heart both to the right and left. The apex beat was felt behind the 6th rib, 5 inches from the mid-line. The rate of the heart was found to be 124 per minute. The first heart sound was hardly audible; a long blowing systolic murmur was heard over the left half of the præcordium. No pericardial friction sound was detected. A diagnosis of coronary thrombosis with peripheral and right-sided cardiac failure was made. After several injections of coramine, veritol, adrenalin and digoxin, the condition of the sinking patient improved. The pulse became palpable; the blood pressure rose to 90/46; the extremities regained their normal temperature. The right-sided heart failure improved on oral administration of digitalis.

On the morning of the 31st July, she again developed signs of severe peripheral failure. An electrocardiogram (figure 4) was taken at this stage. Monophasic downward deflections were noted in leads 2, 3 and 4, with characteristic 'raising' and 'upward doming' of the S-T interval in these leads. Another interesting feature was the duration of P-R which was above normal (0.22 sec.). The P-R interval had changed from an abnormally low to an abnormally high value in this case as the result of the attack. Because of the tachycardia and the length of the P-R intervals, the T waves were not easily discerned in this tracing; they appeared flattened and diphasic in the standard leads.

In spite of treatment, the patient's condition deteriorated rapidly and death occurred early in the afternoon, about three hours after the last electrocardiogram was taken.

Discussion

The association of a short P-R interval with a conduction defect and the tendency to attacks of paroxysmal tachycardia in this case raises the question whether it is not an example of the interesting 'syndrome of short P-R interval, apparent bundle branch block and associated paroxysmal tachycardia' described for the first time in 1930 by Wolff, Parkinson and White (1930). This interesting and rare syndrome, of which about 110 cases are now on record, is sometimes known as the 'Short P-R: B.B.B. Syndrome' or as The Wolff, Parkinson and White Syndrome. Not a single case of this type has been recorded in India or other eastern countries.

The main features of this syndrome have been analysed recently by Hunter, Papp and Parkinson (1940). The syndrome has been observed in individuals ranging in age from 4 to 62. In about 20 per cent of the recorded cases there has been associated heart disease, *viz*, hypertension, mitral stenosis, aortic regurgitation and coronary thrombosis. About four-fifths of

the cases on record were free from detectable organic heart disease. The characteristic electrocardiographic features of this syndrome are: with a normal heart rate, the P-R interval is considerably reduced (often under 0.12 sec.), the iso-electric segment between P and R being abolished; there is a widening of the QRS complex (usually over 0.11 sec.) with marked notching and slurring of its deflections; the condition is apt to be regarded as one of bundle branch block. Between true bundle branch block and the aberrant ventricular complexes of the Short P-R : B.B.B. Syndrome the resemblance is close, but the two conditions are regarded as distinct by the majority of workers. The paroxysms of tachycardia, to which these patients are prone, are usually supraventricular in type, but they may be ventricular or even paroxysms of fibrillation. The condition is essentially benign except for an occasional death usually from congestive cardiac failure; because of the benign character of the condition we are completely ignorant of the pathological lesions responsible.

No satisfactory explanation has been given of the mechanism of the syndrome. It has variously been ascribed to (1) a true bundle branch block from some abnormal vagal effect (Wolff, Parkinson and White, 1930), (2) the presence of a paranodal pacemaker due to an irritative lesion near the A. V. Node (Pezzi, 1931), (3) fatigue of the conducting tracts (Sigler, 1933), (4) a simultaneous block of one bundle branch and of the sino-auricular pathway (Hauss and Schutt, 1938), (5) a double rhythm caused by two interfering pacemakers, one near the sinus and the other in one bundle branch (Hunter, Prapp and Parkinson, 1940). The extensive literature on the subject has been recently reviewed in a masterly fashion by Hunter, Prapp and Parkinson (1940).

A diagnosis of the present case appears to depend on a correct interpretation of the aberrant electrocardiographic complexes observed in figures 2 and 3. The nature and duration of the QRS complexes in these tracings suggest a diagnosis of so-called *intraventricular* or *arborization* block. The latter entity is said to display the following characteristic electrocardiographic abnormalities: prolongation of the individual ventricular QRS complexes to beyond 0.10 sec.; notching or splintering of the R or S or both; low voltage curves; T waves not grossly abnormal; the initial ventricular complexes not necessarily opposite in sign in leads 1 and 3. Though intraventricular block has been attributed in the past to lesions involving the sub-endocardial Purkinje fibres and their terminal endings in the ventricular musculature, the tendency at the present day is to regard the condition as a disorder of one or both main bundle branches rather than as a disorder of the terminal ramifications. In Mahaim's (1932) opinion, intraventricular block results from a 'complete destruction of both main branches of the Bundle

of His without auriculo-ventricular block'. Electrocardiographic tracings somewhat similar to those of the present case, with widened QRS complexes and broad and slurred S deflections, have been recently independently described and classified by von Deesten and Dolganos (1934) and by Bayley (1934) as representative of right bundle branch block. Wilson, Johnston and Barker (1934) have recently reported electrocardiograms 'of an unusual type' in cases of right bundle branch block. Their tracings are very similar to those of the present case. They lay stress on the following electrocardiographic features: Increased duration of QRS complexes in all leads; in lead 1, the ventricular deflections are small, there is a conspicuous S deflection and the T is usually flat or upright; in leads 2 and 3, there is a small R followed by a deep and broad S wave; the T waves in leads 2 and 3 are upright. These authors have been able to show, with the use of præcordial leads, that the above-mentioned electrocardiographic picture constitutes an unusual form of right bundle branch block, where the ventricular complexes owe their aberrant character to some superadded peculiarity, e.g., an alteration in the position of the heart, infarction of the free or septal wall of the left ventricle or disease of some of the branches of the left bundle branch. After a perusal of these recent papers, one feels justified in interpreting electrocardiograms 2 and 3 of the present case as depicting *right bundle branch block*.

The case described here satisfies the three criteria necessary for a diagnosis of the Wolff, Parkinson and White Syndrome. There is the characteristically short P-R interval (0.10 sec.); there is an apparent bundle branch block and there is definite evidence of paroxysmal tachycardia. In view of these features, I have no hesitation in regarding the case as one of the short P-R : B.B.B. Syndrome, described by Wolff, Parkinson and White (1930). The following features in the present case are sufficiently unusual to deserve comment:—

(1) The presence of mitral stenosis. Though in about 80 per cent of the recorded cases of this syndrome there has been no associated heart disease, definite heart lesions have been described in about 20 per cent. Mitral stenosis has been described in association with the short P-R B.B.B. Syndrome on several occasions.

(2) Death from coronary thrombosis. The benign character of the short P-R : B.B.B. Syndrome has been commented on by all writers on the subject; a fatal termination is very unusual in these cases. Wilson reported death in a case of this type during an attack of paroxysmal tachycardia. A patient observed by Hunter, Papp and Parkinson (1940) died of congestive cardiac failure. Though the condition has been described in association with disease of the coronary arteries (Fulchiero, 1935; Katz and Kaplan, 1938), death from coronary

thrombosis, it is believed, has not previously been reported.

(3) The case presents interesting electrocardiographic features. There are frequent ventricular extra-systoles (figure 3); the S waves are widened and display slurring and notching in all leads. It is interesting to note that in the great majority of reported cases of this syndrome, notching and slurring has been more conspicuous in the R than in the S wave of the ventricular complex.

(4) The exact nature of the paroxysm of tachycardia in this case is not easy to determine. Though the general appearance of the curves in figure 1 suggests tachycardia of ventricular origin, a similar, if not identical, appearance may be simulated by supra-ventricular tachycardia occurring in association with a conduction defect. 'During a supra-ventricular paroxysm there may be bundle branch block; this is sometimes observed in young people who have a short P-R interval. The resultant anomalous ventricular complexes may simulate those of a ventricular paroxysm' (Cowan and Ritchie, 1935).

Summary

(1) A case is described for the first time in India of the rare 'syndrome of short P-R interval, apparent bundle branch block and associated paroxysmal tachycardia', also known as the short P-R : B.B.B. Syndrome or the Wolff, Parkinson and White Syndrome.

(2) The electrocardiographic tracings of the case are discussed in the light of recent studies on the subject by American workers.

(3) A short summary is presented of our present-day views on the subjects of intraventricular block and the short P-R : B.B.B. Syndrome.

PARATYPHOID INFECTIONS IN INDIA

By RAJYASEVANIRATA C. O. KARUNAKARAN

and

P. K. SANKARA PILLAI

Public Health Laboratory, Central Research Institute, Travancore

IN a recent communication, Sulakhe (1941) has doubted the validity of Lakin's (1937) statement regarding the prevalence of paratyphoid A infections in India. Out of 75 consecutive cases studied by him, all except one are reported to have been due to infection by *Bacterium typhosum*. Minchin (1939) has also taken the same view. Out of 444 cases which were treated in the General Hospital, Madras, during 1936-38, there were only three cases of *B. paratyphosum A* and two of *B. Soman* (1932) found that 2 out of his 26 positive cases were *paratyphosum A* and in a subsequent paper (1934) he reported that out 112 bacteriologically positive cases, 19 were infections with *paratyphosum A*.

Such divergent conclusions might result from—

(1) Regional or seasonal variations in the incidence of paratyphoid infection in India.

(2) Differences in the standards used for bacteriological diagnosis and (or)

(3) Variations in the type of data selected for study.

A few cases, which have come under our observation in which the diagnosis of *paratyphosum A* has been definitely established by the isolation of the causative organism, may be briefly described below, because they might be helpful in the consideration of the points raised above:—

Case 1.—A male, aged 12 years. Domestic servant in the house of case 2. Fever of 7 days' duration. Blood and stools cultured and Widal done on the 7th day. Result: *paratyphosum A* obtained from blood culture. Widal positive 1 in 25 *B. typhosum* and 1 in 50 *B. paratyphosum A*. Stool culture negative. Temperature reached normal on the 16th day. Widal on the 16th day, positive 1 in 25 *B. paratyphosum A*.

Case 2.—A female, aged 35 years. Fever started 7 days after case 1, but was so mild that patient went about in her usual manner. Blood taken for culture and Widal on the 7th day. *B. paratyphosum A* obtained from culture. Widal positive 1 in 50 *B. typhosum* and 1 in 25 *paratyphosum A*. Temperature normal on the 15th day; was never above 99°F. in the morning. Widal on the 21st day positive 1 in 50 *B. paratyphosum A*, and 1 in 25 *paratyphosum B*. Stools cultured twice in the second week—negative.

Case 3.—A male, aged 15 years, son of case 2. Fever started 5 days after no. 2. Blood taken for culture and Widal on the 2nd day. *B. paratyphosum A* isolated from blood culture. Widal positive 1 in 25 *B. typhosum*. Temperature reached normal on the 12th day (vide chart 1). Widal done again on the 21st day—positive 1 in 200 *B. typhosum* and 1 in 50 *paratyphosum A* and *B*. Stool culture done in the second week—negative. After the temperature had remained normal for 10 days, there was a relapse which ran a course like the first attack.

Case 4.—A female, aged 9 years, sister of case 3. Fever started 14 days after her mother (case 2). Blood culture not done. Widal done on the 9th day—positive 1 in 200 *B. typhosum* and 1 in 50 *paratyphosum A*. Temperature reached normal on the 9th day.

Stool culture—negative (*vide* chart 1). Being a small thin irritable girl, only a few drops of blood could be obtained from her, and so no blood culture was done, but there can be little doubt that *B. paratyphosum* A was the causative organism in view of the other three cases and the Widal result identical with that of case 3. The temperature chart of case 1 was like that of case 3 and case 2 resembled case 4.

CHART 1

This is the second occasion within the last five years when, owing to proximity of the house to this laboratory, a family outbreak of paratyphoid fever could be studied bacteriologically. The salient features of the first outbreak reported by the senior writer in the Travancore Medical Journal (1936) are worth noting here.

Case 5.—A male, aged 32. Fever of insidious onset, with blood stained slime and diarrhoea of 4 days' duration. Blood culture and Widal done on the 4th day. *B. paratyphosum* A isolated from blood. Widal negative. Stools culture—negative. Temperature reached normal on the 12th day. Patient was discharged 4 days later. Widal done a second time, on the 12th day—positive 1 in 25 dilution *B. paratyphosum* A, the titre of agglutination being the same for the formalized stock suspension and the living suspension of the patient's own organism.

Case 6.—A female, aged 12 years, an inmate of the same house. Fever began 5 days after case 5; but was so mild that patient did not take to bed till the 5th day, when culture of blood and Widal were done. *B. paratyphosum* A isolated from blood. Widal negative. The temperature did not touch normal for a month. Widal was done at the end of the second week and third week. Result (second week): positive 1 in 100 dilution *B. typhosum* and 1 in 25 *B. paratyphosum* A; (third week): positive 1 in 200 *B. typhosum* and 1 in 50 *paratyphosum* A and *B. Agglutinated* with patient's own organism to the same titre as the stock suspension of *paratyphosum* A. Stool culture done four times from the 10th to the 24th day. *B. paratyphosum* A isolated on the first two occasions and negative subsequently.

Case 7.—A female, aged 18 years. Inmate of the same house. Fever started 4 days after case 6. Blood taken for culture and Widal on the 3rd day. Result: *B. paratyphosum* A obtained from blood. Widal negative. Widal was repeated 9 days later, with the same negative result. Ran a very mild course and temperature came to normal on the 12th day. Stools not cultured.

Case 8.—A female, aged 22 years. Fever started on the same day as case 7. Blood taken for culture and Widal on the 3rd day. Result: *B. paratyphosum* A isolated. Widal negative. Widal repeated 9 days

later. Positive 1 in 200 dilution *B. typhosum* and 1 in 50 *paratyphosum* A. Temperature came to normal on the 13th day. Stools cultured twice in the second week; *B. paratyphosum* A isolated on the first occasion. The second culture 3 days later gave an organism which resembled *B. paratyphosum* A in sugar reaction, but not in motility and specific agglutination.

Case 9.—A male, aged 15 years, of the same house. Fever commenced 9 days after case 8 and 7 days after he had a dose of T.A.B. vaccine. Blood taken for culture on the 3rd day. *B. paratyphosum* A isolated. Widal not done in view of the T.A.B. inoculation. Temperature remained high for over 3 weeks and did not touch normal till the fourth week.

The salient features of these cases, relevant to laboratory diagnosis, may be noted here:—

(1) Of the 9 cases occurring in two houses, blood culture was done in the first week in 8, and *B. paratyphosum* A was obtained from all.

(2) Widal, done in 7 cases at the time of blood culture, gave negative results in 5, and the results in the other 2 were difficult in interpretation (positive 1 in 25 *B. typhosum* and 1 in 50 *paratyphosum* A in one and positive 1 in 50 *B. typhosum* and 1 in 25 *paratyphosum* A in the other).

(3) Widal repeated at a later stage, in 8 cases, also gave results which were difficult to interpret. In one there was a fall in titre. In three, which were negative at first, the rise in titre was more significant for *B. typhosum* (1 in 200) than for *paratyphosum* A (1 in 50) and the same result was obtained in case 4 in which Widal was done rather late, the 9th day. One continued to be negative throughout. In one the titre rose to 1 in 25 and in another to 1 in 50.

(4) The use of living suspension of the organism obtained from the patients concerned, containing both the H and the O agglutinins (5 to 8), did not give results significantly different from those obtained with the stock formalized suspensions.

(5) Culture of stools was done in seven cases. In five, it was negative and the stools were cultured only once. In two cases (6 and 8) *B. paratyphosum* A was isolated, twice from case 6 and once from case 8. Because in both these cases, Widal, negative to start with, had shown a progressive rise in titre (1 in 200) for *B. typhosum*, a large number of non-lactose-fermenting colonies were tested from several plates to find out if there was mixed infection, but all were found to be *B. paratyphosum* A. From case 8, the second culture of stools gave organisms which resembled *B. paratyphosum* A in fermentation reaction but not in motility or agglutinability, suggesting *in vivo* variation.

(6) In seven out of the nine cases, the course of fever was very mild, the temperature coming to normal about the 10th day. In most of these, the morning temperature was generally 99°F. and the evening temperature 1° to 2° higher; (*vide* chart 1, case 4) while in others, although the temperature was higher, the duration was not longer. In two the course of fever was typical of a classical attack of typhoid fever.

thrombosis, it is believed, has not previously been reported.

(3) The case presents interesting electrocardiographic features. There are frequent ventricular extra-systoles (figure 3); the S waves are widened and display slurring and notching in all leads. It is interesting to note that in the great majority of reported cases of this syndrome, notching and slurring has been more conspicuous in the R than in the S wave of the ventricular complex.

(4) The exact nature of the paroxysm of tachycardia in this case is not easy to determine. Though the general appearance of the curves in figure 1 suggests tachycardia of ventricular origin, a similar, if not identical, appearance may be simulated by supra-ventricular tachycardia occurring in association with a conduction defect. 'During a supra-ventricular paroxysm there may be bundle branch block; this is sometimes observed in young people who have a short P-R interval. The resultant anomalous ventricular complexes may simulate those of a ventricular paroxysm' (Cowan and Ritchie, 1935).

Summary

(1) A case is described for the first time in India of the rare 'syndrome of short P-R interval, apparent bundle branch block and associated paroxysmal tachycardia', also known as the short P-R : B.B.B. Syndrome or the Wolff, Parkinson and White Syndrome.

(2) The electrocardiographic tracings of the case are discussed in the light of recent studies on the subject by American workers.

(3) A short summary is presented of our present-day views on the subjects of intraventricular block and the short P-R : B.B.B. Syndrome.

PARATYPHOID INFECTIONS IN INDIA

By RAJYASEVANIRATA C. O. KARUNAKARAN
and

P. K. SANKARA PILLAI

Public Health Laboratory, Central Research Institute, Travancore

IN a recent communication, Sulakhe (1941) has doubted the validity of Lakin's (1937) statement regarding the prevalence of paratyphoid A infections in India. Out of 75 consecutive cases studied by him, all except one are reported to have been due to infection by *Bacterium typhosum*. Minchin (1939) has also taken the same view. Out of 444 cases which were treated in the General Hospital, Madras, during 1936-38, there were only three cases of *B. paratyphosum A* and two of *B. Soman* (1932) found that 2 out of his 26 positive cases were *paratyphosum A* and in a subsequent paper (1934) he reported that out 112 bacteriologically positive cases, 19 were infections with *paratyphosum A*.

Such divergent conclusions might result from—

(1) Regional or seasonal variations in the incidence of paratyphoid infection in India.

(2) Differences in the standards used for bacteriological diagnosis and (or)

(3) Variations in the type of data selected for study.

A few cases, which have come under our observation in which the diagnosis of *paratyphosum A* has been definitely established by the isolation of the causative organism, may be briefly described below, because they might be helpful in the consideration of the points raised above:—

Case 1.—A male, aged 12 years. Domestic servant in the house of case 2. Fever of 7 days' duration. Blood and stools cultured and Widal done on the 7th day. Result: *paratyphosum A* obtained from blood culture. Widal positive in 1 in 25 *B. typhosum* and 1 in 50 *B. paratyphosum A*. Stool culture negative. Temperature reached normal on the 16th day. Widal on the 16th day, positive 1 in 25 *B. paratyphosum A*.

Case 2.—A female, aged 35 years. Fever started 7 days after case 1, but was so mild that patient went about in her usual manner. Blood taken for culture and Widal on the 7th day. *B. paratyphosum A* obtained from culture. Widal positive 1 in 50 *B. typhosum* and 1 in 25 *paratyphosum A*. Temperature normal on the 15th day; was never above 99°F. in the morning. Widal on the 21st day positive 1 in 50 *B. paratyphosum A*, and 1 in 25 *paratyphosum B*. Stools cultured twice in the second week—negative.

Case 3.—A male, aged 15 years, son of case 2. Fever started 5 days after no. 2. Blood taken for culture and Widal on the 2nd day. *B. paratyphosum A* isolated from blood culture. Widal positive 1 in 25 *B. typhosum*. Temperature reached normal on the 12th day (*vide* chart 1). Widal done again on the 21st day—positive 1 in 200 *B. typhosum* and 1 in 50 *paratyphosum A* and *B*. Stool culture done in the second week—negative. After the temperature had remained normal for 10 days, there was a relapse which ran a course like the first attack.

Case 4.—A female, aged 9 years, sister of case 3. Fever started 14 days after her mother (case 2). Blood culture not done. Widal done on the 9th day—positive 1 in 200 *B. typhosum* and 1 in 50 *paratyphosum A*. Temperature reached normal on the 9th day.

Stool culture—negative (*vide* chart 1). Being a small thin irritable girl, only a few drops of blood could be obtained from her, and so no blood culture was done, but there can be little doubt that *B. paratyphosum* A was the causative organism in view of the other three cases and the Widal result identical with that of case 3. The temperature chart of case 1 was like that of case 3 and case 2 resembled case 4.

CHART 1

This is the second occasion within the last five years when, owing to proximity of the house to this laboratory, a family outbreak of paratyphoid fever could be studied bacteriologically. The salient features of the first outbreak reported by the senior writer in the Travancore Medical Journal (1936) are worth noting here.

Case 5.—A male, aged 32. Fever of insidious onset, with blood stained slime and diarrhoea of 4 days' duration. Blood culture and Widal done on the 4th day. *B. paratyphosum* A isolated from blood. Widal negative. Stools culture—negative. Temperature reached normal on the 12th day. Patient was discharged 4 days later. Widal done a second time, on the 12th day—positive 1 in 25 dilution *B. paratyphosum* A, the titre of agglutination being the same for the formalized stock suspension and the living suspension of the patient's own organism.

Case 6.—A female, aged 12 years, an inmate of the same house. Fever began 5 days after case 5; but was so mild that patient did not take to bed till the 5th day, when culture of blood and Widal were done. *B. paratyphosum* A isolated from blood. Widal negative. The temperature did not touch normal for a month. Widal was done at the end of the second week and third week. Result (second week): positive 1 in 100 dilution *B. typhosum* and 1 in 25 *B. paratyphosum* A; (third week): positive 1 in 200 *B. typhosum* and 1 in 50 *paratyphosum* A and *B.* Agglutinated with patient's own organism to the same titre as the stock suspension of *paratyphosum* A. Stool culture done four times from the 10th to the 24th day. *B. paratyphosum* A isolated on the first two occasions and negative subsequently.

Case 7.—A female, aged 18 years. Inmate of the same house. Fever started 4 days after case 6. Blood taken for culture and Widal on the 3rd day. Result: *B. paratyphosum* A obtained from blood. Widal negative. Widal was repeated 9 days later, with the same negative result. Ran a very mild course and temperature came to normal on the 12th day. Stools not cultured.

Case 8.—A female, aged 22 years. Fever started on the same day as case 7. Blood taken for culture and Widal on the 3rd day. Result: *B. paratyphosum* A isolated. Widal negative. Widal repeated 9 days

later. Positive 1 in 200 dilution *B. typhosum* and 1 in 50 *paratyphosum* A. Temperature came to normal on the 13th day. Stools cultured twice in the second week; *B. paratyphosum* A isolated on the first occasion. The second culture 3 days later gave an organism which resembled *B. paratyphosum* A in sugar reaction, but not in motility and specific agglutination.

Case 9.—A male, aged 15 years, of the same house. Fever commenced 9 days after case 8 and 7 days after he had a dose of T.A.B. vaccine. Blood taken for culture on the 3rd day. *B. paratyphosum* A isolated. Widal not done in view of the T.A.B. inoculation. Temperature remained high for over 3 weeks and did not touch normal till the fourth week.

The salient features of these cases, relevant to laboratory diagnosis, may be noted here:—

(1) Of the 9 cases occurring in two houses, blood culture was done in the first week in 8, and *B. paratyphosum* A was obtained from all.

(2) Widal, done in 7 cases at the time of blood culture, gave negative results in 5, and the results in the other 2 were difficult in interpretation (positive 1 in 25 *B. typhosum* and 1 in 50 *paratyphosum* A in one and positive 1 in 50 *B. typhosum* and 1 in 25 *paratyphosum* A in the other).

(3) Widal repeated at a later stage, in 8 cases, also gave results which were difficult to interpret. In one there was a fall in titre. In three, which were negative at first, the rise in titre was more significant for *B. typhosum* (1 in 200) than for *paratyphosum* A (1 in 50) and the same result was obtained in case 4 in which Widal was done rather late, the 9th day. One continued to be negative throughout. In one the titre rose to 1 in 25 and in another to 1 in 50.

(4) The use of living suspension of the organism obtained from the patients concerned, containing both the H and the O agglutinins (5 to 8), did not give results significantly different from those obtained with the stock formalized suspensions.

(5) Culture of stools was done in seven cases. In five, it was negative and the stools were cultured only once. In two cases (6 and 8) *B. paratyphosum* A was isolated, twice from case 6 and once from case 8. Because in both these cases, Widal, negative to start with, had shown a progressive rise in titre (1 in 200) for *B. typhosum*, a large number of non-lactose-fermenting colonies were tested from several plates to find out if there was mixed infection, but all were found to be *B. paratyphosum* A. From case 8, the second culture of stools gave organisms which resembled *B. paratyphosum* A in fermentation reaction but not in motility or agglutinability, suggesting *in vivo* variation.

(6) In seven out of the nine cases, the course of fever was very mild, the temperature coming to normal about the 10th day. In most of these, the morning temperature was generally 99°F. and the evening temperature 1° to 2° higher; (*vide* chart 1, case 4) while in others, although the temperature was higher, the duration was not longer. In two the course of fever was typical of a classical attack of typhoid fever.

Three more cases may also be briefly noted here, as they are helpful in considering the occurrence of paratyphoid infections.

Case 10.—A female, aged 40 years. A highly qualified doctor working in Madras. Fever started 2 days after her arrival from Madras. She had a full course of T.A.B. a month before and had not exposed herself to risks of infection. Fever was of an intermittent character, coming in the forenoon with a feeling of chilliness. Malaria was excluded and because she had *B. coli* infection before, a recurrence of this was suspected and she tried a course of M.&B. 693. After the fever had lasted a week one of us (C. O. K.) was consulted. Blood, urine and stools were cultured and Widal was done. Urine and blood were sterile. Widal was positive in 1 in 200 *B. typhosum* and 1 in 50 *paratyphosum A* and 1 in 25 *paratyphosum B*. Culture of stools gave almost a pure growth of *B. paratyphosum A*.

Case 11.—A male, aged 28 years. A labourer employed in the high lands of Travancore, 200 miles from this laboratory. Fever started 7 days after patient had an inoculation with 0.75 c.cm. of T.A.B. Sudden rise of temperature. Pulse rate 60 to 70 with a temperature ranging from 100°F. to 102°F. Severe abdominal distress and diarrhoea alternating with constipation. Rapid emaciation from the commencement of fever. Temperature reached normal on the 12th day (*vide* chart II). Widal done 7 days after

CHART 2

PATIENT NO. 11.

the onset of fever, positive in 1 in 800 *B. typhosum*, *paratyphosum A* and *B*. Culture of clot sterile. Culture of stools done in the third week, an organism of

the *Salmonella* group other than *paratyphosum A* and *B* isolated.

Case 12.—A male, aged 10 years. From the same district as the last case, but from another estate and not a contact. Blood sent for Widal on the 9th day. Result: positive 1 in 200 *B. typhosum* and 1 in 50 *paratyphosum B*. *B. typhosum* isolated from culture of clot. Because there was agglutination of *B. typhosum B*, a specimen of stools was obtained 11 days later and *B. paratyphosum B* was isolated.

Discussion

As Topley and Wilson (1936) have emphasized, 'the actual isolation and identification of the causative organism is always the method of choice in the bacteriological diagnosis of enteric infection'. Although it is possible to isolate the organism from the blood, stools and urine, culture of the blood and/or stools is the routine procedure adopted in most diagnostic laboratories. From the cases described above, it will be seen that early blood culture gave positive results in 8 out of the 9 cases, and that stool culture was helpful in 5 out of 11 cases. But as has been stated already, the first 9 of these cases occurred in two houses close to this laboratory and so presented unusually favourable opportunities for study. These results may not therefore be strictly applicable to the routine samples received in any laboratory.

The results of culture examination of stools and blood done for the diagnosis of enteric fever in this laboratory during the administrative years 1939-40 (the administrative year begins about the 15th August) and 1940-41 together with the corresponding figures for the King Institute of Preventive Medicine, Madras, published in the Annual Reports for 1939 and 1940 are given in table I.

It might be thought that if blood culture and/or Widal be positive, culture of stools is not necessary for diagnosis and so the specimens of stools come more from cases which are not enteric in character, vitiating the comparability of the results. It has therefore to be pointed out

TABLE I

Institution	CULTURE OF BLOOD				CULTURE OF STOOLS			
	Total	<i>B. typhosum</i>	<i>B. paratyphosum A</i>	Other organisms of the <i>Salmonella</i> group	Total	Positive for <i>B. typhosum</i>	Positive for <i>B. paratyphosum A</i>	Other organisms of the <i>Salmonella</i> group

1940 ..	1,294	251	..	2	99	..	6*	..

* Not differentiated.

N.B.—Clots of satisfactory specimens sent for Widal are also cultured as noted in brackets.

that about 90 per cent of the specimens examined here culturally for the diagnosis of enteric come from the General Hospital, Trivandrum, which is adjacent to this institution and the practice there is, whenever possible, to collect a specimen of stools from every case of suspected enteric fever on the day or the day after the blood is taken for culture and Widal. If cultural and serological tests are negative and clinically the case appears to be enteric, the stool culture is repeated at least once in the second or third week. In about 80 per cent of the admissions as will be shown later, both the blood and stools have been cultured. That makes the results fairly comparable and it will be seen that if we are to base our judgment of the incidence of the different types of enteric infection on the isolation of the causative organism, we have to depend more on blood culture than on stool culture.

✓ Blood culture to be reliable should be done as early in the course of fever as possible, but usually patients seek hospital admission after the first week when the fever is well established. Soman (1932) had noted that the earliest date of admission was the 7th day, and 23 out of 26 patients came after the 10th day. Only 8 out of his 70 cases were culturally positive. The same author (1934) observed that only 4 out of 38 came within the first week and 53 out of his 400 cultures were positive. Sulakhe (1941) attempted culture in only 4 out of 75 consecutive cases 'because most of the cases came late' and even these 4 cases were negative.

In the series reported by Minchin (1939), '50 per cent of the cases showed a positive blood culture'. It has however to be noted that Minchin's was a highly selected group consisting only of cases which were either culturally positive or positive by Widal to the titre of 1 in 200. His cases, 444 in number, were selected from the years 1936-38, while 1,363 cases were treated as 'enteric fever' in the same hospital (the Madras General Hospital) in 1936. If his culturally positive cases (222) be distributed between the two years of their occurrence, it works out at about 111 positives in about 1,300 cases, clinically diagnosed as enteric, and this proportion is approximately the same as for the groups reported by Soman. It is also worth noting that 71 per cent of the positives in Minchin's group came within 10 days after the onset of fever. That means that only 32 out of about 111 positives were obtained from the later admissions which would have constituted the vast majority of the cases treated. While it was necessary for Minchin's purpose to select cases in which specific diagnosis of typhoid was established, it appears doubtful if an opinion regarding the incidence of paratyphoid fever can be based on such a selected group, particularly in view of the limitations to which both culture and Widal, as practised in routine diagnosis, are subject.

The results of bacteriological tests done in this laboratory in 755 cases of enteric fever admitted to the General Hospital, Trivandrum, during 1940-41, given in table II will be of

TABLE II

Duration of disease	Total number	POSITIVE BY CULTURE ONLY			POSITIVE BY CULTURE AND WIDAL			POSITIVE BY WIDAL ONLY				Negative
		<i>B. typhosum</i>	<i>B. paratyphosum A</i>	Other organisms of the <i>Salmonella</i> group	<i>B. typhosum</i>	<i>B. paratyphosum A</i>	Other organisms of the <i>Salmonella</i> group	<i>B. typhosum</i>	<i>B. typhosum</i> with <i>paratyphosum A</i>	<i>B. paratyphosum A</i>	<i>B. paratyphosum B</i> alone, or in combination	
1st week	135	13	4	7	26	9	2	34	8	9	2	22
2nd week	437	44	6	5	75	4	..	187	25	21	4	69
3rd week	133	4	..	2	29	1	..	66	8	3	1	19
4th week	50	3	7	1	..	30	1	1	..	7
TOTAL ..	755	64	10	14	137	15	2	317	42	34	7	117

Footnote.—The sum total of the results will be found to exceed the sum total of the number of cases by 4 because there were 4 cases from which more than one organism was isolated. One case had both *B. paratyphosum A* and *B* in the blood culture. This had a positive Widal of 1 in 50 for *B. typhosum* and 1 in 25 for *B. paratyphosum A* and *B*. There were two cases with a Widal of 1 in 200 *B. typhosum* and 1 in 50 *paratyphosum A* from the stools culture of which *B. paratyphosum A* was isolated. Another with the same reaction had *B. typhosum* in the blood and *paratyphosum A* in the stools. One case with a negative Widal in the second week had *B. paratyphosum A* in the blood and *B. typhosum* in the stools and another with a negative Widal had *B. typhosum* in the blood and *paratyphosum A* in the stools. It may also be noted that there were 3 cases in which *B. typhosum* was isolated from the blood, two months after the commencement of the fever, 2 of which were Widal negative, and 4 in which blood culture was positive one month after the fever, one of which was Widal negative.

interest. Altogether 789 cases were clinically diagnosed as enteric fever, of which 34, admitted in a moribund condition, died before any test could be done. Out of the remaining 755 cases, Widal and culture of both blood and stools were done in 553 cases, blood culture and Widal in 168, stool culture and Widal in 54.

Table III shows how the chances of isolation of the organism get progressively less with the delay in culture, and how this affects the isolation of *B. paratyphosum* A more than *B. typhosum*.

TABLE III

Time	Total	POSITIVES		POSITIVE FOR <i>B. typho- sum</i>		POSITIVE FOR <i>paratypho- sum</i> A	
		Total	Per cent	Total	Per cent	Total	Per cent
1st week	135	60	44	39	29.6	13	9.6
2nd week	437	131	30	116	24.2	10	2.3
3rd week	133	36	27	33	24.8	1	..
4th week	50	11	22	10	20.0	1	..

It will be seen from table III that among the cases admitted in the first week, there is one case of culturally positive *B. paratyphosum* A for every 3 of *B. typhosum*, while for the second week cases, the proportion goes down to 1 : 11.6. The number of cases from which *B. paratyphosum* A was isolated in the third and fourth week groups is so small (1 in each group) as to be of little significance. The onset of enteric fever being generally insidious, the duration of the disease, at the time of admission, is liable to be understated, and so the first week admissions might be fewer than the hospital statistics suggest. Even if no allowance is made for this, only about 17 per cent of the total—135 in 789—were admitted in the first week. The tendency to seek admission late affects the isolation of *B. paratyphosum* A in two ways :—

(i) The paratyphoid infections being, in general, mild both in the duration and intensity of the fever, the vast majority find no necessity to seek hospital admission. Hospital records are therefore likely to show a disproportionately larger number of cases of infection with *B. typhosum*.

(ii) Bacteræmia being more transient in paratyphoid infections, there is less chance of isolation of the causative organisms by blood culture after the first week.

Isolation of the causative organisms from the stools does not appear to be generally attempted in the routine diagnosis of enteric fever. Soman, Minchin and Sulakhe, in their papers referred to above, do not mention stool culture. This, as stated already, might be due to the chance of isolation of the organism from the stools, particularly in the early stages of the disease,

being more remote than isolation from the blood. But whatever the limitations of stool culture as practised in routine diagnosis, from a purely clinical point of view there can be little doubt that, in the isolation of the causative organisms, especially of the organisms belonging to the *Salmonella* group, stool culture is of importance.

A reference to table II will show that in 1940-41, there were in the General Hospital, Trivandrum, 201 cases from which *B. typhosum* was isolated and 25 from which *B. paratyphosum* A was isolated. But 48 of the blood positives were obtained from 168 cases in which blood culture alone was done and 5 of the stool positive were obtained from 54 cases in which stools alone were cultured. The remaining 173 positive cultures were distributed among 170 cases as in table IV, 3 being mixed infections in which both *B. typhosum* and *B. paratyphosum* A were isolated.

TABLE IV

	<i>B. typho- sum</i>	<i>B. para- typhosum</i> A
Positive by blood culture ..	114	11
Positive by stool culture ..	22	13
Positive by both blood and stools.	12	1
TOTAL ..	148	25

It will be seen from table IV that in *B. typhosum* infections, blood culture was helpful in 86.5 per cent (126 out of 148) of the positive cases and stool culture in 24 per cent (34 out of 148), but in infections with *B. paratyphosum* A, blood culture was helpful only in 48 per cent (12 out of 25) and stool culture in 56 per cent (13 out of 25). The more transient character of bacteræmia in paratyphoid cases and the mild and atypical early manifestations which often lead to the missing of the period of bacteræmia, give to stool culture a significance which it does not have in infections with *B. typhosum*.

Although isolation of the causative organism is the method of choice for the diagnosis of enteric fever and for determining the distribution of the different types of infections, an opinion on both these points appears to be more commonly based on the results of Widal. But the interpretation of agglutination tests presents many difficulties and different workers follow different standards. Soman (1932) considered Widal reaction positive if agglutination occurred in a dilution of 1 in 50. He had in his 26 bacteriologically confirmed cases 2 positives for *B. paratyphosum* A. The same author (1934) considered Widal positive for *B. paratyphosum* A if reaction occurred in a serum dilution of 1 in 25, and 19 out of his 112 bacteriologically positives were infections with *B. paratyphosum* A. Minchin's standard was a titre of 1 in 200 dilution. Only 3 out of

his 444 cases were considered to be *paratyphoid* A. Sulakhe took 1 in 100 as the diagnostic dilution and although he had among his 45 Widal positives three which were also positive for *B. paratyphosum* A and B in addition to *B. typhosum*, he has taken these cases as simple infections with *B. typhosum*. The number of Widal positives will obviously depend upon the titre accepted as of diagnostic significance.

As Topley and Wilson (1936) say 'no arbitrary titre can be selected at or above which an agglutination can be regarded as positive in the diagnostic sense, and below which it can be regarded as negative'. These authors have stressed the importance of the 'natural level of agglutinins among a random sample of the population' in the interpretation of agglutination reaction. No work appears to have been done in India to find out the natural level of agglutination, and the different standards selected by the different authors are arbitrary. Differences in technique and variations in the agglutinability of non-standardized bacterial suspensions used for the test also make comparison of results difficult. The fluctuation in the titre of agglutinins, and the development of the non-specific agglutinins further complicate the correct interpretation of results. The cases cited by Soman (1934) and by Minchin (1939) show that the titre of agglutinins is subject to wide range of variation. This variation is more

1, towards the end of the second week the titre might begin to fall. The clinical course of the infection makes it likely that usually the patients would be discharged by the end of the second week and so a late Widal would hardly be done. If the results of the Widal test, collected from hospitals or diagnostic laboratories, are to be depended upon to find out the extent of paratyphoid incidence, a titre of about 1 in 25 will be more likely to minimize errors than a higher titre.

Table II will show that among the cases in which a diagnosis of enteric fever was based solely on the results of Widal, 317 were positive for *B. typhosum*, only 34 for *B. paratyphosum* A and 42 for both, a titre of 1 in 25 or above being taken as significant for *B. paratyphosum* A, and a titre of 1 in 50 or above as significant for *B. typhosum*.

Table V shows the results of Widal done in this laboratory during the years 1939-40 and 1940-41 and table VI the corresponding figures for the King Institute (1939 and 1940).

At the King Institute (1942)* 'positive results from 1 in 25 upwards are reported as positive' in their reports, while in table V we have taken a titre of 1 in 50 alone as significant in the case of *B. typhosum*. This undoubtedly accounts for a much larger number of positives for *B. typhosum* obtained at the King Institute.

TABLE V

Year	Total done	1 : 50 <i>B. typhosum</i>	1 : 25 <i>B. paratyphosum</i> A	<i>B. typhosum</i> and <i>para-</i> <i>typhosum</i> A	1 in 25 <i>B. paratyphosum</i> B	<i>Paratyphosum</i> B and <i>B. typhosum</i>	<i>Paratyphosum</i> A and <i>typhosum</i> B	<i>B. typhosum</i> , <i>paratypho-</i> <i>sum</i> A and <i>paratypho-</i> <i>sum</i> B
1939-40	2,614	454	43	122	27	32	9	54
1940-41	3,178	397	96	182	10	15	8	51

TABLE VI

Year	Total	Positive <i>B. typhosum</i>	<i>B. paratyphosum</i> A	<i>B. paratyphosum</i> B	Positive to more than one organism
1939 ..	3,900	1,590	12	25	219
1940 ..	4,275	1,812	32	20	381

likely to affect the correct diagnosis of paratyphoid infections than of typhoid cases, probably because, the bacteraemia being more transient, the highest titre obtained is comparatively low. Topley and Wilson say that during the third week of the disease 'with paratyphoid infections the titre against the causative organisms will tend to be at least as high as that observed in typhoid fever' (1 in 100 or over). The cases enumerated above will show that the rise in titre is seldom higher than 1 in 50 and that in some it is only 1 in 25 and that, as in case

With reference to the paratyphoid organisms, the standard being the same, the results, particularly the positives for more than one organism, are comparable. If in these cases, the chances of infection with *B. typhosum* producing non-specific agglutinins for *paratyphosum* and vice versa be considered even, as many cases will be due to the one as to the other and the number of paratyphoid cases will be found to be fairly high.

* Personal communication from the Director.

The development of agglutinins to organisms other than the causative organism, which cannot be explained on the basis of antigenic relationship, is a common phenomenon, but it does not appear to have been sufficiently recognized that the titre for an allied organism may be much higher than the titre for the causative organism. In 4 of the 9 cases mentioned above which were undoubtedly infections with *B. paratyphosum* A alone, the titre for *B. typhosum* rose to 1 in 200 while the titre for the causative organism did not rise above 1 in 50. These were all uninoculated subjects without any history of previous attacks of enteric fever and it may be noted that there was significant rise in titre of agglutinins in the three cases in which two tests were done. Where the diagnosis is based on the results of Widal and particularly if low titres are not considered of diagnostic value, as has been done by Minchin and Sulakhe, it is likely that such cases will be grouped under infection with *B. typhosum*.

Summary and conclusions

(1) Bacteriological findings and clinical course in some cases of paratyphoid fever are described.
(2) The bacteriological findings of the cases diagnosed as 'enteric fever' treated in the General Hospital, Trivandrum, during 1940-41 are analysed.

(3) The results of culture and agglutination done at the King Institute and the Trivandrum Public Health Laboratory are analysed.

(4) Early blood culture is of the greatest value in establishing a correct diagnosis in paratyphoid infections.

(5) The interpretation of Widal is complicated by the low titre of agglutinins in many cases and by the development of non-specific agglutinins in others.

(6) Stool culture is helpful in late cases and cases showing agglutinins to more than one organism.

(7) In general, paratyphoid infection runs a mild course and are not likely to be well represented among the cases admitted in hospitals or specimens tested in diagnostic laboratories.

(8) An opinion on the incidence of paratyphoid infections based on the analysis of hospital statistics is therefore likely to be misleading.

(9) It appears probable that many fevers of short duration in which no bacteriological investigations are done might be paratyphoid in character.

(10) A study of the cases admitted in the General Hospital, Trivandrum, and the results of Widal test done at the King Institute and in this laboratory indicate a fairly wide prevalence of *paratyphosum* A infection.

Acknowledgments

Our thanks are due to Dr. S. John, superintendent of the General Hospital,

THE RÔLE OF *BACILLUS FÆCALIS* *ALCALIGENES* AS A PATHOGEN IN CYSTITIS OF URINARY BLADDER

By N. AHAD, M.B., B.S.

(From the Department of Pathology and Bacteriology, Medical College, Rangoon)

CASE REPORT

AN unmarried female, age about 21, came under the observation of Dr. H. N. Dass, about the middle of February 1940, for the treatment of irregular fever of two weeks' duration, severe pain and tenderness in the suprapubic region, and frequent and painful micturition of about the same duration as the fever. The fever came on with rigor towards the evening, the temperature ranging between 100° and 102°F.

On examination, the tonsils were found enlarged; there was constipation; marked tenderness in the suprapubic region was elicited but the kidneys were free from abnormal signs and symptoms. No abnormality was detected in other systems. Blood films were free from malaria parasites and microfilaria. The patient was treated for three days with sedatives, expectorants and sodium salicylate. The tonsillar condition subsided but the temperature remained unaffected and the patient was then given potassium citrate, dr. 1, four hourly for four days, and then acid sodium phosphate and urotropine for three days. The temperature fell to normal and no relapse has been recorded since.

Investigation of the case

Catheterized urine collected under sterile conditions just before the treatment was started was sent to the writer to confirm the diagnosis of '*B. coli*' infection, already made clinically. The urine was slightly turbid, alkaline in reaction, and albumin was present. The deposit showed pus cells, epithelial cells and red blood corpuscles. No casts were found. 'Hanging drop' preparations showed motile bacilli. Deposit-smears stained with Gram's and Leishman's stains showed Gram-negative short bacilli and the cellular elements mentioned above. A culture was made on a MacConkey's plate incubated at 37°C. for 24 hours. The organisms were found to be non-lactose fermenters.

(Continued from previous column)

Trivandrum, for placing at our disposal his case records, to Dr. Finlayson, chief medical officer, Kannan Devan Plantations, and Dr. Raghava Puduval for their permission to publish records of their cases, and to the Director of research, University of Travancore, for his permission to publish this paper.

Morphology.—A short, rod-shaped, non-spore-bearing, motile bacillus.

Cultures were made on: nutrient agar, nutrient broth, peptone water, buffered glucose broth, MacConkey's agar plate, Dieudonne's blood-alkali agar, potato medium and litmus milk.

Sugar reactions in lactose, glucose, saccharose, mannite and maltose: no acid and gas, but alkali formation only.

Litmus milk: progressive alkali formation.

Indol production: absent.

Voges-Proskauer reaction: negative.

Methyl-red reaction: negative.

Gelatine liquefaction: absent.

Nitrate reduction: nitrates reduced to nitrites.

The organism was therefore proved to be *B. fæcalis alcaligenes*.

Serological reaction of B. fæcalis alcaligenes isolated from the patient's urine

A sample of blood was collected about a month after the signs and symptoms had subsided, the patient not being available earlier. The Widal test with TH, AH, BH and TO suspensions was negative in 1 in 100 and over. The test with the patient's organism (*B. fæcalis alcaligenes*) showed agglutination upto 1 in 200.

Other tests

The behaviour of the isolated organism when grown in acid urine *in vitro* was then studied as follows. A sample of urine was collected from a healthy person and distributed into two test tubes (10 c.cm. in each). The reaction, which was acid to litmus paper, was noted. The tubes containing urine were then sterilized. One was inoculated with the organism; the other was kept as a control. Observations were made after 24 hours. The results are as follows: (a) The tube inoculated with the organism showed definite turbidity and the acidity of the urine was replaced by alkalinity (tested by litmus paper). (b) The control showed no growth and the urine remained unaltered in reaction.

The effects of variation in the pH of nutrient broth on the growth of the organism isolated from patient's urine and *vice versa* were studied and the following conclusions drawn:—

1. The organism can grow under usual conditions (i.e., at 37°C. in 24 hours) in nutrient broths of pH ranging from 5.4 to 8.2 with pellicle formation. Outside this range growth is poor and delayed and there is little or no pellicle formation.

2. The organism has power to produce alkali in broths, with increase in pH. The delay in the growth of the organisms in broth with pH less than 5.4 is possibly caused by the time taken for the conversion of the unsuitable pH into a suitable one, i.e. pH between 5.4 and 8.2. The slowness of the growth in broths with pH over 8.2 is possibly due to the high alkalinity of the media.

3. Broth with pH 8.8 definitely inhibits the growth of the organism for a long time (10 days).

4. The results of inoculation on agar slopes with pH ranging from 4.8 to 5.2 and from 8.4 to 8.8 coincide with the results of inoculation in broths of corresponding pH.

5. In nutrient agar of pH 8.4 to 8.8, the colonies are more numerous but of smaller size than those in nutrient agar of pH 7.6 (control); both the number and size gradually decreasing towards pH 8.8. In nutrient agar of pH 5.2 to 4.8, the colonies are fewer but larger than those in nutrient agar of pH 7.6; both the number and size gradually decreasing towards pH 4.8. The size of the colonies in nutrient agar of pH 4.8 is about equal to those in nutrient agar of pH 7.6.

Discussion

This case is reported on account of the comparative rarity of symptoms due to infection with *B. fæcalis alcaligenes*. 'Although *B. fæcalis alcaligenes* is frequently found in man's intestine, and may be found in large numbers in cases of enteric fever, it is rare to find any evidence of its infectivity. Some regard it as pure saprophyte.' However, many observers, Laforgue (1908), Straub and Krais (1914), Shearman and Moorhead (1916), Rochaix and Marotte (1916), Hirst (1917) and de Magalhaes (1921) have cultivated this organism from the blood of a few cases with symptoms resembling enteric fever. Shearman and Moorhead (1917) and Ledingham (1923) isolated this organism from the blood of a group of cases of a mild paratyphoid-like fever also. Fischer (1899) found the bacillus present in pure culture in the organs of a patient who suffered from tuberculosis and broncho-pneumonia, and Hamm (1910) found it in a patient with pyelonephritis of pregnancy.

On the other hand, 'during the war, in spite of the enormous number of blood cultures made in enteric-like conditions, hardly ever was *B. fæcalis alcaligenes* encountered. Trawinski and György (1918) in thousands of examinations had negative results'.

There are a few cases on record of infection with *B. fæcalis alcaligenes* with the production of agglutinins in the blood. Such are those of Shearman and Moorhead (1917) who have recorded a few cases with agglutination at 1 in 200, and in two cases even upto 1 in 400, Rochaix and Marotte (1916) have recorded two cases with agglutination at 1 in 200 and 1 in 1,000, respectively, and Straub and Krais (1914) have recorded one case with agglutination at 1 in 1,000. Ledingham (1923) and Hirst (1917) also have recorded cases with agglutination at 1 in 1,000. But, compared to the long period of time that has elapsed between their records and the present time, the cases recorded are very few, and none of the authors seem to have established the pathogenicity of *B. fæcalis alcaligenes* on the bladder although this organism, in a few limited

cases, was isolated by Straub and Kraus and a few others from urine.

The development of specific agglutinins to a significant titre—as high as 1 in 200—in the blood of the patient reported in this paper, with definite evidence of inflammation of the urinary bladder, and the isolation of pure *B. faecalis alcaligenes* from the urine of the patient, are strong evidence of the pathogenicity of this organism. The exclusion of infections such as typhoid and paratyphoid fevers affords further evidence of the infection, in this case being primary and due to *B. faecalis alcaligenes* alone. The establishment of the pathogenicity of *B. faecalis alcaligenes* in this case leads one to believe that some cases which have in the past on clinical grounds alone been labelled as 'B. coli infection' may possibly have been cases of *B. faecalis alcaligenes* infection.

The hypothesis advanced is that the cure of the condition depended on the inhibition of growth in the bladder by the increasing alkalinity of the urine as a result of treatment with potassium citras together with the development of immunity, as endorsed by the agglutination test.

Summary

1. The literature on the pathogenicity of *B. faecalis alcaligenes* is reviewed and evidence is presented for the belief that the case reported in this paper is the first recorded case of its kind, one in which infection of the urinary bladder by *B. faecalis alcaligenes* was accompanied by the production of specific agglutinins of significant titre in the blood of the patient.

2. An explanation of the cure of the condition by alkaline treatment is given.

Acknowledgment

A TEN-DAY FEVER SIMULATING TYPHOID*

By STANLEY DE SILVA

Medical Registrar, General Hospital, Colombo

FEVERS in the medical wards, in the absence of positive bacteriological or definite clinical evidence of malaria, typhoid, tuberculosis, pyelitis, etc., are often labelled influenza, 'three-day fever', 'five-day fever' or 'pyrexia of unknown origin'. The clinical features of these fevers are not clearly recognized or correlated, and their cause remains hidden, the physician's interest in the fever falling synchronously with the falling temperature and later disappearing entirely as the patient leaves the hospital.

In this article, I am attempting to demonstrate such a continuous fever of about 10 days' duration which appears to be a well-defined clinical entity, and which though commonly diagnosed as typhoid fever differs from it completely as regards its course, complications, prognosis, sequelae and bacteriological findings.

Clinical description.—The present observations are based on a small series of 10 cases. The fever usually attacks young adults of either sex. The onset is always sudden, the patient developing a high temperature 102°–103.5°F. while apparently in normal health. There is no chill or rigor, and a characteristic feature of the disease is a severe frontal headache on the second day. The patient is usually seen in the hospital on the third or fourth day of illness. The face is usually flushed and anxious. The patient becomes slightly dull on the fourth or fifth day, but one never sees the toxic face or drowsiness of a typhoid patient on this date. The headache at this stage is less prominent and even absent.

Digestive symptoms.—The tongue was coated and dry during the first four days, not unlike that of a typhoid patient. The abdomen showed no abnormality, only one case showing a slight distension for a few hours. The spleen was palpable in 2 cases in the series, one patient had diarrhoea which subsided without much treatment. The stools were invariably solid and never 'pea-soup' in character.

Respiratory system.—No signs or symptoms.

Circulatory system.—The pulse was not recorded accurately in every case but in some cases it appeared to be on the slow side.

Nervous system.—No symptoms except transient headache.

Cutaneous system.—No rash or spots.

Temperature curve.—At first sight it looks like the second half of a typhoid chart, but the onset is sudden and there is no long plateau as in typhoid, the temperature remaining high for 3

* A résumé of a paper read before the Clinical Society, General Hospital, Colombo, on 12th July, 1941.

to 5 days falls by lysis. In this series the average duration of fever was 10 days, the temperature invariably reaching normal on the tenth day and remaining normal from then onwards. No relapses were seen except in one case; the temperature rose on the 23rd day to 101.8°F. for a few hours. The blood on this day proved negative for malaria.

Urinary symptoms.—The urine showed no abnormality beyond a trace of albumin and a few pus cells.

Laboratory findings.—The agglutination tests for typhoid, paratyphoid A, B and C ('H' and 'O') and for *B. columbiensis* proved negative in every case. The clot culture was done in five cases and proved negative. The Weil-Felix reaction was done in two cases and proved negative. The average total white-cell count was 8,200 per c.mm. along with an absolute lymphocytosis, the average differential count being polymorphonuclears 58 per cent,

lymphocytes 40 per cent and eosinophils 2 per cent. Stools on culture proved negative in 4 cases in which it was done. There was no complication in the series, the patient making a rapid recovery in every case. One pregnant woman had abortion at about the sixth or seventh month during the fever.

Diagnosis.—In this series, 8 cases were diagnosed and treated as typhoid and the other two being diagnosed as malaria and colitis.

The diagnosis however is not difficult. It is not entirely based on negative finding. One's suspicion of typhoid is soon set aside when the headache passes off, the patient becomes cheerful and brighter from the fifth day and the fever begins to fall by lysis. The absence of toxæmia is characteristic. So also is the moderate leucocytosis with lymphocytosis and negative agglutination reactions.

Cause.—I am afraid I do not know the cause of this fever. Perhaps it is bacterial in origin. Further laboratory investigations seem to be necessary to trace the origin. It does not appear to be very infectious.

Treatment.—No definite treatment is indicated beyond symptomatic therapy.

SULPHAPYRIDINE IN THE TREATMENT OF TETANUS

By S. M. GHOSAL, M.B., M.R.C.P. (Lond.),
F.R.C.P. (Edin.), D.C.H. (Eng.)

Lecturer in Diseases of Children, and Medical Registrar
and

L. M. CHAUDHURY, B.Sc., M.B., B.S.

(From the Department of Medicine, Medical College
Hospital, Patna)

FOLLOWING its success in the treatment of lobar pneumonia, sulphapyridine came to be tried against a number of different infections including those due to the clostridium group of organisms. In fact the drug has already an important place in the treatment of gas-gangrene. Bryant and Fairman (1940) have obtained with M.&B. 693 encouraging results in the treatment of tetanus. Cole (1940 and 1942) however reports a case of tetanus in which sulphapyridine did not have any effect whatsoever against the fatal course of the disease.

During the period from December 1941 to May 1942, sulphapyridine was used in the treatment of thirty-seven consecutive cases of tetanus in the Medical College Hospital, Patna. The results obtained are reported below.

Treatment adopted.—The patients were nursed in a quiet and dark room of the ward. Nourishment was given in fluid form throughout the course of illness. Bowels were opened by soap and water enema as a rule, since constipation was practically always present. The wounds present were cleaned and dressed regularly. Care was taken to cut down to a minimum all nursing activities likely to induce reflex spasms and essential nursing was done only when the patient was deeply under the effect of the sedatives.

The dosage of sulphapyridine employed was one tablet every four hours for the first three days, followed by one tablet three times a day up to a total of thirty tablets.

A bromide-chloral-hydras mixture by mouth and paraldehyde by mouth or per rectum were used as sedatives. The bromide mixture containing ten grains each of chloral hydras and the bromides of potassium, sodium, and ammonium, was given every two hours for the first three days and then every four hours. (The patients were not awakened for administering the mixture.) Three drachms of paraldehyde with syrup were given in an ounce of water twice daily, or else six drachms of paraldehyde in olive oil were given twice daily per rectum.

In cases with severe spasms the above-mentioned sedatives often proved inadequate. In such cases *Evipan-sodium* was used to control the spasms if the patient could afford to purchase the drug. (This was possible in only eight cases.) Five to 10 c.cm. of a 10 per cent solution of the drug was given intravenously twice daily. The effect of this intravenous anæsthetic was kept up by intramuscular injection of 4 c.cm. of paraldehyde.

Before being warded eighteen cases had received tetanus anti-toxin in doses varying from 3,000 to 6,000 units. But as none of the patients could afford to buy the anti-toxin in amounts generally advocated for a definite therapeutic effect, it was not used in the wards.

No case in the series had taken a prophylactic injection of anti-toxin.

Result of the treatment.—Two cases left the hospital against advice, the results in the remaining thirty-five are given below :—

Total No. of cases	35
Cured	18
Died	17

The following table shows the results in relation to the incubation period and the severity of the disease :—

TABLE

Day of first spasm after sustaining injury	Number of cases	RESULTS OF TREATMENT						TOTAL	
		In relation to the severity of the disease							
		Mild 1		Moderate 13		Severe 21			
		Cured	Died	Cured	Died	Cured	Died	Cured	Died
1 to 7 days	3*	..	3	0	3
8 to 14 days	13	1	..	8	1*	3	..	12	1*
15 days and above ..	3	3	..	3	0
Unknown	16	2	2	1	11	3	13
TOTAL ..	35	1	..	10	3	7	14	18	17

Mild—tonic rigidity without reflex spasms.

Moderate—reflex spasms occurring at long intervals.

Severe—very frequent reflex spasms at long intervals.

* The patient died of measles following cure of tetanus.

Discussion and conclusions.—Of the eighteen cases that recovered, seven had suffered from the 'severe' form of the disease. In five of these seven cases, evipan-sodium was used to control the spasms.

Of the seventeen cases that died, three had the 'moderate' and fourteen the 'severe' form of the disease. The three deaths amongst the cases with moderate symptoms include one case that died of measles after recovery from tetanus. Of the fourteen deaths amongst the severe cases, ten occurred within twenty-four hours of the admission of the cases into hospital—a period too short to allow the drug to act in sufficient concentration. Of these fourteen cases only three could procure evipan-sodium, and only in one of these three was the anaesthetic effective in controlling the spasms, one died thirteen hours after admission to the hospital and received only one injection of evipan-sodium, and in the third case evipan-sodium was given only after the severe and

exhausting spasms had already continued for two days. Thus amongst the cases that died, there was only one case in which spasms were kept under control and sulphapyridine given a proper trial; the incubation period in this case was only five days.

If the eleven cases, one that died of measles and the ten that died within twenty-four hours of their admission, are excluded the mortality rate comes to 25 per cent, since eighteen of the remaining twenty-four cases recovered.

It is not possible to arrive at a definite conclusion from observations made on only thirty-five cases, but we feel that sulphapyridine in conjunction with evipan-sodium as anti-spasmodic will have a definite place in the treatment of severe tetanus. Moreover, this line of treatment is much cheaper than the serum

therapy if the serum is employed in the doses generally advocated*.

A further trial is however needed in this direction before definite conclusions can be drawn.

Acknowledgments.—Our thanks are due to Captain R. P. Ghosh, superintendent, Medical College Hospital, for permission to publish the records of the cases. Thanks are also due to Dr. S. M. Ghosh for his valuable suggestions and untiring help.

Idem (1942) .. *Brit. Med. J.*, i, 148.

* The cost of 200,000 units A.T.S.—the dosage advocated by Leslie Cole—is Rs. 150, whereas M.&B. 693 tablets for the whole course will cost Rs. 4 only. If evipan-sodium is used in addition as anti-spasmodic, it will mean an additional expenditure of Rs. 30 to Rs. 40 for the 10 ampoules that are usually needed in the severe cases.

TRANSLUCENT AREAS IN THE LUNG FIELD

By L. EVERARD NAPIER, C.I.E., F.R.C.P. (Lond.)

and

R. N. CHAUDHURI, M.B. (Cal.), M.R.C.P. (Edin.),
T.D.D. (Wales)

(From the School of Tropical Medicine, Calcutta)

A ROENTGENOGRAM of the lung field varies considerably according to the intensity of the rays, the length of the exposure, and the development of the film. Normally, the lung fields appear as translucent areas which are crossed by striate markings radiating from the hilum. These linear striæ are shadows cast by the blood vessels accompanying the bronchi. They do not signify increased fibrous tissue formation or bronchial ramifications; bronchi, except the ones near the hilum, do not usually cast shadows in the roentgenogram.

In *emphysema* the lung becomes more translucent than normal, the translucency depending on the degree and extent of the process and being due to the presence of air in the distended alveoli. The striations show an increased density which is further intensified by vascular changes due to pulmonary congestion. There are other radiological features characteristic of *emphysema*, viz, the ribs become more horizontal than usual, the intercostal spaces are widened, the costo-phrenic angle is increased, and the diaphragm is flattened; the screen examination shows the limited excursions of the latter, and sometimes its outline loses the dome shape, and becomes irregular owing to basal adhesions, which, if in excess, may even obliterate the costo-phrenic angles. Owing to the lowering of the diaphragm, the apex of the heart tends to rotate forward, and therefore the heart as a whole appears small (Kerley, 1936). The inferior vena cava shadow may appear clearer in *emphysema*, presumably on account of the low diaphragm and rotation of the heart. The pulmonary artery looks prominent in the left hilum, and the right side of the heart may be enlarged.

In spite of there being so many characteristic radiological features, we do not as a rule *x-ray* a chest for the diagnosis of *emphysema*, as the clinical signs are obvious in an established case, but, if some complication is suspected, a skiagram is indicated, and other methods, such as bronchography, tomography and/or bronchoscopy, may be needed to establish a diagnosis, especially if the *emphysema* is a localized one, that is, when a local area of increased translucency is seen. When there is a well-defined local translucency, the condition may be mistaken for pneumothorax, but in localized *emphysema* the lung markings will be faintly seen in the translucent area.

Cavity formation in the lung is another cause of localized increased translucency. This may result from tuberculosis, bronchiectasis, abscess, cyst, or a growth that is breaking down. Tuberculous cavities usually have a well-defined

wall, usually with an infiltrated area around them; the more chronic is the cavity the thicker the wall. If the surrounding tissue, however, is consolidated and the overlying pleura thickened, the cavity may be missed unless serial pictures are taken with the aid of a tomograph. Non-tuberculous abscess usually casts a fairly well-defined shadow, often with a fluid level. Cysts and bronchiectatic cavities as a rule have a thin wall. They may or may not be visible in an ordinary skiagram; sometimes there may be nothing but diffuse haziness or simply an area of apparent fibrosis. Bronchography is often required to confirm the diagnosis; lipiodol enters such a cavity readily, and determines the extent of the damage. The oil usually does not reach an abscess cavity.

Ring-like shadows resembling cavitation may at times be seen in a skiagram. They have a thin well-defined wall of fairly uniform thickness, identical in appearance with that of a cyst. The density of the lung field inside the ring is, however, the same as that of the rest of the lung. They give rise to no signs or symptoms.

Various views have been expressed regarding the cause of these ring shadows. Amberson regards them as pleural rings caused by adhesions between the visceral and parietal pleura.

In other cases the ring shadows surround a translucent area. It has been suggested that these are air-pockets in the pleural surfaces of the interlobar fissure. Some hold that these annular shadows represent silent tuberculous cavities; the mere finding of such an annular shadow should not influence treatment, which should depend on the associated symptoms.

The possibility of these rings being the result of localized pneumothorax has been considered.

Mitchel (Sowerbutts, 1932) has suggested that they are *air-cysts*, the mode of their origin being as follows: a small bronchus or bronchiolus, possibly weakened by disease, becomes strained by repeated coughing and eventually gives way, allowing air to escape into the connective tissue of the lung. This causes a solitary bubble of air, which is confined to the interstitial tissues, but does not cause an interstitial *emphysema*. The compressed tissues around give rise to the annular shadow. If the perforation heals up, the air may be absorbed, with disappearance of the ring.

Other authorities consider that they are *emphysematous bullæ*, possibly of congenital origin. They are differentiated from cavities by their roundness, their extreme clarity, the absence of any fluid level, the thinness of their walls, and the absence of surrounding induration. They may however be present in cases of chronic fibroid phthisis.

They may rupture, giving rise to spontaneous pneumothorax; most cases of non-tuberculous spontaneous pneumothorax are due to rupture of *emphysematous bullæ*. Spontaneous pneumothorax occurring suddenly in otherwise apparently healthy persons is not very uncommon. Recently published studies tend to show that

the most frequent cause is the rupture of an emphysematous bulla. Such bullæ have been demonstrated around scar tissue, such as healed tuberculous foci or collapsed areas. Effusion usually does not follow such a pneumothorax. Complete recovery is usual within a short time, but recurrences may occur. No treatment is ordinarily needed except rest in bed and sedatives during the first few days.

The following case is of interest in this connection :—

The patient was a European, aged 40, who, after a long spell of work in Calcutta without a holiday, had an attack of dengue. He gave a history of tiredness and lack of energy for a few months. He had been given eight injections of emetine, apparently for diarrhoea. A few days before admission he had a sudden pain in his chest over his heart which he attributed to either pleurisy or 'heart'. He said he was unable to rise from his bed at all, and when later he did so, the effort caused him to be drenched with perspiration; the pain disappeared slowly within a few days. The symptoms were more suggestive of indigestion and hypochondriasis, but we admitted him to hospital for more thorough investigation.

Clinical examination of the chest failed to reveal any abnormality, but an orthodiagram was ordered mainly to convince the patient that his heart was sound. There was no evidence of any coronary lesion.

In the absence on leave of the official radiologist, the opinion of another radiologist was obtained. He reported as follows :—

'Apart from slight ventricular predominance the heart appearances are normal.

Extreme cavitation is seen in the right upper lobe. Signs of chronic bronchitis and bronchiectasis to a lesser extent are seen bilaterally.'

Only the first half of the report was communicated to the patient.

The patient was questioned and examined again in view of this report. There was nothing in his history, except that questionable attack of pleurisy, or in the physical examinations to suggest that he had at any time suffered from pulmonary tuberculosis.

A second skiagram was taken by the same radiologist. An almost identical picture was obtained and the radiologist who had now been shown the clinical notes reported: 'See notes on previous skiagram'.

The patient was a nervous individual and we did not feel justified in communicating this report to him. He was discharged from hospital and we have been personally in touch with him for over three years, during which time he has remained in apparently sound health. He has now been in the army for nearly a year.

At our request Col. Shorten, the radiologist to Carmichael Hospital for Tropical Diseases, examined the films and reported as follows :—

'Heavy hilar shadows with calcifications in both sides; in addition, the right lung shows the following : (1) A group of large ring shadows in the right upper zone with thickened broncho-vascular trunks leading to a group of calcifications in the upper part of the hilum. (2) Surrounding the ring shadows there is evidence of a streaky fibrosis but no infiltration. (3) A streaky fibrosis in the periseptal area also extending into the hilum.

THE ROLE OF METHÆMOGLOBIN ON THE LEPTOMONAD PHASE OF *LEISHMANIA TROPICA*, WITH SPECIAL REFERENCE TO ITS REVERSION INTO *LEISHMANIA* FORMS IN CULTURE

By R. ROW, O.B.E., M.D. (Lond.), D.Sc. (Lond.)

and

S. S. KULKARNI, L.C.P.S., D.T.M.

(From the Department of Pathology, P. G. Singhanee Hindu Hospital, Bombay)

In a former communication one of us (Row, 1922) had pointed out that the flagellate leptomonad forms of *Leishmania tropica* reverted to the leishmania O-bodies and these made their appearance in the condensation fluid of NNN culture tubes inoculated with the parasite 2 to 3 weeks previously. These were described as the O-bodies, or resistant forms, and it is the presence of these in old cultures of *L. tropica* which was responsible for their infectivity in mice—even to the extent of inducing a generalized infection in them—indistinguishable from experimental kala-azar (Row, 1914). The observation on the infectivity of old cultures containing these resistant forms was confirmed by Southwell and Kirshner (1938)*. It was also pointed out (Row, 1922) that the reversion was due either to the concentration of the fluid or to the alteration of the oxyhæmoglobin into methæmoglobin.

Subsequent work on the culture of the parasite in the hæmoglobin saline medium of Row (1912)

* No original investigation was undertaken by these workers; in their paper they review work already done, including Dr. Row's.

(Continued from previous column)

Conclusions.—These appearances are suggestive of old healed tuberculous disease.

The ring shadows in the upper zone are due to one of two causes: (a) emphysematous bullæ; (b) an irregular pneumothorax with adhesions.

There is no evidence of cavitation.'

Conclusion.—It seems improbable that the patient had a pneumothorax, as there would have been more clinical evidence of this. We are inclined to accept the second radiologist's (Col. Shorten's) alternative opinion that the translucent areas are in this case due to emphysematous bullæ.

There is little to support the first radiologist's interpretation—which he declined to revise—even on the strength of the skiagram, and when the latter was taken in conjunction with the clinical picture, this interpretation was completely ruled out. Had this verdict been communicated to the patient, the result would have been disastrous.

proved that it was the latter condition more than the former which was responsible for the reversion, but unfortunately it is difficult to demonstrate this feature clearly, even in stained smears, because here the leishmania bodies lie scattered between the large number of flagellates overcrowding and overshadowing them in the form of rosettes which persist in the fluid culture medium even for 100 days, as pointed out elsewhere (Row, 1935), unless one is lucky to hit upon the right day while examining old cultures (*vide* figure 5), and even here the day varies with the strain of the parasite (*vide* figure 6). It was therefore thought interesting to see if any morphological alteration of the flagellates into leishmania bodies could be observed more clearly in the culture fluid containing only methæmoglobin.

Preparation of the culture fluid.—When the parasite of the oriental sore is grown in Row's medium (1912) and the ensuing flagellates allowed to thrive for several weeks at 22°C., the striking character of the culture fluid is its alteration in colour from scarlet lake of the oxyhæmoglobin into a brownish transparent liquid which on spectroscopic examination shows the distinct methæmoglobin absorption band in the red of the spectrum, and the disappearance of the two characteristic absorption bands of the oxyhæmoglobin between the D and E lines. The flagellates flourish in abundance and are found mostly in rosettes of more or less equal size indicating that they continue to grow even when oxyhæmoglobin is altered into methæmoglobin. After a week or two, however, the culture degenerates and consists mostly of granular debris. At this stage the brown culture fluid is centrifuged and the supernatant fluid is distributed in tubes and this constitutes methæmoglobin medium ready for immediate use.

These tubes are inoculated with a drop of young cultures of five to seven days containing only flagellates and incubated at 22°C. and when examined every three or four days reveal the following features:—

During the first week the culture shows that the flagellates have grown in enormous numbers, but is characterized by the presence of rosettes of more or less equal size uniformly distributed in the fluid (*vide* figure 1), and stained smears show that it is from these rosettes that the leishmania bodies are derived and these are found also lying between the rosettes in fair numbers with all transitional forms (*vide* figures 2, 3, and 4).

During the second week the rosettes have a tendency to mass together but slightly degenerate with a large number of oat-shaped bodies and transitional forms, obviously the product of the rosettes (*vide* figure 6). A few days later, all that is left is a degenerate debris of the leishmania bodies with a flagellate here and there.

The transitional forms are exactly like those occurring in the condensation fluid of the old NNN cultures already described elsewhere, except for the absence of the thin capsule-like structure, within which the parasites obviously appear to shrink. These transitional forms, it may be repeated, are briefly as follows:—

(1) The phase where the active flagellates become sluggish with the shortening of the flagellum by its withdrawal inside and its absorption, and with the simultaneous migration of the kinetoplast towards the nucleus.

(2) The shortening phase of the parasite where the shortened stump of the flagellum disappears and where the condensation of the cytoplasm of the parasite takes place side by side with the further approximation of the kinetoplast towards the nucleus, before the final rounding off stage when they become oat-shaped or round bodies (with the differentiation of the nucleus) indistinguishable from those found in the original lesion.

The morphological changes of the flagellates into leishmania bodies when grown in the methæmoglobin medium are illustrated in the accompanying photomicrographs.

Summary

(1) The reversion of the flagellates into leishmania forms can be induced in a few days by growing them in the methæmoglobin medium.

(2) The formation of leishmania forms is always preceded by the appearance of a large number of flagellates mostly in the form of rosettes (distributed uniformly in the medium) from which arise masses of transitional forms and leishman bodies.

(3) The significance of these points may require further investigation.

CONSTRICTION OF THE URETER

By RICHARD E. STRAIN, M.C.P.S., M.D., M.C.C.

CONSTRICTION of the ureter is 'one of the most common lesions of the abdomino-pelvic cavity' (Hunner, 1941) and is still being largely neglected not only by men in active practice but also by teachers even in the better medical schools (Brown and Pennington, 1941). The following case reports illustrate several common varieties of this common clinical condition:—

Miss Y., a 25-year-old single American, developed sudden abdominal pain of generalized aching nature during the night of 23rd December, 1940, at 2 a.m. preventing further sleep. I saw her at 6 a.m. when the pain had localized to an area to the right and slightly below the umbilicus and extending up into the right upper quadrant. Some nausea but no vomiting was present. The last menstrual period had started 14 days previously. There was no history of nocturia, dysuria, frequency or backache. Irregular acquired dysmenorrhœa had been noted in the past. A similar attack had occurred two months previously on a train trip from Calcutta and lasted a few days. The patient had shortly afterwards a routine annual physical examination by another physician and been pronounced in good physical condition. A history of 'hives' three days prior to the onset of the December attack was obtained.

Examination disclosed a temperature of 100.6; pulse 88; respiration 20. The head, heart and blood pressure, and lungs were normal. A broad sub-costal angle was noted. The abdomen was scaphoid, symmetrical; moved well with respiration, and was without visible masses or peristalsis. On palpation, definite pain and tenderness with some spasm was noted just to the right of the umbilicus and extending up into the right upper quadrant. The patient could not take a deep breath while moderate pressure was being exerted in the region between the umbilicus and right costal margin at its mid-point. Gurgling on pressure was noted in the right lower quadrant but no tenderness. The kidney posteriorly was not tender to deep pressure. Pelvic examination was negative. There was a slight leucocytosis. Urine was normal.

I felt the patient had a high retro-cæcal appendix of the mechanical (fecalith) type. I asked Dr. R. H. H. Goheen to see the patient in consultation, as the findings were far from typical. He felt that the appendix was the cause of the trouble and immediate operation was decided upon. Under spinal anaesthesia (150 mg. of neocaine) a right rectus incision disclosed a small, non-adherent normal looking appendix; it was removed and found to contain two strictures and a fecalith. The gall-bladder was normal; a few soft adhesions were felt about the right kidney which was slightly larger than the left. A small fibroid on the right of the uterus was removed. Convalescence was uneventful except for persistence of pain to the right of the umbilicus.

The patient was then well without symptoms for one month; we decided to cystoscope and do pyelography to discover the cause of adhesions and slight enlargement of the right kidney, but the patient wished for postponement. Two months after operation, nocturia developed once nightly and over a four-month period increased to twice each night. Dull ache was present in the right upper quadrant, the patient for relief putting a hot water bottle just below the right costal margin. At my suggestion three months after operation the patient took a full glass of cream in a diagnostic procedure. A severe attack of right upper quadrant pain requiring morphine and associated with nausea and vomiting for two days followed. There was no fever; the pulse was in the sixty's; low mid-backache associated with tenderness over the right ureter was present; some pain was also present in the lumbar area. Fluids were forced but this procedure

so much increased nausea, vomiting and pain that it was stopped. Hospitalization for immediate investigation was urged but delayed at the patient's wish. Six months after operation she entered the hospital for investigation.

Gall-bladder and stomach showed no abnormality. Three films were taken in the pyelogram series; one (figure 1) disclosed a double pelvis to each kidney. On the right was a solitary ureter with a high constriction at the utero-pelvic junction; dilatation and then a constriction at the level of the transverse process of the third lumbar vertebra. The pelvic portion of the ureter was dilated, the lower constriction not being seen. On the left two ureters were seen. Figure 2 shows the left ureters after a retrograde pyelogram.

Indirect cystoscopy disclosed a urethra tight to a 18 F catheter; this was dilated to 26 F; bladder capacity was 400 c.c.m.; the bladder mucosa showed thickened muscle bundles without true trabeculation. The region of the right ureter was reddened and a small ulceration with an adherent blood clot was noted just below the orifice. Two ureteral orifices were seen on the left and appeared normal. The trigone was slightly redder than normal. Urine culture was sterile. Indigo-carmin was given intravenously (20 c.c.m.) and water by mouth but a temporary anuria which persisted for seventeen hours was found; so catheterization was not done. Quinby and Austen (1939) report such anuria following intravenous pyelography. Further cystoscopies showed that a no. 6 ureteral catheter could be introduced to the right kidney easily but was tight in each left ureter. A bee's wax bulb on the catheter demonstrated 'hang' on withdrawal in the right stricture area; also in the upper left ureter four inches from the bladder.

The patient has since had repeated dilatations, one ureter being dilated at a time each week. We have dilated the right ureter to a size 24 by using one 6; two 5's; and two 4's all alongside in the ureter at the same time. During this slow process the patient has had recurring attacks of right upper quadrant pain with nausea and vomiting after dilatations; the urine has consistently been sterile before cystoscopy; she was given anti-spasmodics and bile salts without relief before dilatations were undertaken; acid also failed to relieve her; she is not now completely cured but feels 'better than I have in months'. Her nocturia is now irregularly once nightly where it was for several weeks thrice; her pain no longer incapacitates her as it once did; her left ureters have been dilated only to no. 12 and still give symptoms. Hunner (1941) at Johns Hopkins points out that dilatation should be carried up to a no. 18 and states that when multiple catheters of small sizes are used the resulting dilatation is not the sum total of the size of the catheters; this seems very illogical but is true; we have deferred to his wide experience at the John Hopkins hospital and given a large dilatation as single large catheters were not available.

Case 2.—Mrs. F., a married American woman of 25 years, was seen in March 1941, fearful that she had appendicitis because of sudden onset of cramping abdominal pain of a generalized nature preceded by constipation; associated with nausea, borborygmic flatulence, poor appetite and headache. No vomiting, diarrhoea, nocturia, frequency or discharge. Acquired dysmenorrhœa present eight months; periods lasted eight to nine days and came every twenty-three days. The last menstrual period had just been completed. In 1933 after x-rays of the chest she had spent five months in bed although she had been assured she did not have tuberculosis. Since 1938 she had been anæmic (hæmoglobin 75 per cent Sahli) and had not felt very brisk. The temperature was 98.6; pulse 90; respiration 20; blood pressure 110/70. The patient appeared anæmic; her head, lungs, and heart were normal. The abdomen was flat, symmetrical, scaphoid and moved well; the sigmoid colon and cæcum were both palpable and tender. Tenderness was present over Legge's and Morris' points on both sides but faded into cæcal and sigmoid tenderness. A fixed, retroflexed uterus was found. Chest x-rays, sputum, and

tuberculin tests were negative. Entamoebae were found in the stool; agglutination tests for His bacilli were positive 1/320; negative for Shiga and Flexner. Treatment with entero-vioform relieved the flatulence but ureteral tenderness persisted. Catheterized urine showed an acid reaction; specific gravity 1.018; albumin one plus; no sugar; leucocytes one plus. Because of urinary findings and history of acquired dysmenorrhœa it was decided to investigate the urinary tract. Intravenous pyelogram was done and reported normal (figure 3). Indirect cystoscopy disclosed a urethra tight to a 18 F catheter; this was dilated to 28 F. Bladder capacity was 200 c.cm.; the bladder was dilated to 350 c.cm. A bee's wax bulb on a no. 6 catheter demonstrated 'hang' on withdrawal from the lower left ureter. Dilatation of the ureter to no. 12 has relieved completely the acquired dysmenorrhœa; there has been no recurrence during the past six months. Her urine has repeatedly been normal.

This represents a type of ureteral constriction about which such great controversy has raged. The x-ray report—normal ureterograms; the operator while passing a bulb feels a 'hang' (and quite frequently the patient gets some pain similar to that occurring previously); the other clinicians say that it is due to spasm; dilatation produces relief of symptoms so frequently associated with ureteral constriction. Significant co-existent findings lending support to the diagnosis of ureteral constriction are the constricted urethra and small bladder capacity. The average bladder will accommodate 300 c.cm. and anything below that is regarded as abnormal (Brown and Pennington, 1941). The normal urethra in a woman accommodates a 26 F catheter (Stevens, 1936, and Stevens and Smith, 1937).

Case 3.—R. B. R., aged 37, a married male, Hindu, was seen on 12th September, 1941, complaining of pain, and discharge of pus from the rectum. For ten months he had signs suggestive of pulmonary tuberculosis; for two months suppurating glands of the neck and a fistula of the rectum; for one month bloody urine and nocturia nightly ten times. He was found to have bilateral pulmonary tuberculosis with foci in the glands of the neck, a fistula-in-ano, marked anaemia, and a tender left kidney with very bloody urine. The fistula was dissected out at the patient's instance; cystoscopy disclosed a bladder capacity of 230 c.cm. with blood spurting from the left ureter; no ulceration of the bladder. Retrograde pyelograms (as shown in figure 4) showed constriction on the right side just above the bladder shadow. The left kidney emptied so quickly that we could not obtain a picture. We have been unable to isolate tubercle bacilli from the urine. Bleeding has been much less since passage of catheters but it is not felt that this man's symptoms are due to stricture alone.

Case 4.—Miss J. R., a 17-year-old single girl from Goa, was referred to me by Dr. R. H. H. Goheen on 8th July, 1941, complaining of recurring attacks of pain in the right lower quadrant associated with constipation; duration two years; pain dull aching in character without radiation. Dysmenorrhœa of the acquired type had been present three years. Nocturia was noted 'often'. There were no other genito-urinary complaints. Nausea and vomiting were absent. Examination disclosed very little except tenderness along the right ureter most marked just two-finger breadth to the right of the umbilicus. Blood, stool and urine were normal. The patient was cystoscoped by the indirect method; the urethra was tight to a 18 F catheter; bladder capacity was 200 c.cm.; moderate injection was noted about the right ureter; a no. 6 ureteral catheter met a high obstruction on the right. Further cystoscopy was refused by the patient's father on the ground she was 'too young'. Intravenous pyelograms disclosed a high stricture on the right at the utero-pelvic junction with definite pyelectasis. Further treatment was refused.

Case 5.—B. B. N., aged 23, a married male Hindu, was seen on 25th August, 1941, complaining of pain and burning in the epigastrium for six months. The patient was a strict vegetarian. He had begun to note

fullness after meals; sour eructations; nausea but no vomiting; paræsthesia of the extremities; giddiness; pain over the kidneys and nocturia one time for six months. Slight tenderness to deep pressure was present on both sides of the umbilicus at Legge's point. No kidney tenderness. The epigastrium was normal as was the rest of the body. There was slight anaemia. Stool and urine were normal. Kahn was three plus. Cystoscopy was done after sodium amytal, morphine and atropine and under caudal anaesthesia. As the patient came to the cystoscopy room, he was talking at random as if from a 'barbiturate jag' but was quite willing for cystoscopy. The bladder capacity was 250 c.c.; the mucous membrane was redder than normal with a number of dilated vessels around the right ureter. The right ureter was catheterized; an obstruction was noted three inches up from the bladder which persisted despite withdrawal of the stylet and catheter. The prostate was normal in appearance. The patient was quite restless, therefore the left ureter was not catheterized. Intravenous pyelograms disclosed the lower portion of the right ureter to be dilated; the right ureter deviated sharply at the level of the third lumbar vertebra. The left ureter was small with a sharp narrowing in the pelvic portion. The right kidney pelvis was slightly dilated. Anti-luetic treatment and dilatation were advised; both were refused. There was no evidence of ulcer of the stomach.

Case 6.—M. C., a 24-year-old single male Goanese, was seen on 10th October, 1941, and referred to me by Dr. R. H. H. Goheen with a chief complaint of recurring pain in the right lower quadrant of three months' duration, associated with nausea; induced vomiting seemed to relieve nausea. The pain was dull, aching in character, and localized to the right side lateral to the umbilicus. No cramps, fever, or diarrhoea. The patient had not had nocturia, frequency, urgency, headache, dysuria or hematuria. Attacks lasted three or four days and subsided. Examination disclosed a well-developed young male whose skin, head, chest, heart, extremities, rectum and blood pressure were normal. The abdomen was scaphoid, symmetrical, moved well with respiration and visible coils of intestine could occasionally be seen through the abdominal wall. No masses were seen or felt. There was slight tenderness to deep pressure on the right side midway between umbilicus and the anterior superior spine. In addition there was definite tenderness over Legge's and Morris' points on the right. Slight but definite tenderness was noted in the right lumbar area. There was no leucocytosis. A microcytic anaemia was present. Stool and urine were normal. Kahn plus two. It was felt the patient had some slight appendicular tenderness but also definite signs of ureteral trouble. A long, thin, fibrosed appendix was removed under spinal anaesthesia through a right rectus incision on 24th October. Convalescence was uneventful. On 30th October intravenous pyelograms (figure 5) disclosed definite pyelectasis on the right side; a sharp kink of the right ureter at the level of the transverse process of the third lumbar vertebra with dilatation of the ureter below the kink; a definite constriction with dilatation above the constriction at the lower end of the left ureter with pyelectasis and ureterectasis. Figure 5 shows the constriction at the lower left ureter but does not show the dilatation below the kink on the right which was recognized in other films. The patient refused any further treatment.

Discussion

The ætiology of ureteral stricture is in a debatable stage. This hollow tube twenty-five centimetres long with a lumen four to five millimetres that should normally take a no. 10 to 12 ureteral catheter is narrowed at its origin; at the termination in the bladder and at the junction of its abdominal and pelvic portions.

Foci of infections in the head, tuberculosis, unwise use of x-rays, pelvic operations, trauma of childbirth, and peri-ureteral infections all may play a part in further constriction of this narrow tube. Others are undoubtedly congenital in origin.

The symptoms may be divided clinically into high and low strictures although they are usually associated; are usually bi-lateral; occur at all ages; and affect men and women (Rathbun, 1925) in equal numbers. High constrictions are confused with gall-bladder disease, peptic ulcer, and appendicitis. Many of these patients have had repeated operations for one or all of these diseases without permanent relief. Such a history should always lead to a thorough investigation of the urinary tract. The first step in the diagnosis is to realize that many careful men agree that ureteral constriction is one of the most common lesions of the abdomino-pelvic cavity. The second step is to realize that a negative urine examination does not rule out serious disease of the urinary tract. This is a stumbling-block for many. Only if infection occurs will the urine show positive findings. This occurs in about 20 per cent of cases; 30 per cent present no urinary findings, and the remaining 50 per cent show only a few leucocytes and occasionally albumin or casts. It cannot be too strongly emphasized that the urinalysis is of no value in the diagnosis of this disease. High ureteral strictures frequently present nausea, vomiting, fever, leucocytosis, very little or no kidney tenderness but a rather diffuse pain which cannot be localized except to one side of the abdomen. Case 1 presented such a picture in which backache, nocturia, frequency, dysuria, hæmaturia and other bladder symptoms were conspicuous by their absence. Seventy-five per cent of constriction patients have bladder symptoms which can only be elicited by very careful questioning.

Patients with constriction of the lower portion of the ureter complain of pain in the pelvis, backache and bladder symptoms of mild character. If urinary stasis has reached any marked degree, headache, lassitude, nervousness, and various gastro-intestinal symptoms such as anorexia, nausea, vomiting and flatulence are noted. So many women have been diagnosed as neurotics when such conditions exist that such a diagnosis is no longer tenable unless thorough investigation of the urinary tract has been done. Hunner (Brown and Pennington, 1941) feels at least 50 per cent of cases of acquired dysmenorrhæa are due to ureteral constriction; many patients have symptoms only during menstruation.

Examination in ureteral constrictions may reveal four points of tenderness on each side. Legge's (1926) point situated a finger breadth lateral to the umbilicus; Morris' point one finger breadth lateral to the mid-line at the level of the anterior superior spine; tenderness 1.5 centimetre lateral to the supra-vaginal cervix in

the broad ligament region; and finally kidney tenderness. In searching for ureteral tenderness the palpation must be deep, rolling the ureter against the vertebral bodies at Legge's point and against the sacro-iliac joint at Morris' point. If properly searched for, tenderness is usually present.

To summarize: high constriction gives a history suggestive of gall-bladder affection, peptic ulcer or appendicitis, while low constriction gives pelvic pain, backache, and bladder symptoms of such mild character as to be regarded by the patient and some physicians as falling within normal limits. Many of these patients have had repeated operations without relief, or have been diagnosed as neurotics. The most constant physical sign is ureteral tenderness. Palpation must be deep if this is to be properly elicited. The urinalysis is of no value in the diagnosis.

Cystoscopy and pyelograms confirm the diagnosis. Eighty-five per cent of cases of ureteral constriction have a constricted urethra and a bladder capacity of less than 300 c.cm. Multiple constrictions in the same ureter are not uncommon. Shortly after introducing the catheter, an obstruction may be met; this is usually due to a stiff stylet in the catheter. When this is withdrawn a short distance, the tip of the catheter assumes the natural ureteral curvature and one may proceed. Ordinary bee's wax which has been melted is used to apply a bulb two or three inches from the tip. 'Hang' on withdrawal and pain of a nature recognized by the patient will aid in the diagnosis of early constriction. In high constriction a bulb is placed near the tip of a whistle-tip variety of catheter. Extreme care is essential in passing catheters in high strictures as a sharp angulation may exist and puncture of the ureter result. In two-thirds of cases with constriction, passage of a no. 7 catheter alone will not recognize the stricture. Pyelograms should be interpreted by the man who has passed a bulb as 'hang' on withdrawal frequently tells one where to look in the ureterograms—otherwise many early constrictions will be missed. Hager and Braasch (1941) point out 'the inherent nervous control of the ureter, which has to do with peristalsis, can be stimulated by local irritation; as a result, localized areas of spasmodic constriction may cause not only obstruction to the ureteral catheter or bougie but also variable dilation above and below the point of irritation. This is apparent in the pyelo-uterograms'. I believe that such spasmodic constriction always precedes the formation of a stricture of the ureter and that many of the cases over which arguments have raged regarding x-ray interpretation and 'hang' of a bulb are simply cases seen early in the stage of the disease; they have symptoms; they have a constriction which is best recognized by a bulb; they are relieved by dilation; anti-spasmodics will not relieve their symptoms; but it is correct to say that they do not yet have a stricture. I would so regard case 2 which was relieved of

an acquired dysmenorrhœa by one dilation and has had no recurrence for eight months. Such successes are few; many writers have emphasized that if one is in quest of spectacular results, one will be disappointed as it is only after much drudgery by both physician and patient that relief is obtained.

12.5 per cent sodium iodide is given for the retrograde pyelogram and any of the intravenous preparations are satisfactory. Crane (1939) and Dolan (1940) report deaths from the intravenous preparations so it is wise to test for iodine sensitivity by having the patient hold 1.2 c.c. of iodine containing solution in the mouth for ten minutes.

Treatment is by dilation; only one ureter should be dilated at a time as traumatic œdema may cause anuria. Both ureters are usually affected; a ureter should not be dilated oftener than once a week. Patients will usually have a moderate to severe reaction within two or three days of dilation. This is of definite value in further substantiating the diagnosis, as a normal ureter should have little or no reaction after passage of a catheter, while in ureteral constriction over half (Hunner, 1941) have a reaction designated as 'bad', 'extremely severe', or 'terrible'. Reactions consist of pain, fever, nausea and vomiting. It is possible that nausea and vomiting may be associated with dilation and reverse peristalsis of the ureter as Alvarez (1940) believes it is with the bowel. Sodium amytal, morphine with atropine and tissue extracts are ordered immediately after dilation, while hot water bottles are placed over the ureter. Fluids are forced only after one is certain that drainage is present. Dilation should be carried out to no. 18 and occasionally dilation to a no. 24 F (Lowsley, 1936) may be needed.

Summary

Ureteral constriction is a common lesion of the abdomino-pelvic cavity which is daily being missed because this diagnosis is not thought of.

The urinalysis is of no value in diagnosis of the lesion.

Ureteral tenderness is almost always present.

The findings of a contracted urethra, a small bladder capacity and 'hang' on withdrawal of a bee's wax bulb on a ureteral catheter should make one extremely suspicious of ureterograms reported as normal.

The presence of acquired dysmenorrhœa should lead to thorough investigation of the urinary tract, as should a complaint of symptoms suggestive of gall-bladder disease, peptic ulcer or appendicitis unrelieved by operation.

Patients with abdominal complaints diagnosed as neurotic should always have a urinary tract investigation.

Cystoscopy and pyelograms are essential in diagnosis.

Treatment is dilation—only one ureter being dilated at a time. Dilation should be carried to a no. 18 F in all cases and to no. 24 F in

(Concluded at foot of next column)

SPIRILLUM MINUS INFECTION ACQUIRED FROM AN INDIAN SQUIRREL (SCIURUS SP.)

By B. M. DAS GUPTA

Department of Protozoology, School of Tropical Medicine, Calcutta

SYMPTOMS similar to those caused by the bite of rats may follow the bites from other animals. Thus Futaki and Ishihara (Izumi and Kato, 1917) each discovered a spirochæte from cases of cat-bite fever and the identity of this

(Continued from previous column)

those unrelieved by the smaller dilation. Several cases presenting a varied clinical picture and seen within the space of a few months have been presented.

DESCRIPTION OF PLATE XIX

- Fig. 1.—Case 1. Intravenous pyelograms 10 minutes after the dye showing a double pelvis to each kidney; one ureter on the right with a constriction at the utero-pelvic junction; a constriction at the transverse process of the third lumbar vertebra; and a dilated pelvic portion of the ureter. A double ureter is seen on the left.
- Fig. 2.—Case 1 showing the left kidney's double pelvis and double ureters after retrograde pyelograms.
- Fig. 3.—Case 2 taken 30 minutes after intravenous pyelograms showing bi-lateral pyelectasis and only suggestive narrowing of the pelvic portion of the left ureter. A constriction was demonstrated in this area by the use of a bulb and dilatation has relieved symptoms.
- Fig. 4.—Case 3 showing a constriction of the right ureter 10 minutes after dye was injected by the retrograde method. The left kidney emptied so quickly it was not visualized on any of the films.
- Fig. 5.—Case 6. Intravenous pyelograms 30 minutes after injection of dye showing a sharp medial deviation of the right ureter and narrowing of the pelvic portion of the left ureter.

organism with the spirillum of rat-bite fever was established.

Ripley and van Sant (1934) describe two cases of 'rat-bite fever' acquired from a dog. One of the patients contracted the infection by mere contact with infected tissues. Mice inoculated with the blood of the patient showed spirilla in their blood. A patient suffering from nerve syphilis was inoculated with the blood of the infected mouse and developed typical symptoms of rat-bite fever.

Iyer (1936) records a case of monkey bite which developed a clinical condition exactly like that of rat-bite fever. The causal organism was not isolated, but the patient recovered after treatment with neosalvarsan.

Dick and Tunnicliff (1918) have noted that a boy who was bitten by a weasel developed a relapsing fever with eruptions and lymphangitis. The inoculation of patient's blood into guinea-pigs proved negative for spirochaetes. Blood cultures made at the height of fever gave a growth of a gram-negative streptothrix.

Smallwood (1929) reports a case of 'rat-bite fever' from the bite of a pig. The disease was diagnosed on clinical grounds. The patient showed an uninterrupted recovery following an injection of 0.6 gm. novarsenobenzenc.

Schottmüller (1914) describes a case of a woman who was bitten on the forefinger and the thumb by an African squirrel (*Taraxerus cepapi*). In addition to the usual clinical symptoms the patient developed little nodules in one eye. These increased in size and completely destroyed the sight of that organ. Later on, the animal bit another man but no untoward symptoms developed in this case. A streptothrix which he named *S. taraxeri cepapi* was cultivated from the eye lesions.

Nixon (1914) reported a case of 'rat-bite fever' caused by a ferret. Apparently no attempt was made to isolate the causal organism. On looking up the literature, the author found that a similar case had previously been described.

The present case is that of a boy of 12 years; he was bitten on the finger by a squirrel, while attempting to catch it. The wound healed up in a few days. About two weeks after the bite, he had a sudden attack of fever. The area round the site of the bite became tender and oedematous, and the axillary glands of the same side were enlarged and painful. The patient came under the writer's observation on 18th June, 1942, about 6 weeks after the bite. A four-hourly chart has since been maintained and

animal inoculations were made as a diagnostic measure.

On 18th June when the patient had high fever (103.8°F)*, 6 c.cm. of blood was obtained and inoculated into two young guinea-pigs of the same litter, weighing 102 and 106 gm., respectively. Next day when the patient still had fever, 4 young mice (*Mus musculus*) born on the same day were inoculated intraperitoneally each with 0.25 c.cm. of blood. The blood and peritoneal fluid of these mice were carefully examined in view of the possibility of natural infection with *Spirillum minus*. From the 10th day of inoculation, the peritoneal fluids of all these animals were examined daily. On 14th July the guinea-pig showed an infection with the spirillum, but the other guinea-pig has proved negative till the day of writing this note (16th July).

Of the 4 mice, one became positive for spirilla on 3rd July, 2 others on 6th July, and the remaining mouse is still negative.

One injection of 0.3 gm. novarsenobillon caused the fever to disappear. Another dose of 0.45 gm. was given after a week to prevent a relapse.

Comments.—No spirillum but a streptothrix was isolated from Schottmüller's case. Serious eye symptoms, which were a conspicuous feature in Schottmüller's case, were totally absent in the present one. The incubation period in the inoculated animals was unusually prolonged and the animals, although of the same age and receiving same dosage of infected blood, were not equally susceptible to the infection.

Summary

Reference is made to the fact that the bites of animals other than rats may give rise to 'rat-bite' disease.

A case of *Spirillum minus* infection following the bite of an Indian squirrel (*Sciurus* sp.) is recorded.

My thanks are due to Dr. A. K. Hazra of Messrs. Bengal Chemical and Pharmaceutical Works, Calcutta, for kindly supplying me with the mice used in this experiment.

A Mirror of Hospital Practice

A CASE OF SPONTANEOUS DISLOCATION OF HIP JOINT FOLLOWING TYPHOID ARTHRITIS

By A. K. GUPTA, M.B., B.S.

(From the Department of Surgery, Medical College Hospital, Patna)

R. S., male, 36 years, was admitted to the Medical College Hospital on 24th October, 1941, for the treatment of dislocation of the left hip joint.

History.—Patient had typhoid fever in December 1940 and was confined to bed till the first week of May 1941. During the later part of his ailment he used to keep his lower limbs in flexed position. About the middle of May he noticed that his left lower limb was shorter than the right. He was subsequently treated in a mofussil hospital for dislocation of the left hip joint and manipulative reduction was attempted without success.

On admission.—Patient of average build; afebrile. Pulse 80 per minute. The left lower limb was in a position of flexion, adduction and inversion. There was real shortening of 2½ inches. The femoral head could be palpated posteriorly in the gluteal region. Extensive scarring was present in the left buttock. No fluctuant swelling was detected anywhere. Telescopic test was negative.

Skiagram of left hip joint.

A clinical diagnosis of spontaneous dorsal dislocation of the left hip joint was made.

Progress.—From 15th November the patient started running a temperature of 99°F. to 101°F. On 20th a fluctuant swelling appeared over the left gluteal region. An exploratory puncture was done on 22nd.

Investigations. 1. X-ray on admission—Dorsal dislocation of the left hip joint and inter-trochanteric fracture left femur. No acetabular deformity shown.

2. Sedimentation rate on admission—First hour 23 per cent; second hour 37.5 per cent.

3. Exploratory puncture of the fluctuant swelling—20 c.cm. of serous fluid withdrawn.

Culture—*B. typhosus* isolated.

4. Wassermann reaction was done on admission to exclude syphilis and was negative.

Summary

1. A case of spontaneous dislocation of the hip joint following typhoid arthritis is reported.

2. Arthritis must have developed during the course of enteric fever and was responsible for the prolonged confinement to bed.

3. Arthritis led to adoption of the characteristic attitude of the lower limb referred to above.

4. The scarring noticed in the region of left buttock was responsible for the negative telescopic test and failure of manipulative reduction.

5. The manipulation apparently caused the inter-trochanteric fracture.

6. There is evidence of the occurrence of arthritis for the second time which may be due to lighting up of a quiescent focus.

Discussion

The interest of the case lies in its extreme rarity. Watson Jones in a series of 27 cases of spontaneous dislocation of hip did not report a single case occurring as a sequel of typhoid arthritis. In Bihar not a single case has been reported so far.

Another point of interest in the case is the complete absence of acetabular deformity or any bony changes in the femoral head in the radiogram, a fact which makes it difficult to explain the occurrence of dislocation. Lamy in reporting spontaneous dislocation in two cases of pneumococcal arthritis suggested that the roof of the acetabulum is softened though not destroyed so that it cannot support the femoral head. Watson Jones maintains that dislocation can occur without bone destruction. The exciting cause of luxation is muscular action deranged as a result of muscular spasm and muscle atrophy being unequally distributed in different muscle groups. Arthritis of the hip if untreated almost inevitably results in flexion and adduction deformity and it is this position which is most favourable for dislocation of the joint.

Acknowledgments

My thanks are due to Captain R. P. Ghosh, superintendent, Medical College Hospital, Patna, and Captain N. Pal, F.R.C.S.E., professor of surgery, for permission to publish the records of the case.

REPEATED RESPIRATORY FAILURE IN A NEW-BORN BABY

By S. K. DUBEY, M.B., B.S.

Assistant Surgeon, Bengal-Nagpur Railway, Titilagarh

ON 23rd August, 1939, I was called to attend a case of obstructed labour at about 3 o'clock in the morning. The patient was a primipara of about 19 years of age and of a good constitution. She had marked oedema of both feet—duration about 2 months. Her urine had never been examined but the marked diminution in the quantity had been noticed by the relatives for some time. The patient was suffering from a severe type of eclampsia. The fits were very frequent and severe, and there was a marked degree of cyanosis. The patient had been given an injection of morphia gr. 1/2 at about 1 a.m. by a local doctor, but it had failed to produce any effect either on the number or on the severity of the fits.

Examination.—Pulse was 130 per minute, temperature 103°F., cystolic blood pressure 140, diastolic 110 mm. of mercury.

The patient was in the second stage of labour. Uterine contractions were weak and ineffectual. There was no obstruction anywhere in the passage, as the foetal head was in the perineum. But there had been no progress of the head for some time.

An injection of pituitrin 0.5 c.cm. was given, and healthy good-sized but asphyxiated female child was delivered in about 8 minutes after the injection at 5 a.m. The child started breathing normally after she had been given artificial respiration for about 15 minutes. She was then given a hot bath and handed over to the *dai*. In the meantime, the mother was cleaned, dressed and otherwise attended to. The delivery, however, did not seem to produce any effect on the eclamptic fits, so I advised the relatives of the patient to have her moved to the B. N. Railway hospital at Titilagarh of which I am in charge. When preparing to leave, I noticed the child had stopped breathing again. She did not start breathing again until after half an hour of vigorous artificial respiration. The mother and the child were then brought to our hospital at about 7 a.m. The mother was put in a modified form of Stroganoff's treatment, but her condition gradually became worse and she expired at 11 p.m. that night.

The child had an attack of respiratory failure at 8 a.m. Another at 11 a.m., then at 2 p.m., and again at 5 p.m. that day, and every time it lasted for about 45 minutes. Injection of adrenalin, atropine and strychnine was tried without any result. In the night the child had three similar attacks. Next morning I tried to give a feed of glucose water by mouth at about 8 a.m. but respiration failed again. So all feeds by mouth were stopped. But the stoppage of food by mouth did not have any effect on the number of attacks. More attacks occurred at 10-30 a.m., 3 p.m. and again at 5 p.m. when glucose was tried per rectum. As any disturbance seemed to bring in an attack immediately, attempts at artificial feeding were stopped. The child continued having similar attacks of respiratory failure 6 to 8 times on an average in the 24 hours for the next 2 days, also every time requiring approximately three-quarter hour's vigorous efforts to resume normal respiration.

If the child happened to be crying or moving her hands and feet she would at once lose her voice and all movements of hands and feet would stop when an attack came. The eyes would remain open if the child happened to be awake. Gradually all the limbs would come back to their supine positions. The mouth and eyes would slowly close. Then the face and the whole body would turn blue.

The child went on without a feed for fully 4 days. On the fifth day I arranged a wet nurse, but the child would not suck and breathing would again cease. Breast-feeding was tried twice and on both the occasions the baby stopped breathing. On that night the child had only one attack. We had given up all hopes about her life, but to everyone's surprise, the child took a good breast-feed on the sixth morning without any incident. Since then her progress has been uneventful.

Discussion.—The nature of the attack and the onset suggest some toxic cause with profound action on the nerve centres of the child. I am definitely of the opinion that the condition could not have been due to the injection of morphia given to the mother 3 or 4 hours before the delivery, as the rate and depth of respiration were quite normal in between the attacks. It was not due to partial atelectasis of the lungs either, as the air entry into the lungs was quite free. Most probably the eclampsia of the

mother was responsible for the condition of the child as no other cause could be found. The labour was not unduly delayed, there was practically no moulding of the scalp. Head injury as a factor appears to be ruled out. Points of interest in this case are:—

1. The number of attacks of respiratory failure although normal breathing had been established.

2. The suddenness of onset and the long duration of the attacks.

This is the first case of the kind I have ever seen. I venture to publish this case report as it would, I presume, be of interest to many, because of the rarity of the condition.

Acknowledgment

My thanks are due to Dr. A. W. J. Morgan, chief medical officer, and Dr. M. N. Sarkar, district medical officer of the B. N. Railway, for kindly permitting me to report the case and also to my staff of the hospital for the untiring help in the constant supervision and treatment of the child.

RETENTION OF URINE IN A NEW-BORN

By M. L. DIDI, L.S.M.F.

Chief Medical Officer, Kumarsain State (Simla Hills)

I was called on to see a newly-born female child on 29th June, 1942, who did not pass urine since her birth on the 24th. On examination the vulva was found much congested; thick muco-purulent discharge could be noticed escaping from the external urethral orifice; and the parts round about the external urethral orifice appeared to be sloughing. Enquiry did not show the mother as suffering from any venereal disease, nor did the father admit of ever having had it. The discharge was not examined microscopically for want of facilities. However, it was believed that the infection had crept up due to the unclean handling by the untrained rustic *dai*, or it might have been contracted on account of the extremely unhygienic and insanitary conditions. The baby was extremely restless, crying continuously.

India rubber catheter no. 4 was passed, and about three drachms of semi-viscid yellow urine was evacuated. This made the child absolutely calm and quiet. As a curative measure sulphanilamide was administered in one-grain doses well crushed and dissolved in a little milk every six hours by mouth, and locally hot potassium permanganate compresses were given.

Next day, i.e., on the 30th, the father of the child reported that she passed urine twice after catheterization and that there were no more signs of distress. Sulphanilamide and hot compresses were repeated as above.

Afterwards I was told that the child was all right, with no signs of inflammation of the remaining genitals.

The points of interest in this case are urethritis in a new-born child of parents free from any venereal ailment, retention of urine from the very birth, absence of relation between the quantity of urine retained and the agony experienced, appreciable tolerance to sulphanilamide of the baby of such tender years, and the speedy recovery as a result of the treatment stated above.

Indian Medical Gazette

SEPTEMBER

THE KIDNEY IN MALARIA

LITTLE attention has been focused on the pathological effects of malarial infection on the kidneys. The attitude of the experienced practitioner in the tropics has been that transitory albuminuria is common, as it is in any febrile disease, and that this 'febrile' trace of albumin probably indicates some cloudy swelling of the parenchyma cells of the kidney, a condition that is usually found when such a case comes to the post-mortem table. This is not an indication of nephritis, and, though it may persist throughout the febrile period, it will usually disappear, apparently leaving no permanent damage behind.

In some cases, however, this albuminuria persists, indicating that the damage done is of a more permanent nature, and a form of subacute nephritis is visualized, which again is sometimes seen post mortem. This subacute nephritis is observed in infections by any plasmodial species, but the practitioner has been taught to expect it in quartan infections, is therefore usually on the look out for it in these infections, and retains the impression that nephritis is mainly associated with *Plasmodium malariae*.

The textbooks are similarly vague about the kidney lesions in malaria, but they all maintain the tradition, which was originally of course based on past investigations, that nephritis is almost solely associated with quartan malaria. We have not been able to find many references in medical journals to this subject, but in 1891 Marchiafava and Bignani reported glomerular nephritis in quartan malaria, and, in 1912, Clark went as far as to say that in the tropics albuminuria was an indication for searching for quartan malaria parasites, or for syphilis!

Deeks (1916) working in the Panama Canal zone, considered that nephritis was one of the commonest complications of malaria; it usually responded to treatment with quinine. Manson-Bahr and Maybury (1927) observed the association of nephritis with quartan infection in two patients and treated them successfully with quinine.

Giglioli (1930) working in British Guiana, reported albuminuria in 25 per cent of 550 cases of malaria, 25 per cent in benign tertian, 20 per cent in malignant tertian and 46 per cent in a much smaller number of cases of quartan infection. The frequency increased with the duration of the infection and was more common in relapses. He observed the following sequence in chronic relapsing benign tertian and quartan malaria; 'fever with normal urine; fever with

intermittent albuminuria; fever with persistent albuminuria, casts, leucocytes and renal elements in the sediment; fever and subchronic nephritis with dropsical symptoms; and chronic parenchymatous or chronic interstitial nephritis'. During seven years' observation, he encountered 102 cases of nephritis, mostly presenting chronic dropsical or interstitial nephritis. He obtained good results by treating these patients with quinine.

On the other hand, Allen (1928) reported degenerative changes in the tubular epithelium in 46 per cent of post-mortem examinations in cases of malignant malaria.

In India, the occurrence of albuminuria has often been reported, but there has been a tendency to associate it with quinine, and Sinton and Lal (*I. J. M. R.*, 12, 47) reported that if alkalies were taken with quinine, this toxic effect of the alkaloid was reduced.

Interest in this subject has been revived by Heilig (*I. M. G.*, 76, 519) who reported that in four out of six cases of acute glomerulo-nephritis there was a clear association with malaria, and that all these four cases responded well to treatment with quinine, whereas the other two patients were discharged with evidence of permanently damaged kidneys. He has followed up this observation by making a careful study of this pathological aspect of malaria and a report of his recent observations is included in this number of the *Gazette* (see p. 513).

His main evidence of the malarial origin of the subacute glomerular nephrosis which he described is the response to quinine; this is certainly very striking and is shown graphically in the figure below which is based on the data Professor Heilig and his collaborator have given in their paper.

Graph showing diuretic effect of quinine in a case of glomerular nephritis.

Suggestions have been made regarding the mechanism of production of the condition; perhaps the most plausible one is that it is an allergic phenomenon due to previous sensitization of the kidney, in susceptible individuals, by

'foreign' protein substances derived from parasite and host-tissue destruction resulting from the malaria infection and its cure.

The belief that *Plasmodium malariae* is the only species that causes nephritis is being steadily undermined, and it is quite evident that *P. falciparum* can also produce as serious changes in the kidney. Professor Heilig believes that *P. vivax* was the responsible parasite in his cases, but as in most malarious countries mixed in-

fections are the rule this conclusion must be examined more closely.

Nephritis is by no means an uncommon condition to encounter in practice in malarious districts, and now that attention has again been drawn to it, perhaps further studies will be undertaken, but it is hoped that these will not take the form of indiscriminate administration of quinine, of which there is already an acute shortage in this country.

Special Article

THE FUNCTIONS OF A CENTRAL MATERNAL AND CHILD HEALTH DEPARTMENT

By JEAN M. ORKNEY, W.M.S.

Director, Maternity and Child Welfare Bureau, Indian Red Cross Society, Red Cross Building, New Delhi

THE Central Advisory Board of Health at its second meeting in Madras in 1939, in adopting the report of the special committee on maternity and child welfare work in India stressed the fundamental importance of appointing in each province and state a senior medical woman to organize and direct maternity and child welfare. The principle of a government agency to consider the problems and welfare of mothers and children, and to further the interests of this vitally important section of the nation's resources has therefore been accepted and no further advocacy for the establishment of such agencies seems necessary. A logical sequel to the appointment of medical women at provincial headquarters is the establishment of a department for maternal and child health with the central government. It may therefore be timely to ask what are the functions of such a department, what services can it render to the nation, and what organization is required to carry out the duties?

Central federal or dominion departments dealing with child health and welfare have already been established for example in the U.S.A. and Canada, and, while neither the field of activity nor the organization of these departments may be exactly applicable, a brief account of the organization and activities of the children's bureau, U.S. Department of Labour and the Child Hygiene Department of the Dominion Health Department, Canada, may serve as a guide in planning for India.

The children's bureau is under the U.S. Department of Labour; the chief is a lay woman and the assistant chief a physician. The bureau at the time of its establishment in 1912 was directed by Congress 'to investigate and report on all phases of the welfare of infants, children and young persons under 18 years of age especially infant mortality, the birth rate,

orphanage, juvenile courts, desertion, dangerous occupation, accidents and diseases of children, employment, legislation affecting children in several states and territories'. The field of activity of the bureau is gigantic; it deals with the child of every age, at home, at school, in industry, with the normal child and the child who is handicapped either physically, mentally or socially.

The work of the bureau is carried out through divisions each of which is in the charge of a technical director, who may be a physician, a social worker, a psychologist, an orthopaedic surgeon according to the nature of the work. Each director is assisted by a technical staff and an advisory committee of experts which meets annually. The divisions include the maternal and child health division, crippled children, child welfare, delinquency, industrial, editorial divisions as well as divisions for statistical and clinical research and a public health nursing unit. In addition to acting as a central office for the collection and dissemination of information, the bureau has been charged with the administration of central federal laws affecting child welfare, and with the distribution as grants-in-aid of certain monetary allocations under the Social Security Act.

The child hygiene department in Canada is simpler in organization, and the scope of activities is more limited. It is an integral part of the Dominion Health Department, and the director is a physician. He is assisted by two advisory committees of specialists, one for maternal hygiene and one for child hygiene. The recommendations of these committees are submitted for discussion at the bi-annual meetings of the public health advisory committee before being put into practice; thus the schemes are backed both by the public health authorities and by the leading members of the medical profession. The central department is wholly advisory and no grants-in-aid are provided from Dominion funds.

Stated briefly in the words of an admirable pamphlet *The Children's Bureau, Yesterday, Today and To-morrow* published by the U.S.

Department of Labour, the specific functions of the bureau are to *investigate*, to *report*, to *administer* and to *consult*. To these may be added to co-operate with other agencies and organizations, national, international, voluntary and official. These functions are discussed in subsequent paragraphs in relation to requirements in India. Considerable use has been made of the publication *The Children' Bureau, Yesterday, To-day and To-morrow* in preparing this note.

To investigate.—A central office for the collection of information on all aspects of maternal and child health is unquestionably necessary if the newer developments in other countries are to be made readily available in India, if the facts about maternal and child life and health in India are to become more accurately and more widely known, and if legislation relating to maternity and child welfare is to be relatively uniform. Statistical data are collected by the provincial health and census departments, but there is much variation in the procedures adopted, in the forms used in recording data, and in the completeness of the returns, which make advice and stimulation from a central department desirable.

Provincial returns require to be compiled, correlated and analysed, and the reasons underlying differences in birth rates, mortality and morbidity rates in the different provinces and districts studied and brought to the notice of the local authorities. Much of the statistical and field investigation will have to be done locally, but advice in planning the studies will be needed to prevent needless reduplication and to ensure full utilization of previous experience.

Apart from statistical investigations, the central department, whether or not it has the control of funds for carrying out special researches on maternal and infant mortality and morbidity, child development and nutrition, or for administrative studies in the field, should have an important rôle to play in advising on the nature and directing the lines of scientific research in this special field.

Actually since 1936 several of these functions have been carried out in India by the Maternal Mortality Advisory Committee of the I. R. F. A. A voluntary organization, the Maternity and Child Welfare Bureau, Indian Red Cross Society, acts at the moment as the co-ordinating link between the research association, the health departments and the field workers in M. & C. W. The Maternal Mortality Advisory Committee, apart from advising on research, has prepared a pamphlet on the conduct of maternal mortality enquiries, has made several suggestions for the improvement of vital statistics relating to stillbirths and neo-natal deaths, for the use of fresh milk mixtures in infant feeding, and has under consideration the preparation of a pamphlet on the conduct of infant mortality enquiries. In this committee there exists the

embryo of a technical advisory committee to a central department for maternal and child health.

To report.—A natural corollary to the collection and analysis of facts and figures is the interpretation of the data and the preparation of material which will make available the knowledge gained not only to public health authorities and the medical profession, but also to the general public and to individuals, groups and committees interested in or engaged in promoting maternal and child health.

A good deal has been done by the M. & C. W. Bureau, Indian Red Cross Society, to provide leaflets, pamphlets, folders, posters and other popular material for the guidance of individual parents in the nurture of their children, but even in this field much remains to be done if the knowledge is to be brought home equally to illiterate and literate parents. The preparation of popular articles, broadcast talks, and other literature interpreting the tables of the statistician in terms easily understood by the general public and lay authorities responsible for health has not, however, received the attention necessary if the public conscience is to be awakened to the vital importance of expanding the services caring for the mother and her children—nor have the channels for getting such material across been sufficiently developed. Very little has been done towards the preparation of scientific articles for publication in medical journals and for use by the medical profession, and while the M. & C. W. Bureau, I. R. C. S., has a certain amount of semi-technical material for the guidance of local activities, groups and committees responsible for the organization and administration of the maternity and child welfare services, progress could be greatly speeded up by the extended use of directive circulars, maps, charts, graphs and other technical material. In this field there are vast uncharted areas, which will not be filled in until the preparation of popular, semi-technical and technical and scientific material receives the attention it merits, and until the material is made readily accessible to individual parents, to the general public, to lay administrators, to voluntary organizations, to the medical profession and to experts in other fields of social service.

To consult.—The consultation service of the Maternity and Child Welfare Bureau is one of the better developed of its activities, and there is every reason to believe that an even wider field of usefulness in this direction would be open to a central department for maternal and child health. The problems for which advice is sought range at the moment from the individual difficulties of individual parents, to the administrative difficulties of local committees, industrial concerns, local authorities and government departments. The problems cover the whole field of maternity and child welfare, in its widest sense. Many of the requests for advice can be met by supplying popular and

semi-technical publications, others by correspondence, others only by studying the problem on the spot and after personal consultation with the authorities concerned. As the provincial maternity and child welfare services develop, the nature of the assistance required is likely to alter. Less time may be necessary to meet personal needs or the problems of small local schemes, but more consultation will be necessary for instance in planning the organization of larger schemes, for the training of personnel, and for the carrying out of enquiries into special problems and conditions affecting health. In order to give a worth-while service, it will in many instances be necessary to study local conditions at first hand, and to depute a member of the staff of the central department to make statistical and field surveys on which sound recommendations can be based.

To administer.—The provision of grants-in-aid of provincial schemes would carry with it various advantages in stimulating and controlling the development of maternity and child welfare, but even in the absence of grants, a central department could provide the stimulation and impetus needed. Of more importance is the provision of a central appropriation for special purposes, for example for the employment of experts to carry out special studies in the administrative or clinical fields, for the training of personnel, the appointment of special staff at provincial headquarters, the establishment of model demonstration and experimental units, for the holding of conferences and for research.

To co-ordinate and co-operate.—Co-operation in the *international* sphere with foreign governments and with organizations such as the League of Nations requires a central department for maternal and child health in India if the maximum potential mutual benefit is to accrue. Here again the Maternity and Child Welfare Bureau, Indian Red Cross Society, serves in some measure to bridge the gap by supplying replies to questionnaires and other requests for information and publicity material from foreign and international agencies. In the reverse direction the resources of a voluntary organization are more limited. The volume of publications received embodying the experiences and practices in other countries is not regular or automatic, and the channels for the passing on information about internationally and nationally accepted standards and procedures, particularly those of a technical nature, are ill developed. Government departments automatically receive such particulars, but at present much information that would be useful to India is filed away with other government records without being brought to the notice of the executive health authorities.

In the future, co-operation in international health is likely to be greatly increased, and it is not inconceivable that India may desire representation on any conference called to discuss

the problems of maternal and child health and to make recommendations for the sound development of the services.

In the *national* sphere, co-operation at the centre must be maintained with other central departments. Health whether in infancy, in the pre-school or school period, in industry or in old age is indivisible, and should logically come under a federal health department, but many problems will require joint action by two or more authorities if the right of the child to life, health, happiness and social security is to be safeguarded. The health of the pre-school child will require co-operation with the education department, the health of the nursing and expectant mother in industry with the labour department, the delinquent and mentally defective child with the home department, the nutrition of mothers, infants and young children with the agricultural department, the interpretation of vital statistics with the registrar's department, and in the field of publicity and propaganda much can be done through organizations like the Indian Red Cross Society and various women's organizations to achieve more concerted action, less diffusion of effort and energy, and consequently quicker results.

Co-operation with provincial, district and local agencies whether voluntary or official has already been outlined under the consultation service, and it only remains to say that without the generous co-operation of these agencies in placing at the disposal of the central department the results of their experiments and experiences, its function as a clearing house for all information regarding the life and health of women and children would be largely nullified.

Contacts with other *authorities* training doctors for the health services, pædiatrics and obstetrics, public health nurses, nursery school teachers, midwives and social workers, is another field for mutual co-operation, in order that the training may be linked up with the services required from the workers in the field. Various types of post-graduate courses will have to be planned either at teaching institutions, medical and health centres, or by sending experts to give advice and instruction to groups in their own locality. Advice in planning courses or in selecting and financing instructors may be required of a central department.

Many of the functions outlined above are undertaken by the Maternity and Child Welfare Bureau, Indian Red Cross Society, but in view of the constitution, status and resources of the Bureau, there are very definite limitations to what it can accomplish.

The nation's children are its most valuable assets and it is for consideration whether the time has not come for the nation to have a central department to ensure the sound development, the health happiness and security of its future citizens.

PUBLIC HEALTH ORGANIZATION

III. PUBLIC HEALTH AND NUTRITION

By W. R. AYKROYD, M.D., Sc.D.

Director, Nutrition Research Laboratories, Indian Research Fund Association, Coonoor, South India

'No preventive campaign against malaria, against tuberculosis or against leprosy, no maternity relief or child welfare activities are likely to achieve any great success unless those responsible recognize the vital importance of this factor of defective nutrition and from the very start give it their most serious attention. Abundant supplies of quinine and the multiplication of tuberculosis hospitals, sanatoria, leprosy colonies and maternity and child welfare centres are no doubt desirable, if not essential, but none of these go to the root of the matter. The first essentials for the prevention of disease are a higher standard of health, a better physique and a greater power of resistance to infection. These can only be attained if the food of the people is such as will give all the physiological and nutritional requirements of the human frame'.

The above passage appeared in the 1935 Report of the Public Health Commissioner with the Government of India. How far is it true?

India is a very unhealthy country. The expectation of life at birth was reckoned in 1931 as 26-27 years, a low figure which may be compared with 58.9 for England and Wales (1933), 61.9 for Sweden (1926-30) and 68 for New Zealand (1933). The nutrition worker often asks himself the question: what proportion of disease in India has its roots in malnutrition? Medical officers in hospitals will readily advance statements such as: 'half the patients wouldn't be here if they'd had enough of the right kind of food to eat', but such estimates scarcely constitute scientific evidence. Actually, it is quite impossible to make any satisfactory quantitative assessment of faulty and insufficient diet as a disease-producing factor in India. Some light may, however, be thrown on the question by the study of available morbidity and mortality statistics, and in this connection the trend of disease in famine times is of considerable interest.

Mortality in infants and children

The recorded infantile mortality rate for British India in 1939 was 155 per 1,000 live births. This means that a little less than a million and a half infants died before reaching the age of one year. Deaths in infants amounted to 23.6 per cent of total mortality. Of total infant deaths, 47.3 per cent took place during the

first month of life, and, of these neonatal deaths, 61.3 per cent occurred during the first week after birth. The percentage of still-births to live births is known to be abnormally high, though the recorded figures for still-births are very inaccurate. Respiratory diseases account for a large number of deaths in the later stages of infancy.

At present there is very little accurate information about the causes of infantile mortality in India and investigations of this problem are badly needed. In the Northern Circars, where adult beri-beri is prevalent, a very high mortality in breast-fed infants in the third and fourth months of life, almost certainly due to infantile beri-beri, has been recorded (Aykroyd and Krishnan, 1941); this is an example of how a deficient maternal diet may profoundly influence infantile mortality. Who can doubt that in India generally the faulty feeding of mother and child is a factor of major importance in producing the high infantile mortality rate? In any ill-fed population group, whether human or animal, it is the newly-born and the very young that suffer most severely from the ill-effects of malnutrition. In Coonoor, as Sir Robert McCarrison has often pointed out, we have eliminated 'infantile mortality' from our colony of rats by providing an excellent diet based on whole wheat, milk, and fresh vegetables. Mother rats invariably rear successfully their litters of 6 to 12 young. In an ill-fed rat colony the vital statistics of suckling rats would be of a very different nature, resembling, in fact, much more closely the statistics of mortality among infants in India.

Mortality in India remains high throughout early childhood. 'About 49 per cent of the total mortality in any given year is among those below 10 years of age, while the corresponding figure for England is only 12 per cent. During the first year of life India's proportionate mortality is about three and a half times that of England, at the next period (1 to 5) it is about five times greater, and between five and ten years it is more than three times as high' (Public Health Commissioner's Report for 1936). In 1939 total deaths under 10 years amounted to 2.9 millions, or 47 per cent of all deaths. It will be recalled that in most Western countries early childhood is one of the healthiest periods of life.

The causes of the high mortality in India during early childhood have not been investigated. In this connection the observations of de Haas (1940) in Java are significant. Haas finds that in Batavia about 22 per cent of total mortality occurs in what he calls the 'pre-school' group—children aged 1 to 4—whereas in Holland the percentage in 1939 was 3.1. The actual death rate within this group in Batavia was 76

per thousand. The same worker (1939) strongly emphasizes the importance of malnutrition as a factor in producing this very high mortality :—

'Tropical nutrition in general and the food of pre-school children in particular show deficiencies for the poorer classes among which shortage of calories, animal protein and vitamin A are the most important*. Dairy produce practically does not appear in the native diet of Batavia.... After breast feeding has ceased, the children, then about one year old, are still too small to select food for themselves. It is the children of pre-school age, therefore, who suffer most from the insufficient tropical nutrition. Their menu consists mostly of rice and a few vegetables, and so it is not surprising that such serious deficiency diseases as xerophthalmia and nutritional œdema are found most among children of pre-school age and that dystrophic development is most conspicuous among those from a half to three years old'.

Haas goes on to say that among children of pre-school age, pneumonia and bacillary dysentery take the first place as causes of death. He remarks that 'it appears likely that the frequency and fatality rate of broncho-pneumonia and the general state of nutrition of the children are in closer interrelation than is the case in the majority of other infectious diseases'. His general experience in the Children's Department of the Medical College in Batavia leads him to believe that malnutrition is a major factor in causing disease and death in young children. 'Since the state of nutrition is nearly always defective, too much significance cannot be given to the causes of death in children of pre-school age'.

There is no reason to suppose that the state of nutrition of poor children in most parts of India is in any way better than that of children in Batavia, and the conclusions of Haas can probably be applied to India. A visit to a children's ward in an Indian hospital will provide confirmatory evidence, for such wards are always thronged with cases of nutritional disease and of disease indirectly due to malnutrition.

Maternal mortality

The female death rate during the reproductive period (15 to 45) is higher than the male, and the excess is largely due to mortality from child-bearing. Estimates of maternal mortality in various parts of India vary from 16 to 24 per 1,000 live births—a very high rate. In an enquiry carried out by Neal Edwards (1940) in Calcutta, it was found that 23.3 per cent of maternal deaths were due to anæmia. Co-existent anæmia probably plays a part in the high death rate from puerperal sepsis, the principal recorded cause of maternal mortality.

Here again, while a quantitative assessment is impossible, it is reasonable to suppose that diet

deficiency is responsible for much of the illness among pregnant women in India. The relation between diet and the anæmias of pregnancy requires further elucidation, but it can be assumed that faulty diet is one factor in their causation. All nutrition workers know that the pregnant organism is highly sensitive to the ill-effects of diet deficiency. It is the invariable practice, in drawing up dietary standards, to set the requirements of pregnant and lactating women for vitamins and mineral salts at a higher figure than those of non-pregnant women.

Nutrition and various common diseases

A full discussion of the relation between nutrition and the common diseases of India would make this article too long. We can probably at once dismiss the possibility of any association between malnutrition and cholera, small-pox and plague, diseases which occupy the major part of the attention of public health departments. It is to be observed that they are to-day, numerically speaking, not important causes of death. It has often been suggested that deficient diet is a predisposing cause of leprosy, but there is really very little evidence in support of this hypothesis. Further investigation of this problem is required. The greatest single cause of deaths in the mortality returns is 'fevers', a heterogenous group in which malaria stands pre-eminent. It has been estimated that about a hundred million persons suffer annually from malaria in India and that the annual number of deaths exceeds 1.5 millions. Many malariologists have drawn attention to an association between malaria and economic stress, and the invariable accompaniment of the latter, malnutrition. This question has recently been discussed by Passmore and Sommerville (1940), who found that the course of primary attacks of experimental malaria in monkeys was unaffected by differences in state of nutrition. There does not appear to be any conclusive evidence that nutrition influences the epidemiology of malaria or the susceptibility to, or severity of, the disease in individual cases. There is, however, a close relation of the opposite kind between malaria and malnutrition. Malaria is a direct cause of malnutrition because its languid victims cannot cultivate their land properly and improve their lot. Vigorous anti-malarial measures will improve food supply and the national diet.

The voluminous reports of famine commissions published during the second half of the last century contain much material of interest about the effect of famine on the birth-rate, the death-rate, and the influence of food scarcity and famine on the incidence of various diseases, which even to-day would repay further study. In more recent times, Lieut.-Colonel Nicol (1941), Director of Public Health in the Punjab, has published an interesting analysis of mortality and morbidity in the Hissar famine of 1939-40. The total number of deaths in Hissar in the worst

* The author would place more emphasis on deficiency of vitamins of the B₂ group.

famine year (1939) was 37,767, as compared with 20,910 in 1937. The rise in the death rate was greatest in the age groups 'under 10 years' and '60 years and upwards'—i.e., among the very young and the very old. Of the 37,767 deaths in 1939, 21,160 occurred in children under 10. There was no rise in the incidence of malaria, and small-pox and cholera were kept under control. But there was a striking increase in the number of cases of almost all other diseases during the period when food supply was deficient in quantity and also in quality. The following figures, showing the number of cases of various conditions treated in hospitals and dispensaries in Hissar, in 1937 and 1939 respectively, are taken from Nicol's report:—

	Number of cases	
	1937	1939
Respiratory diseases (excluding pneumonia and pulmonary tuberculosis)	25,178	44,117
Pneumonia	1,409	1,942
Tuberculosis of the lungs	696	973
Dysentery and diarrhoea	10,263	19,907
Enteric fever	282	539
Trachoma	21,031	26,550
Pyrexia of uncertain origin and other diseases due to infection	2,925	5,216

Some of the increase can no doubt be attributed to the disorganization of living conditions inevitable in famine times, and allowances must be made for the inaccuracy of hospital and out-patient department statistics. The figures are nevertheless striking, and illustrate how the resistance of a population to disease in general is conditioned by the dietary factor. A large percentage of the population of India lives on a diet which is defective in quality and often in quantity. It is not unreasonable to suppose that the incidence of diseases which become more prevalent in times of food-scarcity is influenced by diet in normal times.

Much has been written about the association between malnutrition and tuberculosis, a disease of growing public health importance in India. It appears to be generally accepted that a poor diet lowers the resistance of the body to the tubercle bacillus. Special attention may be drawn to one group of diseases—those falling into the category 'dysentery and diarrhoea' in the health returns. As a result of experiments carried out in Coonoor, McCarrison (1921) reached the conclusion that 'the health of the gastro-intestinal tract is dependent on an adequate provision of accessory food factors' and observed that 'experiments with animals have led us to expect that acute intestinal disorders will be among the commonest of the consequences of deficient and ill-balanced food'. More recently Rao (1942) has produced in monkeys a chronic diarrhoea accompanied by atrophic changes in the small intestine by feeding with ill-balanced rice diets. It is perhaps significant that the death rate from dysentery and diarrhoea in the Punjab is usually from one-fourth to one-sixth that of Orissa, the Central

Provinces and Madras. The Punjab is a wheat-eating province with a relatively high consumption of milk, while in the latter provinces rice is the principal or an important staple and consumption of milk is low.

Food deficiency diseases

Deficiency diseases—i.e., diseases directly due to insufficiency of some necessary constituent in the diet and capable of being prevented or cured by supplying that constituent—are in themselves a problem of public health importance. In the Northern Circars beri-beri in adults is a common disease, leading to much suffering and disability but not often to death. Beri-beri in infants, as has already been pointed out, is probably the cause of many infant deaths in this area. Keratomalacia is probably the commonest cause of permanent blindness in South India; it is also prevalent in other parts of the country. Osteomalacia and rickets present a formidable public health problem in certain parts of northern India. One of the commonest of deficiency states is a syndrome including stomatitis, dermatitis in the genital regions and sometimes superficial keratitis, which is associated with lack of the B₂ group of vitamins, and in particular with riboflavin deficiency. Goitre is another nutritional disease, highly prevalent in certain Himalayan and sub-Himalayan areas. Severe scurvy is uncommon, except in famine times. Further clinical research will probably reveal other deficiency diseases, at present unrecognized. Diabetes—the scourge of the middle classes in India—can scarcely be included under this head, though its cause is presumably some long-continued error in diet. It has so far received little attention from nutrition research workers in India.

Epidemic dropsy is a nutritional disease of considerable importance in Bengal. Recent work seems to have established that it is due to a toxic factor in the diet rather than to diet deficiency, but it can none the less be described as a nutritional disease. The most satisfactory proof that it is caused by contamination of mustard oil by *Argemone mexicana* would be its elimination by public health measures based on this hypothesis.

Public Health Nutrition Work

There is thus no lack of evidence that nutrition is a factor of basic importance in public health. Nutrition work is an essential part of public health activity, and any organizations concerned with public health in general which do not include nutrition work in their programmes are neglecting their manifest duty. But while methods for dealing with infectious diseases, etc., have been evolved as the result of experience, methods of tackling the problems of nutrition are less clearly defined. At the outset the public health worker comes up against the difficulty that the basic cause of malnutrition in India and elsewhere is the economic factor over which he has little control.

But even in the existing economic circumstances, progress can be made in raising dietary standards if the best use is made of available resources. The first essential is the education of those who in turn can educate the people. This means that greater emphasis must be laid on nutrition in the training of doctors and public health workers of all grades. It means that school teachers should be taught simple facts about food and diet, and impart them to their pupils. It means the education of the professional and administrative classes generally, including workers in agricultural, animal husbandry, and development departments.

Within the strictly public health sphere, it is desirable that all public health departments of any size should include a specialist in nutrition who can undertake, among other duties, educational and propaganda work. In a small public health department, it may not be feasible to employ a full-time 'nutrition officer'; if this is so, some member of the department can combine nutrition work with other activities. In India, full-time nutrition officers, trained in Coonoor, have been employed in public health departments in Bengal, the Punjab, Bihar, the Central Provinces, Baroda and Hyderabad. A nutrition officer was also employed in Burma. Workers in other health departments have also taken the course and have carried out some educational work.

Other aspects of public health nutrition work may be briefly mentioned. The League of Nations Intergovernmental Conference of Far-Eastern Countries on Rural Hygiene (1937) outlined the work of public health nutrition specialists as follows: 'They can carry out field investigations, engage in propaganda work, organize school-feeding schemes, advise regarding the dietary aspects of maternity and child-welfare work, regulate diet in government and charitable institutions, such as schools, mental homes and leper asylums and so on, and in general assist in the practical application of nutritional science'.

School medical inspection, particularly if it includes the instruction of parents whose children's state of nutrition requires attention, is an important branch of public health nutrition work. So are school-feeding schemes. Maternity and infant welfare work is primarily nutritional in character, or, if it is not, it should be. In India there is valuable and essential public health work in the sphere of nutrition to be done in famine areas. A full discussion of the different branches of public health nutrition work will be found in 'Nutrition and Public Health' by Burnet and Aykroyd (1935) and in various subsequent League of Nations publications.

Half the mortality recorded in India occurs in children under 10 years. Malnutrition is one of the chief causes of the rapid exit of young human beings from the world so soon after their

PREVENTIVE PÆDIATRICS :

AN ACCOUNT OF HEALTH WORK IN TRENGGANU, MALAYA

By J. W. SCHARFF, M.D., D.P.H.

and

CICELY D. WILLIAMS, D.M., M.R.C.P., D.T.M. & H.

With a preface by Hon. G. A. DE C. DE MOUBRAY

British Adviser, Trengganu

Condensed by JEAN BIGGER

[The full report of which this paper is a condensation would in ordinary times have been printed by the Government of Malaya. Because it contains much of interest to workers in preventive medicine and to those interested in rural health problems, we take this opportunity to print it here. The problems with which it deals are comparable to those of workers in India. The methods and achievements of the authors may well prove an inspiration to us.]

PREFACE

By G. A. DE C. DE MOUBRAY

My own regeneration in matters medical started with reading Dr. Victor Heiser's 'A

(Continued from previous column)

arrival in it. It cannot be said that public health has disposed its forces so that this, the most dangerous section of the front, is the most strongly defended. In fact, most of it is defended weakly or not at all; for in India, as in most other countries, the pre-school child is almost completely neglected in the organization of public health.

With certain qualifications, the statement from the Public Health Commissioner's Report with which this article began may be endorsed. The vital statistics of India, inaccurate though they may be, provide clear indications for the future orientation of public health work. The improvement of diet is of essential importance if the goal of a healthy nation is to be attained.

Doctor's Odyssey'. Dr. Heiser, after being Director of Health in the Philippines, was selected by Rockefeller to organize the health campaign in the Far East. It is in the circumstances not surprising that he combined with a 'health' approach to medical problems a hard-headed emphasis on finance. The lessons which I, together with numbers of others, have learnt from his book have been that medical policies should be judged by results, not merely clinical results, but statistical results of mortality and morbidity. Moreover, the relation between expenditure and statistical results should be kept well in the foreground. For a given expenditure, one should set out to obtain the greatest statistical results in the way of reduction of morbidity.

Dr. Heiser points out that judging by these standards the hospital approach to medical problems fails if divorced from the preventive approach. He quoted as an example the tremendous expenditure in Japan in organizing an extremely modern hospital system. The Japanese Government eventually realized that this vast expenditure had in no way reduced the death rate or the sickness rate.

Dr. Heiser emphasizes the necessity of starting by an investigation of the health problem in each country and in each part of a country, and the necessity for concentrating on the diseases causing the greatest sickness and mortality.

On my arrival in Trengganu nearly two years ago, I was disappointed to find that in the 20 years, since Trengganu had come under British Advice, expenditure and effort had been concentrated almost entirely on the clinical approach to the medical problem. A development of preventive work seemed however almost impossible owing to the financial situation.

In September 1940 I met Dr. J. W. Scharff and discussed the problem with him. It interested him to such an extent that he offered to come to Trengganu on six months' secondment. I accepted his offer with alacrity. Shortly after his arrival here he suggested that Dr. C. D. Williams should be asked to visit, so that he could have her assistance in checking his conclusions and proposals in the matter of infant welfare. She subsequently acted for Dr. A. L. Shield, medical officer, Trengganu, when the latter went on long leave.

Their methods were an inspiration to me. They obviously made use of (and re-examined) all the vital statistics available and all the information accumulated in the hospitals. What was new in their technique was, instead of the laborious accumulation of data in the field and writing of a report on which action might, or might not, be taken, the rapid evaluation of the situation followed by the equally rapid formulation of policies and their immediate execution, if only on an experimental scale. I accompanied them on a few of their expeditions. There was little difficulty in assembling all the children and most of the adults in the kampongs in which we

spent any time. A rapid examination of the children was sufficient to tell us whether in that locality malaria was a problem which had to be dealt with or whether it could be disregarded for more urgent problems.

One could roughly estimate the importance of yaws, malnutrition, worms, and other diseases as causes of morbidity, and therefore, in the long run, of mortality. Whole tracts of country were rapidly compared in this fashion. Special attention was devoted to areas with a high general death rate or high infantile mortality rate. I was much impressed with the rapid formulation of policies and the almost more rapid putting of them into effect. In a medical and scientific enthusiast such as was Dr. Scharff, I was astonished to find such a keen appreciation of the financial aspect of his schemes. He had costs per head of population at his finger tips. Coming from the heavily populated and comparatively rich Colony of the Straits Settlements he was fully aware that different methods would probably have to be used in Trengganu. As an example of this, engineering works and large-scale oiling were ruled out in the fight against malaria. Trengganu must depend on naturalistic methods.

Welfare organization

The financial nexus takes an important place in the philosophy of welfare work. The thesis is, I think, generally recognized that a given amount of well-directed effort, and therefore a given expenditure, will produce the greatest long-term results if spent on the unborn child and progressively lesser results on infants and older children. In spite of the fact that expenditure of effort and money on children of the youngest ages is the most remunerative from the point of view of building up an A-1 population, the graph of return in terms of health plotted against increasing ages of children flattens out only gradually. There is no hard and fast line. Moreover the health of the infant cannot be maintained without attention to that of the rest of the family. Yaws, worms and malaria afford excellent examples. It is no use devoting attention to infants if other members of a household are infected with yaws and worms. In those areas in which infant mortality is due to malaria, one can obviously do next to nothing without dealing with the malaria problem in that locality. This principle, developed in the monograph, is paralleled by the American theory that infant welfare must merge into family welfare and that again into community welfare.

Relation between hospital and welfare work

There would appear to be a tendency to consider clinical and preventive work as rivals. In the Anglo-Saxon world another tendency has been rapidly increasing, that of considering that

there should be a balance between them. There should even be more than a balance; a correlation. This correlation has been realized from early days as in the Rockefeller Foundation attack on ancylostomiasis. But the convincing argument in this monograph extending this principle of functional correlation to welfare work appears to me new.

From a philosophical standpoint the balance between clinical and preventive methods is a balance between methods designed to have short-term and long-term results. It is a great philosophical advance to realize that the relation goes even deeper, that clinical and preventive methods should be articulated together as though they were parts of the same living organism.

There are three medical arms: hospital, preventive work, and education. The hospital is the short-term approach to health problems. Preventive work is the medium-term approach and education the long-term approach.

Results

In the matter of nutrition, the campaign for getting the population to eat under-milled rice has had such success that the Kuala Trengganu mill has for many months been producing only under-milled rice. The demand has been greater than the supply.

Antimalarial work has had clear statistical results in the main experimental area. The peasants have not only realized their comparative freedom from malaria, but, much to my surprise, and no doubt owing to the health inspector who had lived among them, have realized that it was due to the herbage-packing of seepages, and to the consequent diminution in anopheline mosquitoes. This has been an educational as well as a preventive victory.

At the other end of the social scale the anti-malarial work has been much appreciated by members of the Malay Government. A point of interest is that this has perhaps been due not so much to the success of the work in Trengganu as to rumours of Dr. Scharff's successes in Singapore seeping up through various channels. It shows that successful preventive work can gradually spread an aura of adaptability to such work.

I accept Dr. Williams' statement that it is still too early to assess the success of the welfare work on statistical results. The great success in this field has been that the Malay women have shown their belief in it by visiting welfare centres in such numbers that the demand has exceeded the capacity of the present organization.

The educated Malays have been won over to a long-term policy of working through the education of girls. The Malay Superintendent of Education is enthusiastic about the English, domestic science, and welfare classes to be started in the girls schools.

SECTION I

CONDITIONS IN TRENGGANU

By CICELY D. WILLIAMS

1. Introduction

THIS is an attempt to describe the health programme lately undertaken in Trengganu.

It has always appeared to me that there could with benefit be more co-operation between the preventive and curative sides of medicine, between welfare centres and hospitals. As a welfare worker I have been reprimanded for attempting to cure my patients, and as a pædiatrician I have been discouraged from having anything to do with preventive medicine. In Trengganu there has been a precious opportunity of establishing work on sound lines of preventive pædiatrics.

The objectives were:

- (a) to discover what actually were the conditions and diseases that led to the large infant mortality, the prevalent ill-health, backwardness and lack of initiative in the population;
- (b) to apply methods of dealing with these conditions that would be adapted to their needs;
- (c) to do this at minimum expense.

This report covers a large number of activities. They are every one of them essential to preventive pædiatrics.

2. Conditions in Trengganu

(a) *General*.—Trengganu is an unfederated State on the east coast of Malaya, covering 5,050 square miles and with 160 miles of coast line. Only about one-seventh of the land is in occupation, the mountainous inland is covered in deep jungle. There are few roads and no railways. The population, estimated at about 200,000, is 90 per cent Malay. They are poor. The land is not very fertile. Paddy and fruit and vegetables are grown, but the foothills in many places run close to the sea, making these districts malarious. A great deal of land which could be used for cultivation and for grazing is lying idle. Fishing is a very important industry. Rubber and copra are produced in small quantities and there are some tin and iron mines, but the mine labourers are nearly all Indian and Chinese. Weaving and boat building and the manufacture of goods in 'white brass' are beautiful and highly skilled, though poorly paid industries.

The State is governed by the Sultan and his Council with the help of a British Adviser. There are about 20 Europeans employed in the Government service.

(b) *Finance*.—The total revenue of the State in 1940 was \$3,305,006 including \$171,189.68 war taxation and a windfall of \$149,000 from the Currency Surplus Fund. (One dollar Straits equals two shillings and four pence sterling.) Medical expenditure rose from \$69,601 in 1935 to \$141,324 in 1940, the percentage of medical

to total expenditure being respectively 3.4 per cent and 5.4 per cent.

(c) *Health*.—It was most particularly to the Malays, who are at the same time the most numerous, the most unhealthy and the least health-conscious members of the population that we had to address our attentions. Dirt and ignorance, poverty and prejudices produce their most unnecessarily large mortality and morbidity. The people mostly live in scattered rambling kampongs where sanitation there is none. Every bit of the ground is infected with excreta which is of great benefit to the coconut trees. To bathe is to stand beside a well and slosh water over the sarong-invested body. The children have skins that are constantly subject to trauma and infections. The consequence is yaws and ulcers externally and worms and dysenteries internally. People are nearly all indolent and conservative, largely as a result of their diseases.

(d) *Family life*.—Mohammedan beliefs are modified by pre-Islamic tradition. Each man is allowed four wives at once, but in practice few have more than one or two, however rapidly they may succeed each other. Most women are married more than once. Eighteen times was the maximum that was admitted to, but three or four times was usual. The more well-to-do men may be forced into marriage by their female relatives sometimes as early as 15. The girls usually marry at 14 to 16. The women have a good deal of indirect authority or nuisance value in affairs. A woman cannot divorce her husband but she can become so irritating that she can ensure her freedom. The semi-purdah lives of the women have a serious effect on their development, mentally, emotionally and physically. There is little in the way of amusements. Happily football for the men is becoming very popular in the kampongs, but as there is no drama or music or dancing, there is little entertainment for the women except the 'makam besar' (feasts) for weddings, funerals and circumcisions and amorous adventure. The women know that as soon as they are old and ugly they may be neglected, and they naturally make the most of youth and beauty while these last. The plague of the adopted child, the 'anak angkat', is a serious one. The physical and psychological evils of these unnecessary and often mercenary transfers are too well known to need emphasis. The instability of family life has an adverse effect on the health of the population both mentally and physically, on the care of the children and on the general prosperity.

(e) *Education*.—There are 40 schools in the State with a total of 4,281 pupils. This represents 20 per cent of the estimated number of children of school age.

(f) *Vital statistics*.—Figures are at present of necessity, unreliable. There has been no census since 1931. Only 5 per cent of deaths are reported by qualified practitioners, all the others

being done by police and by penghulus (village headmen). There is a list of 80 causes of death from which they may select. In practice it is found that all adults die from 'deman panas' (hot fever) up to the age of 35; after that the cause of death is 'sakit tua' (senility). Among infants it is about fifty fifty between 'deman panas and sawan or sewan tenges' (convulsions and crying convulsions). These deaths from 'deman panas' were just as freely entered in the non-malarious as in the malarious districts. On investigating infant deaths and getting fuller histories (post mortems were difficult to obtain, but one was generally able to view the dead body), it was found that both fever and convulsions were rare. The deaths were in fact due to beri-beri, prematurity, congenital debility and emphatically most of all due to dietetic indiscretion. It is possible that more complete registration would reduce the infant mortality rate. There is a great deal more celebration over a death than over a birth. While the latter may go unreported, the former is not likely to do so. It is likely that the large reduction in the I.M.R. for Trengganu in 1940 was partly due to improved registration which followed on some prosecutions for failing to report births.

The birth rate in the State has varied in the last four years between 34 and 41, and the death rate between 22 and 25. Maternal mortality is estimated as 5 per thousand births. All these figures are probably only approximate.

(g) *Nutrition*.—Rice is the staple diet and about one-third of the total consumption is grown within the State. Most of the paddy is cultivated by primitive methods, including shifting cultivation, which is tending to silt up the rivers. For a variety of reasons, the overall average yield of paddy per acre is particularly low in this State. In the towns and among the fisher people who have little or no paddy land the rice eaten is 'Barat No. 2', a second quality Siam rice, rather broken but not highly polished. Yet beri-beri is a very frequent complaint, particularly in the towns. Paddy can be pounded on the 'lesong' until all the pericarp is gone and much of the home-pounded grain is robbed like this of its nutritional value. But it is not difficult to persuade these people that unpolished rice is a better food. They bought and used it readily when advised to do so. A great deal of fish is eaten, both dried and fresh. The oils that it may contain are largely driven off by drying and by roasting over the coals. In any case most fish is a poor source of vitamin A, and this makes it rather worse. According to the recent work of Professor Rosedale and his co-workers, many of the larger varieties of shark caught in Malayan waters provide a liver oil which has a very high value of vitamin A, but these large fish are seldom seen in the local markets. Meat is eaten only very occasionally. The rest of the diet consists mainly of coconut oil and coconut-sugar, cassava, yams and cocoyams, sweet potatoes, beans and

a large variety of green leaves used for spinach, pumpkins, cucumbers, egg plant, onions, tomatoes, generally taken with a great deal of chili and curry stuff. Bananas, pineapples, oranges and water melon are varied with other and stranger fruits, such as durian. Cows, buffaloes and chickens are kept and in the coastal areas a few sheep and goats as well. Milking is practised in a few kampongs, and rather spasmodically. Buffalo milk is made into clarified butter for cooking curry. Curdled, in bamboo joints, it is also sold for a few cents as an indigenous variety of curds and whey or yoghurt. (This can easily be made into an excellent cottage cheese.) Milk is drunk either fresh or heated, mostly by the men. With a little education, it should not be difficult to introduce it more lavishly into the diets of children and pregnant and nursing women. In the rest of Malaya there seems to be an antipathy among Malays to the consumption of fresh milk from a cow as distinct from milk from a tin. This is probably due to the almost universal migration of the well-to-do Malays into the towns, the traditional sophistication of the food of town dwellers and fresh milk being looked upon rather as an indelicacy.

The actual fishermen and their families may consume an adequate amount of protein during the fishing season. But in general the diet is deficient in proteins and animal fats. This deficiency becomes more marked inland, and is very pronounced in the upper regions of the rivers. For young children the diet is also too coarse and irritating.

3. Diseases

(a) *Methods of investigation.*—To determine what were the diseases of greatest importance, the hospital statistics were of little value. Of the population of the State 90 per cent is Malay, but of the hospital admissions, less than 30 per cent are Malays. Children under 5 years provide half of the deaths, but only 5 per cent of the hospital series. It was necessary, therefore, to explore the kampongs and then get admission into the huts. We went to the houses as soon as a death was reported, and, by getting data, often wildly contradictory, from the assembled guests and relatives, it was possible to ascertain some of the important facts that are concerned with mortality and morbidity, particularly those relating to the children and infants.

(b) *Malnutrition* produces ill-health in various ways. These may be classified as food that is improper in quantity, improper in constituents, and food that is contaminated by harmful substances. In the first category we get a number of people who are underfed and a few who are overfed.

Improper constituents of food may be physical or biochemical. Among the former we have the quantities or coarse, bulky carbohydrates and substances that are irritating, such as pepper and dried fish which are given to young children

and which may produce distension and severe intestinal indigestion. Biochemically the food as a whole is poor in protein and animal fat. It is also conspicuously lacking in vitamins A and B. If polished rice is the main diet, then beri-beri often occurs, sometimes in the acute cardiac and sometimes in its more chronic forms. The skin conditions that are generally associated with lack of vitamin A are not uncommon; no statistics of the number of blind people are available, but there are many. Rickets occurs occasionally. As in Singapore, it is not uncommon among babies brought up in dark houses away from the sunlight and fed on sweetened condensed milk. The low fat and high carbohydrate content of this milk makes babies fed on it peculiarly liable to develop keratomalacia and rickets unless they are given cod-liver oil or some other source of vitamins A and D. Both Chinese and Malaya, in their misguided admiration for a pale skin, are wont to keep babies far too much indoors even when the exigencies of slum houses do not force them to live in the dark, ill-ventilated cubicles. Rickets is not seen in older children, or with gross bony deformities. Either the baby dies young from one of the eatarrrhal conditions (of chest, stomach or intestines) to which rickety children are particularly subject, or else, on reaching the toddling stage, they go into the sun enough to arrest the disease.

Two cases of pellagra were seen, both in Chinese who also had beri-beri. Nutritional dermatitis of the various types ('mosaic' and 'pellagroid') was perhaps rather less common than appeared to be the case among the poorer classes in Singapore.

Food is generally speaking kept, prepared and eaten by insanitary methods. It is often infected, with the result that worms, diarrhoea and dysenteries are common.

Artificial feeding of infants is almost universal among the sophisticated and the high born. Even among the kampong people it is not uncommon.

Even people in a good position and 'well educated' are ignorant of what and how to eat. Emaciation, asthenia, apathy and chronic malaise are the result. Malnutrition, lack of initiative and lack of discipline lead to such conditions as 'latah' and 'amok'. These are not specific diseases, but merely the evolution of quite common attitudes of mind.

(c) *Worms.*—The population is almost universally infected with worms, and this is some indication of the sanitary standards. The presence of intestinal parasites not only does active harm, but also does so much to interfere with the absorption of food that it has a very sinister influence on nutrition. This applies especially to babies and to young children who have not yet acquired any immunity towards the parasites. The chief trouble is the round worm. It has been estimated that about 90 per cent of the population has been infected. Hookworm is

present in some 30 per cent of people; *Trichocephalus dispar* is practically universal and in some cases seems to do damage. Strongyloides and clonorchis are both very rare.

Round worm infection generally starts much earlier than any other. Babies may be infected any time after birth, presumably from the dirty fingers of the mother or other attendants as they push the 'tepong' and 'sugi' down the infant throats. As early as three months babies have been known to pass ascaris eggs.

It is common all over the world to find ascariasis underestimated as a cause of sickness and death. It is high time that this complacent attitude should be changed.

(d) *Yaws*.—According to all accounts, yaws in the past was very much more common than it is now. As in other countries, it seems that yaws is tending to die out in the towns where children are inclined to wear more in the way of clothes, and spend less time 'carousing in the dirt', and are therefore less certain of infection. However, in Kuala Trengganu hospital it will be found that the majority of the patients have sought admission for some sort of ulcers, and that the cause of the great majority of the severe and intractable ulcers is yaws. On going through the kampongs it will be found that there are ghastly cases of mutilation and crippling that are due to yaws and that are kept hidden away.

It is remarkable that the late results of yaws, chronic ulceration, rheumatic pains, gangosa, dermatitis, bursitis, epiphysitis, sinovitis, leucoderma, etc., are not recognized by the people themselves as having any relation to yaws. Textbooks contain the misleading statement that one attack protects. It would be more correct to say that one attack may never finish unless rigorous treatment is adopted. The patient is always liable to suffer from some form of recrudescence right into old age, 40, 50, 60 years after the primary attack.

It was found that the medical staff sometimes missed diagnosis of the sequelæ of yaws, and even of the earlier stages. In 1940 the Kahn test was done on 122 patients of which 18 per cent were positive. There are now nearly 100 examinations being made monthly of which nearly 50 per cent are positive. This is possibly in some measure due to increased yaws consciousness.

Among yaws-infected members of the population are found numbers of cases of sterility, both relative and absolute, of still-births and of neonatal and of infant deaths. There are also cases of anæmia, and ulcerations that only improve on treatment classed as anti-specific. As far as I know cases of congenital yaws have not yet been proved, but it is quite certain that untreated yaws in the mother has an adverse effect on the progeny. Yaws and syphilis appear to be very much the same disease. So many of their manifestations are indistinguishable. The former is non-venereal

and derma-osteotropic, while the latter is generally venereal and genito-neurotropic.

Treatment has been available for many years. A few years ago it was decided to overcome the objection to treatment by offering stovarsol pills instead of injections. These pills have a great reputation for their aphrodisiac effect. They sell for 20 cents each in the shops and it was thought that this form of treatment would be popular. But whether the wrong people take the pills or whether they are not taken at all, yaws still remains one of the major health problems.

We are now trying to re-establish treatment by injection, and in recent months the numbers of patients willing to receive this form of treatment has showed a satisfactory increase.

Even if few patients attend sufficiently regularly to receive a complete course or a complete cure, still one or two injections will dry up the lesions enough to make the disease less infective and in time to reduce its prevalence. Preparations of organic arsenic are expensive and are becoming increasingly difficult to obtain, and so bismuth salicylate in oil for intramuscular use is being prepared in the dispensary. There are very few complaints of any after-effects or of pain, the results on the yaws are very satisfactory, and it has the advantage of being extremely cheap.

(e) *Malaria*.—Malaria is a very serious problem in some areas. But in the State as a whole it only accounted for a small proportion of the mortality and morbidity. The average spleen rate in the schools is under 4 per cent. Of the 3,503 deaths in 1940 that are ascribed to 'malaria and unspecified fever', only 76 could actually be certified to be malaria. In one of the dispensaries in one month 176 cases were reported as malaria, but of nine blood films examined only one contained parasites.

(f) *Other diseases*.—Anæmia is very prevalent, owing mostly to malnutrition, worms and the indoor habits of many of the people. At a guess I should say that the average hæmoglobin of the State is less than 50 per cent.

Respiratory diseases are fairly common, but among hospital patients there are very few pneumonias among Malays and Chinese compared with the large numbers among Tamils. Chronic bronchitis and asthma, probably associated very often with worms, are very common among Malays. Tuberculosis is a very serious scourge, phthisis, especially in young adults, being the variety most usually met with. Adolescent girls and young women scarcely ever go outside the houses and their resistance is therefore extremely low. It is probable that when Malays start bringing their children for hospital treatment it will be found that tuberculosis is responsible for a great deal of trouble. It is exceedingly difficult to get even the educated Malays to understand the dangers from tuberculosis, and how they can be

avoided, and to alter their way of life one whit in order to avoid them.

Malay children, if they are breast-fed, generally have fairly good teeth, but in older people pyorrhea and dental sepsis are very pronounced.

Veneral disease is fairly common but it is impossible to estimate either extent or severity.

4. The Medical Service

Kuala Trengganu.—Medical officer, assistant medical officer and dental surgeon. Hospital with 160 beds and dispensary. Town dispensary, travelling dresser and midwife. (Senior health nurse and five welfare centres.)

Dungun.—Assistant medical officer. Hospital with 20 beds and dispensary. Travelling dresser and midwife.

Kemaman.—Assistant medical officer. Hospital with 56 beds and dispensary. Travelling dresser and midwife.

Besut.—Dresser, travelling dresser and midwife.

Kuala Brang.—Dresser and travelling dresser.

Kampong Buloh.—Dresser.

Kemasik.—Dresser.

One or two mines and estates have their own dressers and doctors.

The dressers are most of them trained in the State of Trengganu. Naturally the facilities for a conventional type of training are not very good, but in spite of that much has been done to make them both keen and efficient. One handicap is that no trained nurse or sister has ever been regularly stationed here.

Medical reports have always included a section on 'Maternity and Child Welfare', but in the absence of any specific work on this subject, in practice it has meant that infants and children attending for treatment of any description have been classified under this heading.

On examining the medical reports it will be found that :

(1) Only a small proportion of Malays seek admission to the hospitals, and they form two categories, firstly accidents and police cases, and secondly chronic ulcers.

(2) A very small proportion of women and children come for in- or for out-patient treatment. Yet infancy and childhood are the ages most in need of protection and care of health.

(3) Chinese women form a very small proportion of the total female population, but it is chiefly they who patronize the government maternity service.

It is obvious that the health of this State can only be improved by bringing health education to those who need it most, that is, the Malays, and most particularly to the Malay women and children.

It is likewise obvious that conditions cannot be remedied on any large scale by the methods

(Concluded at foot of next column)

COMPOSTING : A PUBLIC HEALTH PROBLEM

By GAURCHANDRA GHOSH, B.E., M.R.S.A.I.

Definition.—Composting may be defined as preparation of manures by the fermentation of bulky organic refuse materials, of either plant or animal origin, brought about by a complex flora of living organisms.

History.—From ancient times the Chinese have led the way in the methods of utilization of both habitational wastes and farmyard refuse. All the dry portions of refuse they generally add to the compost heap, while liquid refuse including night-soil is directly put on the land. Although the application of crude night-soil to the land may be undesirable from a sanitary point of view, rice is specially benefited by it, and the demand for this is so great that the city of Shanghai in 1908 entered into a contract with a Chinese allowing him, in return for a payment of 31,000 gold dollars, the privilege of entering the houses and removing the night-soil.

Hutchinson and Richards in 1921 first enunciated the scientific principles of composting straw and other organic matter into synthetic farmyard manure. Since then various methods have been introduced to suit varying local conditions. Richards introduced his 'Adco' process in 1921. The Indore process of Howard and Wad (1931) and Jackson and Wad (1934), the 'activated compost' process of Fowler (1934), the Bangalore hot fermentation process based on the Edelmist process devised by Krantz and Beccari process, are some of the more important methods of composting.

Some of the recent experiments have been directed towards composting of sewage sludge with town refuse (Maidenhead and Leatherhead in England).

Problem of Composting.—Composting is becoming of interest to both public health and agricultural administrations in proportion to the degree that satisfactory methods have been evolved, which depend upon local customs and meteorological conditions. However, China is the only instance (Winfield experiments) of scientific investigation of the microbiological health aspects of composting which in the other instances has been studied from an agricultural standpoint.

(Continued from previous column)

associated with purely institutional medicine. It is only by reforming the outlook on health and domestic and nutritional habits that improvement can be effected. It is superlatively obvious that a well-aimed scheme for maternity and child welfare would be the method *par excellence* for introducing these improvements.

[Section II on the scheme for health work by both the authors will be published in our next issue.]

The efficiency of any method of composting has to be determined from three different aspects :

1. Sanitary efficiency.
2. Agricultural efficiency.
3. Economic efficiency.

Existing conditions in rural India (with special reference to Bengal).—In most of the villages people have no latrines and they use the fields, banks of tanks and ponds and other vacant land for evacuation. In some of the more advanced villages there are bucket latrines maintained by local bodies or union boards. These local bodies in most of the villages have no means of maintaining first-class sanitary conditions and in many cases these latrines are cleared twice or thrice a week and the night-soil is simply dumped into low lands outside the village. This practice, combined with the unsatisfactory sources of water supplies, which in many cases are from polluted tanks, leads to frequent outbreaks of cholera and other epidemic intestinal diseases.

Composting has often been suggested as a method for safe disposal of night-soil for rural and semi-rural areas. However, there are various problems which must be solved and more research carried out before composting can be successfully applied in practice.

The following are some of the factors which influence the choice of a system of composting:—

1. Rainfall.
2. Humidity.
3. Sub-soil water level.
4. Seasonal temperature variations.
5. Social customs.

Before composting can be successfully introduced as a public health measure in a particular area, it is desirable to have scientific investigations on the following lines and considerations :—

Materials.—The type of refuse available is very important. In many rural areas in India the only types of refuse available are grass, shrubs and vegetation removed from tanks.

There is very little kitchen refuse, and the little that is available is given to domestic animals, such as cows and dogs. In many places water hyacinth is available in enormous quantities throughout the year, and is sometimes removed by the villagers and is heaped up by the side of tanks, but unless the hyacinth can be disposed of, the seeds are again washed into the tanks, where they soon germinate and fill up the tanks. If composting could be carried out with such materials, it would have the additional advantage of giving an impetus to the people to keep their waterways clear.

Composting of water hyacinth however presents certain difficulties. When hyacinth is dried it becomes fibrous, like sugarcane trash, and takes a long time to decompose, unless some other materials are added. It may be possible to decompose it properly by starting the process

with moist green hyacinth. In such a case, however, the temperature may not be suitable to keep the sanitary efficiency at a high level. The high calcium and potassium contents of hyacinth, if successfully conserved in a compost, would make a good fertilizer. It is thus both a public health as well as an agricultural problem. The author carried out several experiments using such materials and cowdung as a starter. However, the rise in temperature was never satisfactory, and so far as the sanitary efficiency was concerned the experiments were a complete failure.

Sanitary efficiency of composting.—Composting has mostly been studied so far from an agricultural point of view, the appraisal of the sanitary efficiency having been judged by a mere visual inspection of fly-breeding. A scientific investigation of sanitary efficiency should include the following studies:—

(a) *Fly-breeding.*—It will be necessary to devise a suitable sampling technique as otherwise sampling errors are very large owing to the tendency of the larvæ to congregate in particular places in the heap. The species as well as the number of the flies should be studied.

(b) *Temperature records.*—The rise in temperature inside the heap is an index of the sanitary efficiency as it is due to the rise in temperature that most of the pathogenic organisms are destroyed. Temperatures should be recorded not only at different places of the heap but also at different depths.

(c) *Helminthological studies.*—The survival of ascaris eggs, hookworms, etc., and their viability may be used as guides to the sanitary efficiency of a system.

The following conclusions regarding the sanitary efficiency of aerobic composting were reached by Winfield *et al.* (1939) in their experiments in the Cheeloo and Yenching Universities in China :—

Fly-breeding.—The amount of fly-breeding was measured by determining the number of larvæ, pupæ and pupal skins present per cubic foot of material. Because of the tendency of larvæ to concentrate in certain parts of the stack while active and to seek special places, which for some species involves leaving the stack, to pupate, sampling variations are very large. Quantitative data are therefore only very rough measures of the intensity of fly-breeding.

It is impossible to prevent fly-breeding entirely in stacks which contain 60 per cent or more of faeces. If stacks are made with 40 or more per cent of vegetable matter and a 5, 10, 18-day turning schedule is followed, it is possible to prevent entirely maggots from reaching maturity. A large percentage of the larvæ leaving the stacks to pupate are killed by ants or eaten by birds if the ground around the pits or stacks is hard packed.

Ascaris eggs.—This method of composting is quite efficient in destroying ascaris eggs, and all or almost all eggs can be killed by this process.

At the same time emphasis is laid on the fact that intelligence and care must be exercised to obtain satisfactory results, and certain precautions must be taken for overcoming special difficulties.

Protozoan cyst destruction.—*Entamoeba histolytica* cysts are usually present when the stacks are made but they do not persist as long as the time of the second turn though they have been found at the first turn. *Entamoeba coli* cysts on the other hand persist longer, having been demonstrated at the second and third turns.

Winfield's experiments regarding anaerobic composting (Edelmit process) provided conflicting results, but they suggest that there is enough evidence of merit to warrant a more extensive study of the method.

For ensuring sanitary conditions, care should be taken to reduce handling of night-soil to a minimum. The author suggests a night-soil cart of special design having rotating blades inside, so that water can be poured into the tank and the night-soil liquified by rotating the blades. There should be a flexible pipe connection from the bottom of the tank so that liquid night-soil can be sprayed directly on the compost heap.

Agricultural efficiency.—Successful composting technique lies in producing a fertilizer with a high nitrogen content. However, the fertilizer value can not be judged on chemical analysis alone, and has to be determined by actual plot experiments, noting the yield of crop, etc.

Chemical analysis of compost should include determination of carbon, nitrogen, phosphate, carbon nitrogen (C/N) ratio, organic matter and moisture content.

The following conclusions were reached by Winfield *et. al.* (1939) regarding aerobic composting :—

There was a heavier loss of nitrogen in the faeces-straw group of experiments as compared with village unit group, at all C/N ratios. Optimum C/N ratio is 38 or 39 : 1.

When C/N ratio of 40 to 1 is exceeded the amount of nitrogen lost increases, and, if this latter point is true, it is of very great significance for agricultural sanitation, since it indicates that the fly-control level of composting faeces and straw is also the level of maximum nitrogen conservation. C/N ratio is probably more important in determining variations in nitrogen conservation within any one group of experiments than in any other factor.

Acharya in Bangalore (1939) carried out comparative experiments on different methods of composting, which, when judged by plot trials in the fields and by nitrification experiments in the laboratory, showed the superiority of the hot fermentation process (modified Edelmit process) over the usual aerobic methods. The former gave a higher recovery of organic matter and of nitrogen than the latter (about $1\frac{1}{2}$ times) and the resulting manure was equally efficient in crop production and in several cases superior.

Economic efficiency.—In many countries, including India, the disposal of household waste and faecal materials has been considered as an expense which must be borne by the community. With a very few exceptions, faeces has never been utilized directly in agricultural practice in India. The economics of composting in India, therefore, would not be the same as in North China where the farmer is so conscious of the value of human excreta, and the practice of using faeces is so thoroughly entrenched, that changes in procedure must be justified purely on grounds of agricultural merits and economy.

In most of the provinces in India there is very little demand for compost manure, although the land needs it badly. The reason for this is the great prejudice against night-soil, so much so, that the mere knowledge that the manure had been prepared from night-soil, however innocuous the final product might be, would prevent the people from touching it. Due to lack of demand for this kind of manure, the saleable value of compost is almost always much less than its production cost, and instances are not rare where many municipalities were thinking of abandoning this system of disposal for want of space due to accumulation of innumerable heaps of undisposed-of compost.

The solution lies in a vigorous campaign of education and practical demonstrations by the agricultural departments on the value of compost manure. A very much wider publicity is essential, and unless the people can be made conscious of the value of compost manure, and a demand is created for its wider use, the system will never fully succeed as a solution to our public health problems, notwithstanding any high degree of perfection we might reach in its technique.

ADMINISTRATION REPORT OF THE PUBLIC HEALTH DEPARTMENT, GOVERNMENT OF TRAVANCORE, FOR THE YEAR 1116 M. E. (DECEMBER 1941)

THE usual activities of the department such as the control of communicable diseases and the registration of vital statistics were continued. The number of births registered was 114,487 which is 2,521 less than in the preceding year. The birth rate per mille of the population was 18.86 as against 19.01 in 1,115. The number of recorded deaths and the death rate per mille of the population were 69,248 and 11.41 as against 59,406 and 9.65, respectively.

There was no plague or cholera during the year. The incidence of malaria was lower than in the preceding year. One thousand four hundred and seven attacks of smallpox and 582 deaths therefrom were reported. There were 3,066 cases of typhoid, of which 360 were fatal.

The vaccination campaign was continued. About 24.36 per cent of the people were vaccinated, including cases of primary as well as subsequent vaccination.

There was no plague among men, but a few rat-falls on account of plague-infection occurred at Munnar, Alleppey and Quilon. The situation, however, was soon brought under control and rat-plague was eliminated.

The temporary post of malaria special officer was abolished during the year, the district health officer, Southern District being put in charge of the anti-malaria measures as well.

In January 1941 sanction was accorded for the opening of a clinic for the treatment of filariasis at Shertallay. It is noted that the clinic commenced work recently.

The health unit, Neyyattinkara, was free from cholera and smallpox. Sporadic cases of typhoid fever, however, occurred throughout the year. The usual activities of the health unit, such as maternity and

child welfare work, medical inspection of school children, etc., were continued.

The maternity and child welfare service in rural areas was continued as usual. The midwives in charge of the centres carried on the work of visiting homes and giving advice to women in various stages of pregnancy and confinement. The number of visits they paid was 52,346 and they assisted at 1,202 deliveries.

The medical inspection of school children was also continued. Two hundred and seventy-four schools were visited by the staff and 42,712 pupils were examined. Various defects were observed in 21,252 pupils of whom 17,354 received the necessary treatment.

Public health education was carried on as usual. Altogether 3,525 lectures and group-talks were organized, reaching an audience estimated to be 279,800 strong. The number of pamphlets and posters issued was 10,991.

In the field of rural sanitation the main feature of the work during the year under review, as in the preceding year, was the effort to popularize bore-hole latrines. Six hundred and seventy-two latrines were constructed.

The receipts and expenditure of the department were Rs. 6,431-5-2 and Rs. 2,83,210-0-5, respectively.

Sulphathiazole Treatment of Gonorrhœa in the Male

By ELWOOD A. JENKINS, M.D.

and

WILLIAM L. SHERMAN, M.D., F.A.C.S.

(From the *Urologic and Cutaneous Review*, Vol. XLVI, January 1942, page 6)

SULPHATHIAZOLE was synthesized by Fosbinder and Walter in 1939. It has been shown that sulphathiazole is rapidly excreted from the human body. About 90 per cent can be recovered from the urine in 24 hours. Little of this is in the acetylated form in contrast with sulphanilamide and sulphapyridine. Many observers have noted that the satisfactory therapeutic action of sulphathiazole in gonorrhœics does not depend upon a high blood level as is the case with other sulphonamide drugs.

This paper is based on a study of 300 cases of gonorrhœa in the male. No medication except sulphathiazole was employed in this series. No blood level studies were taken on any of these patients. We feel that the low dosage employed would have given very low readings. We know from previous experience that sulphonamide derivatives are efficient in low doses, even when blood titres are zero. Also, there is less likelihood of untoward reactions and toxæmias. Since all of our patients are ambulatory, most of them employed and many driving cars, it would not be safe to give them large doses.

This work was done at the Social Hygiene Clinic, Detroit Department of Health. An idea of the clinic load may be obtained from the following statistics for the month of May 1941:—

New cases admitted	610
New cases diagnosed as gonorrhœa	361
Cultures taken for gonorrhœa	1,390
Smears taken from gonorrhœa	2,566
Treatments given for gonorrhœa	2,186
Total patient visits	11,055

Every patient reporting to the clinic with gonorrhœa is given an individual educational interview with emphasis on the seriousness of the disease and its possible complications. Most of these patients appear

to regard their disease lightly. Forty-two per cent gave a history of having had previous infections. Although some of these may have been recurrences it would not seem that gonorrhœal infection tends to alter or improve a person's social behaviour sufficiently to prevent his acquiring the disease again. Under such a clinic load it is apparent that patients can report routinely but once a week.

Further analysis reveals that 82 per cent were coloured, the remainder white. Seventy-eight per cent were single. Of the 300 cases who started treatment 239 completed the course as outlined, a lapse of only 20 per cent. Pelouze claims that usually 80 per cent of dispensary patients lapse treatment. We feel our success in holding the patients may have been due to: (1) they were able to see favourable results of treatment early, (2) the treatment was simple to follow, (3) there were no unpleasant reactions and (4) the individual educational interview given by the nursing staff.

The subsequent statistics in this report will be based on the 239 patients who completed the course as outlined.

History of one or more previous infections	42 per cent
Complications on admission	52 "
Prostatitis	18 "
Epididymitis	7 "
Arthritis	0.8 "

The complicated cases made rapid and satisfactory progress. The average time to effect a cure in this group was five weeks, in spite of complications.

The diagnosis was based on the history, clinical symptoms, signs and positive bacteriological studies. All of the patients had a urethral discharge on admission which showed Gram-negative intracellular diplococci and the culture was positive for gonococci. We have been using an inexpensive practical method for the culture of gonococci (Difco) both for diagnosis and as a criterion of cure. The course of treatment consisted of sulphathiazole 1 gramme three times a day for five days, a total of 15 grammes. The patients were seen at weekly intervals or until five consecutive negative prostatic smears and two negative prostatic cultures were obtained.

Tests of cure were five negative prostatic fluid smears, two negative prostatic fluid cultures, alcohol,

and sexual excitement. The patients were re-checked one month after dismissal from the clinic for any evidence of clinical or laboratory recurrence.

Two hundred and twenty-eight or 95 per cent of the patients were discharged as cured. The discharge stopped in the majority in less than four days. All of the 228 had negative prostatic smears in one week and every one had five consecutive negative slides within five weeks. However, we know from subsequent study that cultures become negative in one week or less.

There were no complications in those responding to treatment after sulphathiazole was started. Only one patient developed a slight dizziness from the drug, but he did not have to discontinue it.

Of the 11 drug failures all but one gave a history of previous infection; and he had no apparent complication on admission. The other drug failures were patients that had failed to respond to sulphanilamide or sulphapyridine.

The following is a comparison of our results with those of other reported series:—

	Number of cases	Per cent of cures
Sherman and Jenkins ..	300	95
Burkholder and Bang ..	100	92
Hibbs, Day, Jung and Brady	57	94.74
Knight, Uhle and LaTowsky	50	96
Stockwell	30	100
Culp	21	80.9

Conclusions

Sulphathiazole is a very effective therapeutic agent for the treatment of gonorrhoea in the male.

It is apparently the least toxic of the sulphonamide drugs to date. There was only one slight reaction in 300 cases.

Sulphathiazole is potent in the low dosage of 1 gramme three times a day for five days. However, we feel it is better to continue the drug for ten days to two weeks as an extra precaution.

In the majority of cases the urethral discharge will stop within four days or less. If the discharge does not stop within a week the case should be classed as drug failure, in our opinion.

The Allergic Approach to Epilepsy : A Critical Review

By D. C. DEWAR, M.D., D.P.M.

(Abstracted from the *Practitioner*, Vol. CXLVII, December 1941, p. 776)

THE author draws attention to the fact that certain types of idiopathic or essential epilepsy rest on a sensitization basis, and recommends an exhaustive allergic investigation in all cases of epilepsy in which there has been a failure to respond to other methods of treatment. Especially is this urged when there exists either a personal or familial history of other allergic phenomena. Epileptics, as a class, have been shown to exhibit a greater degree of protein sensitivity than either psychotic or control groups, as evidenced by the greater percentage among them of positive skin reactors, and the higher incidence of other forms of allergy.

Allergic epilepsy displays the criteria common to allergy occurring elsewhere, viz.:—

- (1) Multiple sensitivity.
- (2) Alleviation of symptoms following elimination of the guilty substance.
- (3) Recurrence of symptoms on re-introduction of the substance.

In view of the established association of epilepsy and allergy, in a proportion of cases, it would appear strange that further systematic investigation along similar lines

has not been attempted. Such a line of research would present distinct possibilities.

The keynote of treatment has been, whenever practicable, the complete elimination of the offending protein. The detection of this protein, however, is not always simple and may be impossible. In such cases diet elimination tables, as compounded by Rowe, may be utilized as an aid to diagnosis and treatment. Non-specific desensitization has given good results in the hands of some workers, notably Spangler. In those few cases in which specific desensitization has been attempted uniformly favourable reports have followed. This latter method seems to invite further consideration, either alone or combined with elimination.

From a prophylactic point of view the early recognition of the hypersensitive state is most important, and undoubtedly the bulk of the work done and successes achieved have been with young subjects, in whom sensitivities are more readily detected and influenced. Nevertheless, this is not sufficient reason to condemn, without trial, the adult epileptic, whether institutionalized or not, and it is here that there exists a considerable field for further study.

A few investigators have been unable to find, on repeated examinations, any evidence to support the contention that epilepsy and allergy are related.

Some Effects of Vitamins B and C on Senile Patients

By W. STEPHENSON, Ph.D.

C. PENTON, B.M.

and

V. KORENCHEVSKY, M.D.

(Abstracted from the *British Medical Journal*, Vol. II, 13th December, 1941, p. 839)

Forty senile patients were treated with the vitamin B complex and vitamin C, the whole period of observation lasting for about a year. B complex was given as dried yeast in single doses of 25 grammes 3 times a week. The yeast was supplemented by tablets of aneurin (B₁) 5 or 3.3 mg., lactoflavin 5 or 3.3 mg., and nicotinic acid 50 or 33.3 mg., in each case administered three times a week.

Vitamin C was given as pure ascorbic acid, 200 to 300 mg., three times a week. The condition of these patients was compared with that of 18 senile patients of a control group receiving dummy tablets. All patients were on a usual hospital diet not rich in vitamins.

Treatment with vitamins B and C, as with any other remedy, did not stop the biologically inevitable development of senility, and therefore did not affect those basic features which are specific for and present in even the most physiological type of senility.

By treating the aged people with vitamins, however, it was possible to prevent or improve, in some cases to a striking degree, certain of these senile features which could be considered as pathological, because they appear prematurely or in an extreme degree (e.g., muscular, cardiovascular, and mental deterioration) or which do not seem to be inevitable in normal physiological senility (e.g., dementia, insomnia, skin rashes and itchings, constipation).

During the period of observation improvement or disappearance (apparently not of a lasting nature) of some pathological senile features was observed in numerous cases, while a number of other cases were not improved by the treatment, and a few patients who had been free from certain senile features developed them during and notwithstanding the treatment.

In spite of the comparatively limited and modest results which aged people might expect from treatment with vitamins, it seems clear that in suitable cases the relief obtained in some pathological senile features might be considerable.

The authors believe that their results provide strong support to the argument, repeatedly emphasized by several specialists in the modern science of nutrition,

that the greatest care should be taken to prevent the occurrence of partial or latent vitamin deficiency, apparently widely spread in the population. This will result not only in the prevention of certain vitamin-deficiency diseases but probably also in the approach to a less pathological senility.

An Investigation of the Effect of Diet on the Course of Experimental Malaria in Monkeys

By R. PASSMORE, B.M., B.Ch.
CAPTAIN, I.M.S.

and

T. SOMMERVILLE, M.B., Ch.B.
CAPTAIN, I.M.S.

(Abstracted from the *Journal of the Malaria Institute of India*, Vol. III, December 1940, p. 447)

It has often been stated that malaria runs a more severe course in people who are ill-nourished and in poor health than in those who are well fed and healthy. As such statements are matters of opinion rather than the result of controlled experiments, the authors decided to make observations on the course of monkey malaria in well-fed and under-fed animals. Monkeys (*Macacus radiatus*; syn. *Silenus sinicus*) were kept for varying intervals on two different diets. In the one there was a resemblance to a good human lacto-vegetarian diet as consumed by certain groups in Northern India. It was based on whole wheat and contained liberal amounts of pulses, vegetables, fruits and milk. The other diet resembled that of poor rice eaters all over India. Its main ingredient was parboiled milled rice and only small amounts of pulses, vegetables and fruits, but no milk were included.

The monkeys on the first diet put on weight and remained in excellent condition, while those on the poor diet lost weight steadily, some dying within 6 or 8 weeks. The majority, however, survived for 6 to 12 months and then died, after suffering for several weeks from diarrhoea associated with inflammatory or degenerative changes in the small intestine. The monkeys of the first group were active and playful, while those of the second group were listless and uninterested in their surroundings. The two groups were thus clearly differentiated. When animals in the two groups were infected with malaria by the injection of equal doses of parasites (*Plasmodium knowlesi* or *P. cynomolgi*) there was little if any difference in the reaction. The course and severity of the primary attacks of malaria were unaffected by the differences in the state of nutrition of the monkeys.

Discussion on the Therapeutic Value of Transfusion of Derivatives of Blood

By L. E. H. WHITBY, C.V.O., M.C.

J. VAUGHAN

and

H. BROWN

(Abstracted from the *Proceedings of the Royal Society of Medicine*, Vol. XXXIV, March 1941, p. 257)

(I) TRANSFUSION is practised for two main reasons:—

1. To restore oxygen-carrying capacity.
2. To restore blood volume.

On rare occasions transfusions are given with a view to contributing leucocytes, platelets and other clotting elements, and for immunological purposes. Stored blood and blood derivatives are extremely efficient for blood volume restoration. Red corpuscles, either from fresh or stored blood, are essential for increasing oxygen-carrying capacity. The survival time of the red cells of stored blood is a function of their fragility. Up to 3 or 4 weeks stored blood has quite good

oxygen-carrying power and when under a week old it can be regarded as almost the equivalent of fresh blood from this point of view; stored blood and its derivatives, however, are useless for contributing leucocytes, clotting factors and immune bodies. Leucocytes perish within a few hours, clotting elements deteriorate within a few days, immune bodies and complement slowly decline.

The corpuscles of young stored blood are available for the preparation of concentrated red cell suspensions used for the treatment of anaemia. They provide the maximum increase in oxygen-carrying power rather than blood volume increase.

The experimental survey, carried out by the Army Blood Transfusion Service in a search for the best blood derivatives for use in resuscitation work, gave the order of preference of the various fluids tried as plasma, serum, haemoglobin-Ringer, gum saline, isotonic saline. The plasma used contained 4 to 5 per cent protein, sterility being ensured by Seitz filtration.

A hundred air-raid casualties have been studied, and 165 pints of plasma administered, with only 3 rigors. The maximum amount given has been six pints. Where large transfusions are needed it is an advantage for at least 1 pint in 3 to be of blood. In 24 cases the efficiency of citrate plasma for approximately quantitative replacement of blood loss has been unequivocal. The quantitative nature of the replacement must be controlled by blood pressure examinations. Experience has shown that the need for transfusion rarely ends in the resuscitation ward.

(II) In the area served by the N.W. London Blood Depot the following blood derivatives have been used: unfiltered plasma, filtered plasma, filtered serum, dried serum reconstituted with sterile distilled water.

Two mild rigors were noted in 26 cases treated with unfiltered plasma and 2 rigors in 83 cases treated with filtered plasma. Seven cases have been treated with liquid serum, with 2 rigors. Ninety-one injections of reconstituted dried serum have been given, with 19 reactions, mostly when the serum was given in concentrated form. All the products gave the impression of being effective in the treatment of shock.

For air-raid casualties, combined treatment with blood and a blood derivative seemed to be indicated, as anaemia was usually present, even when there was no obvious haemorrhage. In the treatment of burns the administration of concentrated serum has reduced the local oedema. The results, however, of using concentrated serum in nephrosis and nephrotic oedema have been disappointing.

Apart from clinical considerations, serum is an easier fluid to handle in large quantities than plasma, as the latter is readily infected and tends to form clots. The use of concentrated red cell suspensions for anaemia with normal blood volume is advised.

Experience with the Intravenous Use of the Follicle-Stimulating Hormone of the Anterior Pituitary in Menstrual Disorders

By M. KENNY, M.R.C.O.G.

and

D. DALEY, M.D.

(Abstracted from the *Proceedings of the Royal Society of Medicine*, Vol. XXXIV, October 1941, p. 804)

THE authors have attempted to test the efficacy of follicle-stimulating hormone from pregnant mares' serum in cases of metropathia haemorrhagica, menorrhagia and secondary amenorrhoea. Five hundred units of Gestyl (Organon Ltd.) were injected on three consecutive days after testing for serum sensitivity. Results were controlled when possible by endometrial biopsy.

Results

(A) *Metropathia haemorrhagica*.—Four cases were treated. Regular menstruation has been induced in three cases and continued for at least a year in each.

One case was resistant to this as to all other treatment given. Two successful cases had had long-continued treatment by other methods with no improvement. One case relapsed when her house was bombed after apparent cure for a year. Ovulation was probably produced in all three successful cases and was confirmed by endometrial biopsy in two of them.

(B) *Menorrhagia with ovulation*.—There was definite clinical improvement in the two cases treated.

(C) *Secondary amenorrhœa*.—Three cases were treated with one success. The successful case was 29 years old and had had three years complete amenorrhœa. Oestrogens were given for three months and oestrum-withdrawal bleeding was produced. Gestyl injections in the 4th month were followed by regular periods lasting three days each month. This cycle has continued for 11 months. Biopsy to confirm ovulation has not been possible.

The results are as yet inconclusive but appear to be sufficiently encouraging to warrant an extended trial of treatment by intravenous follicle-stimulating hormone in menstrual disorders, especially those associated with absence of ovulation.

Preparation and Use of Concentrated Red Cell Suspensions in Treatment of Anæmia

By G. E. O. WILLIAMS, M.D.

and

T. B. DAVIE, M.D., F.R.C.P.

(Abstracted from the *British Medical Journal*, Vol. II, 8th November, 1941, p. 641)

THE modern method of blood storage involves the separation of plasma from stored citrated blood. This plasma can be stored for long periods, but the remaining red cells are usually discarded. Owing to their potential value in the treatment of anæmia, however, they have recently been used in increasing amounts for separate transfusions.

By using a long needle thrust through the rubber caps of the blood bottles, plasma can be separated aseptically for bottling and storage. The red cells can be similarly transferred into sterile bottles, each full bottle of concentrated blood thus containing cells from two or three donors.

Concentrated blood prepared in this way varies in composition, but approximately consists of 8,500,000 red cells and 3,000 leucocytes per mm.³, the hæmoglobin being 150 per cent. The cells are more fragile than normal, and the suspension is more viscous than whole blood of normal strength. It should therefore be given within 48 hours of preparation, and administered slowly to avoid cardiac embarrassment. Otherwise it may be given by the same method as plasma or whole blood.

Seventy-seven transfusions were given, most of them consisting of over 1 litre concentrated blood. Results, in terms of percentage increase in hæmoglobin, were obtained in 35 cases, and for comparison adjusted to equivalents of 'standard transfusions' of 500 cm.³ of concentrated blood.

Results :—

Type of anæmia	Number of cases	Mean rise of hæmoglobin % per 500 cm. ³ of concentrated blood given
1. Post-hæmorrhagic	17	14.3
2. Associated with severe infection.	6	9.6
3. Associated with pregnancy and the puerperium.	4	10.8
4. Dyshæmopoietic	8	8.0

In 77 transfusions, 15 reactions were noted. Of these seven produced rigors, and the others were mainly simple rises of temperature. One fatal reaction, probably of allergic origin, is fully reported. This reaction rate was lower than that produced by transfusions of whole blood during the same period of observations, when abnormal conditions caused a greatly increased reaction incidence.

Paratyphoid B and Acute Gastro-Enteritis

By S. H. WARREN

(Abstracted from the *Public Health*, Vol. LIV, May 1941, p. 139)

OUT of 64 persons who shared in a wedding feast at Consett on 8th June, 1940, as many as 56 were infected with the paratyphoid B bacillus. Of these 41 developed clinical enteric fever type of illness, 9 had only early acute symptoms and 6 had no symptoms at all. Of the 41 cases, in 34 there were preliminary symptoms, beginning within 12 to 72 hours, of diarrhoea, vomiting and abdominal pain. These 43 cases (i.e., 34 + 9) at their onset appeared to be ordinary acute bacteriological food poisoning. Throughout only paratyphoid B was found and the agglutination titres suggest that this was the only organism present. The epidemiological enquiries implicated a home-made trifle. This was prepared by a woman later found to excrete profusely paratyphoid B bacilli in both fæces and urine. It had been kept overnight at atmospheric temperature during a spell of particularly hot weather. The woman continued to excrete the bacilli for five months. While it is possible that she was infected from the trifle it is suggested as probable that she was suffering from an ambulant paratyphoid infection at the time of its preparation. (The high proportion of cases with acute gastro-enteritis is of great interest and is no doubt associated with very massive infection of the food, thus allowing the naturally low irritant properties of *Bact. paratyphosum B* to operate by their cumulative effect.)

Caloric Requirements of Full-Term and Premature Infants in the Neonatal Period—A Formula, its Uses and Limitations

By H. M. M. MACKAY

(Abstracted from the *Archives of Diseases of Child*, Vol. XVI, September 1941, p. 166)

THE day-to-day caloric needs of new-born babies is a subject which has been much neglected and about which textbooks provide the most diverse statements. In this paper the caloric value of colostrum and early human milk is discussed. Its value is taken in the author's calculations as 20 per fluid ounce (about 30 cm.³), though individual variations may be considerable.

A formula is suggested whereby the food intake of new-born babies may be regulated. According to this the baby should receive on the first day of life calories equivalent to $1/2 \times 110 \times$ birth-weight in kilograms, and his feeds should increase by this same amount each day of the first week, so that by the seventh day of life he would be given 110 calories per kilogram birth-weight. It is pointed out that the formula over-estimates the intake of normal breast-fed babies during the first two days when breast secretion is scanty. In the second week of life 110 calories per kilogram birth-weight was taken as the usual requirement. The importance is emphasized of using these figures simply as guides and not to enforce a rigid system of feeding;

If the baby is artificially fed the rate of increase must often be rather slower, especially in the first four days; certainly if there is any tendency to vomit or the baby's abdomen is distended a more gradual increase is indicated perhaps reaching 110 calories per kilo birth-weight about the tenth day of life.

The calorie intake of twenty healthy breast-fed babies at the Mothers' Hospital, Clapton, London, has been compared with the quantities calculated from this formula. The average intake on any one day after the first two days of life, of those who regained their birth-weight by ten days old, was found to be within 3 to 12 per cent of the schedule. Three other series of full-term babies making good progress, whose average food intake for the first ten days has been recorded by different workers, received in these ten days a total quantity within 1 to 8 per cent of the formula requirements: those who took larger quantities in the first days of life tended to take less than others in the latter part of the first ten days, and vice versa.

Calculations from test feeds on twenty-five full-term babies showed that estimates of total intake based on the feeds given during the duty-periods of the day staff gave, on the whole, a fairly accurate figure for the twenty-four-hour intake, hence three or four test feeds in the twenty-four hours should generally provide an adequate check on a baby's intake.

One hundred and seven consecutive premature babies at the Mothers' Hospital, who had their food intake checked and guided by the formula, made good progress and averaged one ounce (30 grams) over their birth-weight at ten days old.

For a group of forty-three premature babies in this series complete figures are available. Their birth-weights varied between 1.125 kg. and 2.5 kg. and their intake for the first ten days was within 6 per cent of that allowed by the formula. During the second week of life, the intake averaged 117 calories per kg. birth-weight per day, *i.e.*, again within 6 per cent of the formula requirement.

All artificial feeds were given in a strength to provide approximately 20 calories per fluid ounce (30 cm.³). Dilute feeds were not given. The fluid intake was augmented by giving water to full-term babies during the first three to five days of life or longer, to premature babies generally during the first fourteen days. Premature babies during the first two to five days received water between feeds in about the same volume as provided in their feeds.

The author expresses the hope that wide adoption of a scheme for calculating the approximate calorie needs of new-born babies may bring about a fall in the neonatal death rate, as well as improved health in the subsequent months, by contributing to better management in the most critical period of life.

The Treatment of Burns

By T. E. WILSON, M.D., M.S., B.Sc., M.R.A.C.P.
(From the *Medical Journal of Australia*, Vol. I,
31st January, 1942, p. 131)

WHILE there are more than a few surgeons who complacently regard the result of their treatment of most diseases as satisfactory, probably none would dare to affirm that the immediate or late results of their treatment of other than the mildest of burns were such that further improvement was unlikely. The increased interest in the subject of burns now being displayed in England, as exemplified by the discussion at the Royal Society of Medicine, London, on 6th November, 1940, and the improved results which have followed and which will in the future undoubtedly follow this interest, are a few of the minor benefits which we may hopefully expect to derive from the present war.

Shock, toxæmia and sepsis

The three well-known factors responsible for the fatalities accompanying burns are shock, toxæmia and sepsis. The last-mentioned is often quite obviously due to hæmolytic streptococci; but as to the causes of the other two, shock and toxæmia, while there are many theories, no agreement has yet been reached. The application of coagulants to burnt surfaces was

certainly a notable advance in the treatment of burns. This method was introduced to lessen the dangers of the triad shock, toxæmia and sepsis, and except in certain situations and types of burns in which its use is ineffectual or dangerous this type of treatment relieves pain, lessens the exudation of fluid, decreases the autolysis of the tissues and produces conditions inimical to the growth of bacteria. Morphine and warmth are the essentials in the treatment of primary shock, whereas in secondary shock, since the most potent factor in its causation is the great loss of plasma from the burnt surfaces and into the tissues (the latter being the more important of the two), intravenous administration of plasma or serum is indicated in order to raise the plasma osmotic pressure, to maintain the normal distribution of fluid between the blood and the tissues and to reduce the hæmoconcentration of the blood.

Wilson found a lowering of the serum sodium level during secondary shock following burns, and treatment with desoxycorticosterone acetate tended to elevate the serum sodium level, with coincident improvement of the patient's clinical condition. Wilson therefore recommended the use of this drug in addition to plasma transfusions in the treatment of severe shock. The use of the 'B.L.B.' mask to attain a high alveolar oxygen tension has helped to lessen the mortality rate from shock and to reduce the incidence of fat embolism (quite a frequent occurrence in fatal cases of burns). This high alveolar oxygen tension is also of importance if in addition to the burn there is an associated 'blast lung'. Glucose infusions, even in large quantities, scarcely affect the hæmoconcentration and are indicated only to protect the liver during severe toxæmia. Even then, only small quantities should be used. Aldrich suggested that the acute toxæmia of burns was due to infection by streptococci; but while infection undoubtedly frequently plays a part in the production of the toxæmia of burns in the majority of cases, there are some cases in which the toxæmia develops in the absence of infection. According to Wilson, the hypothesis of absorption of autolytic products from the burnt area is not proven. The most serious objection to it is that completely aseptic autolysis does not produce potent toxins. Although the toxæmia of burns, when fatal, is always accompanied by bacterial infection, yet liver lesions such as are found in these fatal cases of burns are never produced by common bacterial infections, even of the most severe type. It may be, however, that infection and absorption together result in the production of the toxæmia. The coagulation of the surface of the burn definitely inhibits the growth of the organisms and diminishes the absorption from the burnt area, and should therefore be doubly effective in lessening toxæmia. If a serious attempt is to be made to reduce the incidence of sepsis in burns, the burnt area should be treated by the same careful aseptic routine method, both for the first and for later dressings, as an ordinary wound would be.

Treatment

Professor McIndoe has pointed out that coagulation therapy has often been used in cases in which it is unavarranted or in which it is definitely contra-indicated. The production of a coagulum over a burnt area has been likened by Hudson to primary suture of a surgical wound without drainage, and therefore such treatment should not be used indiscriminately. When the burn is of only the first or the second degree, the method of coagulation gives excellent results provided that sepsis can be excluded. In cases in which the loss of skin is of the third degree (that is, full thickness), it is impossible to coagulate the whole burnt area and sepsis inevitably occurs beneath the superficial coagulated layer. Thus, instead of being extinguished, the septic process may be considerably enhanced with the result that months may elapse before the slough separates. Even then, healing is painful and accompanied by dense scarring, anæmia and general debility of the patient. Localized third

degree burns are probably best treated, in the light of present knowledge, by immediate excision and grafting. If they are too extensive for excision, the best treatment then available is either the recently described envelope method or the use of saline baths and saline dressings, followed in each case by grafting. In this war most of the burns have been on the exposed parts of the body (the hands and the face), areas usually unsuitable for coagulation therapy. Because the tannic acid jellies when used at the first-aid posts are often applied hurriedly and inadequately over unclean burnt surfaces without any consideration of the depth of the burn, McIndoe recommends a simpler application, such as gentian violet jelly, with which it is usually possible later to determine the depth of the burn. An Emergency Medical Services memorandum issued by the Medical Research Council of the Privy Council suggests that after being cleansed and dried the burnt area should be dusted with sulphanilamide before the coagulant is applied. After the use of tannic acid preparations as the final dressing in special situations, such as on the hands, movement of the fingers may be limited for months and pressure effects may develop. As McIndoe pointed out, the oedema developing beneath the coagulum as a result of the burn immobilizes the tendon sheaths very early and is a definite factor in causing fixation of the joints. Sepsis, when present, further increases the oedema. The pressure effect is also intensified by the fixed encrusted tan which does not yield with the increase in size of the part. Embarrassment of the circulation of the fingers leads to crippling deformities, such as spindle fingers, partial necrosis or even partial loss of digits. A common complication is pressure necrosis of the tissues overlying the proximal interphalangeal joints with perforation into the joints. The final result is then a fixed, clawed, useless hand. Such a chain of events may happen with a burn of the second degree if it is converted into a third degree burn by necrosis. On the eyelids, if the burn is of the third degree, and unless grafting is carried out early, sepsis is inevitable, with rapidly developing ectropion and exposure of the globe, corneal ulceration and perforation beneath the coagulum.

For the first-aid treatment of burns Wakeley favours gentian violet jelly with merthiolate (1 in 5,000). This may be dispensed in a collapsible tube and is therefore unlikely to be spoilt by water, oil, grease, *et cetera*. Being an efficient antiseptic, it has the advantage that it may be temporarily applied to the burnt area without any cleansing, as may be necessary during the stress of battle. It is also painless, soothing and effective. As a coagulating agent the aqueous solution of tannic acid has been almost completely replaced by such combinations as gentian violet (1 per cent), silver nitrate (10 per cent) and tannic acid (15 per cent). Triple dye, which is a solution containing 1 per cent (or 2 per cent) of gentian violet, 1 per cent of brilliant green and 0.1 per cent of neutral acriflavine, is sprayed or painted on the injured surface after cleansing with saline solution and excision of all blistered and dead epidermis. Ether soap should be used for cleansing the burnt area only when an oily or greasy application has been used as the first-aid dressing. At all times it is important that the body of the burnt patient is not unduly exposed during the cleansing and dressing of his burns. This especially applies to the patient on whom it is necessary to use ether soap during the cleansing of the burn. It is said that two or three applications of triple dye will result in a nice, thin, supple tan; but it is sometimes found that several applications are necessary before a suitable tan is acquired. If, as sometimes happens, sepsis appears at the edge of the triple dye tan, cleansing and retanning under anaesthesia are sometimes recommended; but the application of saline dressings over paraffin-impregnated net and grafting later are usually to be preferred, for the burn by the time sepsis develops has become of the third degree. Many authors who advocate the use of triple dye seem to have overlooked the occurrence of infection

beneath the tan; but there is no doubt that in insufficiently cleansed areas it happens frequently. For the late after-treatment of burns, Wakeley suggests that lanolin be rubbed into the healed surface each day for at least six weeks. This massage is said to result in a skin which is more supple and more vascular. In the *Medical Journal of Australia* of 25th October, 1941, de Vidas and McEachern reported the use of a tannic acid jelly containing 7.5 per cent of sulphanilamide. They found that the absorption of the sulphanilamide continued until the coagulum of the tannic acid formed, after which absorption ceased. These results, when translated to the probable absorption of autolysed tissue products, would confirm the advisability of producing a tan whenever possible. Robson and Wallace have recently described the good results obtained with a glycerine-sulphonamide paste containing 'Albucid', glycerine, kaolin and cod-liver oil for local application to burns of the hands and face. On theoretical grounds its use should be attended by good results, and further trial of this paste is indicated. In the treatment of burns of the hands and parts subjected to pressure, good results have followed the use of a single application of triple dye after the burnt area has been cleansed with saline solution, then dried and coated with a layer of flavine emulsion (Australian Pharmaceutical Formulary) about an eighth of an inch thick, the entire part being covered with a bandage which is left undisturbed for seven days. On removal of the dressing after this time, if the wound is not healed the dressing is repeated.

From a consideration of the factors essential in the healing of wounds in general and of burns in particular, Bunyan has evolved a method of treatment of burns which consists of intermittent irrigation with weak solutions of electrolytic hypochlorites. The advantages of these solutions are: (i) their selective action dissolves the dead tissue and stimulates healing tissues; (ii) the breakdown products are salt and oxygen; (iii) the bactericidal powers are great in non-irritant concentrations; (iv) stock solutions are stable and of constant strength; (v) pain is relieved and desensitization is obtained. The method of treatment described by Bunyan consists of hosing down the burnt area with a 5 per cent solution of electrolytic hypochlorites to remove all surface contamination, much of the charred tissue and all the exudates, and to kill most of the bacteria present. A special envelope (Bunyan Standard) is then applied to the part for purposes of irrigation. These envelopes are made of fine silk coated with synthetic resins; they have an inlet and an outlet, and the open end of the envelope may be sealed around the part by adhesive silk, strapping and rubber or pneumatic bands. Bunyan has used various sized envelopes up to those enclosing the body and limbs. Irrigation with 2.5 per cent hypochlorite solution is carried out for twenty minutes three times per day until the infection is overcome, and then twice a day. When necessary, the part may be dried by blowing warm air or oxygen through the envelope. The envelope is left in place until epithelialization is complete. One of the advantages of the method is that the silk of the envelopes is transparent and the process of healing can be followed throughout its course. This method of treatment is also applicable to cases in which extensive burns coexist with compound fractures or multiple wounds. Since his original paper Bunyan has again discussed this method, and up to that time he had satisfactorily treated 200 patients.

In third degree burns the method of soaking off slough by saline packs or by repeated or continuous saline baths produces a clean, granulating surface much more quickly than does the coagulation method. Saline baths for the whole body are useful for extensive mixed second and third degree burns. In the Royal Navy it has been noticed that those men suffering from burns who have been immersed in the sea suffer less pain and shock than would have been expected. The saline bath apparently exerts its beneficial effects whether intended or enforced.

The sulphonamides

The question of the prophylactic use of the sulphonamides in the treatment of burns has recently received attention. Although this treatment may have little effect on the local septic process, it has been recommended as a protection against the dangers of septicaemia and pyaemia. Bunyan is of the opinion that chemotherapy is usually unnecessary when the envelope method is used, because of the disinfection and the actual prevention of toxæmia and secondary infection by this method. Wakeley also thinks that the sulphonamides are rarely necessary in the treatment of burns, and points out that any vomiting induced by the drugs would further impair the patient's fluid balance. Colebrook differs from these surgeons, for he thinks that there is great benefit to be derived from the local application of the sulphonamides, either as a powder or in some form of paste. In my limited experience it has been found that the local application of sulphanilamide to infected second degree burns was of use only in those cases in which the formation of pus or the exudation of fluid was limited in amount before the drug was applied. If the pus formation or the exudation of fluid was large in amount, eusol or saline pads gave better results than sulphanilamide powder.

Burns due to chemicals

Special treatment is required for burns due to chemicals. For burns due to phosphorus one application of a 2.5 per cent aqueous solution of copper sulphate followed by drying of the burnt area and then tanning with triple dye is recommended. In the absence of such treatment these burns are apt to become deeper as the phosphorus continues its thermal action on the tissues.

First Aid Teaching Technique

By C. J. POTTHOFF, M.D.

(From the *Journal of the American Medical Association*, Vol. CXVII, 25th October, 1941, p. 1417)

PRESENT-DAY warfare, with participation by the entire population in the defence and offence effort, necessitates training of the whole population, each segment for its duties. Into the public mind to-day the need for preparation is being instilled, and much thought is being given to devising the direction and method of training. If the whole population is to be trained for the emergencies of war, one of the first objectives will be the training in methods of first aid. In Britain such training has formed an important aspect of defence work. In this country the American Red Cross is even now extending its first aid programme; plans call for an immense expansion of this training.

Without doubt, physicians will play an important part in the local programmes. Red Cross units commonly have physicians among their directors and look to them for guidance in phases of activity related to health work. Whether he has a hand in directing the local programme or whether he actually does the teaching, the physician may find himself in a rôle which he does not ordinarily have, that of participating in classroom teaching. Because of his long experience as a student, as a teacher of the individual patient and perhaps as a public speaker, he will have many qualifications valuable for classroom teaching. Nevertheless such teaching is a specialized procedure, requiring study and practice for mastery, and the physician who is equipped with and applies knowledge of good educational methods should represent the best first aid teacher.

It is possible that some of the training of the physician may condition him unfavourably for certain aspects of first aid teaching. Because of his own experiences, he may rate the pupils too high on the basis of background information and ability to understand explanations and to memorize. Even when warned and wary of dangers, mistakes may occur. In one class, after the topic of broken bones had been

considered, one pupil asked 'Now that we have studied about first aid for broken bones, won't you tell us how to take care of fractures?' This pupil was a college student! On another occasion a pupil asked 'Will digital pressure, applied to the right arm, stop bleeding in the left arm?' The right arm had been used in the class demonstration. Just as the first aider should 'splint 'em where they lie', so the instructor must 'know the pupils'. The beginning instructor almost invariably overrates the pupils as students.

The approach to becoming a good local adviser or teacher in this programme entails (1) acquisition of organized knowledge relating to accident prevention, (2) acquisition of knowledge concerning good first aid procedure, (3) acquisition of knowledge concerning what the public is being taught generally in first aid classes and (4) acquisition of knowledge concerning methods in first aid teaching. Usually first aid courses consider accidents common to civilian life, using the American Red Cross First Aid Textbook. It may be that soon instructors will be provided with additional material based on the experiences in Europe and that thus the course may include topics pertaining especially to prevention and first aid care of disabilities common to warfare. The Red Cross textbook, written with the collaboration of medical men eminent in their respective fields, is exceptionally good. It gives in simple language information concerning accident prevention and first aid procedures. It is not written primarily as a textbook for physicians but rather for lay people. It considers cognitive levels and assimilative abilities of these people.

The Red Cross also issues an instructor's manual. This book is based on the large body of experience of the national organization in first aid procedures and

Fig. 1.

A, fracture of elbow with arm straight; B, fracture of femur without traction.

teaching. It allocates the ground to be covered in each lecture, gives lesson plans and suggestions for class management and lists mistakes commonly made by the novice instructor.

During recent years, many lay persons having been trained in first aid, it has been possible to study the effects of first aid teaching, to ascertain whether accidents are reduced, whether graduates do good first aid work and what is the nature of the mistakes made by graduates in their first aid efforts. Conclusions can thus be drawn concerning the improvement of first aid courses.

Many studies show beyond reasonable doubt that first aid training represents an effective way to reduce accidents. Accident prevention is a major objective of first aid training; it is not a will-o'-the-wisp objective but rather one which the instructor may with confidence expect to attain. The trained first aider also handles accidents better than does the non-trained person. Physicians may smile occasionally at the work of first aiders, but by and large the trained person does good work when compared with that of the untrained. And course graduates also commonly have an improved attitude concerning matters of general health.

While the trained lay person does improved work, mistakes are occasionally made. Such mistakes include the following:—

1. He is overwhelmed by the scene of the accident, modifying learned methods to the detriment of the victim's interests.

2. He fails to examine carefully.

3. When the victim has several injuries, the first aider pays attention only to the worst one.

4. He uses splints that are too short.

5. He gambles that the injury is a sprain rather than a fracture.

6. He is too free with the application of a tourniquet.

7. He handles burns poorly.

8. He applies artificial respiration when he should not do so.

9. He does not organize his first aid efforts efficiently and thus copes poorly with shock.

These mistakes suggest three avenues toward improvement of first aid teaching: better preparation of the pupils concerning general difficulties faced at the scene of an accident; presentation in succinct form of essentials for care of each accident type, with emphasis thereon rather than on details; provision in the home and automobile of splints and bandage material of adequate size for coping with major accidents.

In preparing the first aid course, it is necessary to plan for the entire course rather than for the isolated lecture. The subject-matter we want to teach must be specifically defined; then such subject-matter objectives must be weighed against the pupils' abilities to learn in the allotted time. One cannot teach nearly everything one may want to teach; the subject-matter must be ruthlessly slashed perhaps, for only the most important can be considered. But the total usable learning is increased through the indelible imprinting of the essential. These most important facets should be presented in brief form with crystal clarity; they should be emphasized again and again. Before a class, the instructor should have in mind the things he expects to emphasize specifically; thus 'To-day I will clinch the idea that accident victims must be carefully examined', or 'To-day, in considering first aid for concussion, I am going to drive home the idea that victims must be kept quiet'. The instructor will keep to his outline and to his sequence and not be diverted into a morass of side aspects. The physician knows so much, he has had so many interesting experiences, that it becomes easy for him to overflow the banks of the essentials. Eliminating consideration of aspects fairly but not essentially important is like pulling teeth; but it must be done often in first aid teaching for the lay public if the heart of the topic is to be presented emphatically.

In preparing the pupils for the scene of the accident it is important that they visualize the difficulties and common mistakes of the first aider. The lecture which treats of this topic and imparts general rules applicable in any accident is no doubt the most important one in the entire course.

To appreciate the difficulty of preparing an effective lecture on this topic, one which will in the dim future result in a good first aid job, one need only reflect on the teaching task. Ordinarily the students in the course are not conditioned to sweat in study. They expect the facts to come in gently. Yet it is the teacher's responsibility to face the teaching situation. The course is usually of only twenty hours, and there is much ground to be covered. Much of the time must be spent in doing first aid practice procedures, so that only part of the time can be devoted to lectures. Yet, despite possible deficiencies of the pupil in ability, motivation and time, this pupil must remember—if the teaching is to be effective—material for an accident, which may not occur for many years. There are many kinds of accidents, but the student must remember what to do for the one which, unheralded, occurs. Meanwhile he has seldom had time for review.

Then, when the accident occurs, this pupil is in a new situation, a dramatic one perhaps. He does not

have an opportunity at this time to sit down and cogitate about the whole matter in peace and quiet. He may be deluged by the enormity of the harm, by the presence of death, by the onlookers, hysterical relatives, injured victims, importunate bystanders. Necessary apparatus, prepared or improvised, may be difficult to obtain. Zero weather, heavy rainfall or concomitant traffic may in effect represent forces which nullify all the teaching. And so he may regard the accident he meets as different from any studied or, while knowing what is correct procedure, surrender to the exigencies of the occasion and give poor first aid.

Attention may then well be directed at the following:—

1. Every accident seems different, unique. The general rules should be followed unless one is positive that modification is indicated. The student who knows the common mistakes of the first aider is fortified against making them himself.

2. A careful examination is very important. The first aider is strongly tempted to give only a superficial examination, to hurry through it. A good examination requires deliberation, time, tact.

3. In the presence of serious injuries, other injuries should be searched for and, if present, treated with care.

4. There is tremendous pressure, at the time of a serious accident, that something be done. Doing nothing other than keeping the victim quiet and warm for the time being is often the indicated procedure, but such action is most difficult. The victim and the onlookers interpret this deliberation as a sign that the first aider does not know what to do. Physicians, police and firemen in first aid work subscribe to the statement that this great importunity exists at the scene of the accident.

5. Advice from bystanders is often confusing, occasionally commanding. The first aider, recalling only tenuously what is right, may easily be swayed by others.

6. The drunken are usually hard to handle when injured; they are especially likely to be hysterical, often claim to be hurt far worse than they really are. Yet drunkards are often involved in accidents, may be seriously injured; hence the first aider can take no chances and must be persistent in his examination. Some people seem to feel that a drunkard has forfeited the right to receive good first aid.

7. Very often it is wise to call a physician to the accident scene. Permission of the victim or of a responsible person should first be secured, if possible. In all serious accidents, the first aider should consider carefully this possibility of getting a physician to the scene of the accident.

Students occasionally do not learn clearly some of the first aid procedures. In the flood of details presented to them, they do not see the principles of care. The instructor should think of (1) imparting the facts and (2) having the students bring the facts back to him. Thus they learn better, for they must do the stating and must participate; they secure repetition through the process and learn of their own deficiencies. The instructor learns of their misconceptions and finds where his teaching has fallen short. The Red Cross textbook has more than 250 pages; the material in it will not be uniformly well remembered through the years. If the teacher considers carefully every paragraph, he will not gain emphasis; he will fail to impress the essentials indelibly. It is easy to get far too much detail, to lose perspective view. The teaching should conform to the practical situation and the teacher bear in mind the weighting of topics and be guided by subject-matter, pupils, objectives.

Let us take the case of fracture care. There are more than two hundred bones in the body. One cannot reasonably expect that students will remember through the years the ideal splint for each type of fracture considered in the textbook. Yet teachers occasionally spend time to no real purpose on requiring the memorization of such terms as femur, humerus and vertebra. The student should understand thoroughly the idea in splinting: to keep the broken ends quiet.

He should understand thoroughly the treatment of shock and the factors that increase shock. For emphasis the following suggestions may be stressed:—

1. Don't let the broken ends move.
2. Treat shock.
3. Treat every possible fracture as a fracture.

A general rule for splinting is that the splints should extend well beyond the joints adjacent to the fracture. For purposes of lay education, one may state that by and large a splint can hardly be too long except it becomes unwieldy. A heavy splint, poorly attached, may contribute more to shock than a light one so placed. Students should have considerable practice in applying splints so that they learn to organize, prepare and expedite their efforts and to apply them well. They must learn how to transport a victim a few feet, if such is necessary in order, for instance, to escape traffic. They must get practical help concerning improvisations. Too often recommendations are impractical to the scene of the accident. The first aider may find that raw material for improvisations may not be as easy to find as he had thought, for he may encounter his accident in heavy rainfall, darkness or bitterly cold weather. Under these circumstances, if he spends time looking for fallen boughs, fence posts, or random boards, the victim may sink into deep shock. It is exceedingly important that the teaching recommendations foresee the practical situation.

I have used the accompanying diagrams in summarizing where splints should be placed and I ask students to repeat the drawings after they study the textbook.

The students are commonly surprised that the learning on this aspect becomes easy through the method used. Concerning back injuries, the students should know the implications of spinal cord injury; they should know of the insidiousness, as far as history, symptoms and signs are concerned, of this type of injury. Certainly first aid for fractures of the neck should be rendered by a physician called to the scene of the accident.

Head injuries and cerebral circulatory accidents are often encountered. Almost 50 per cent of fatal traffic accidents show concussion as the cause of death, according to National Safety Council reports. Whether concussion or stroke, the victim should be kept quiet. The care may be outlined as follows:—

1. Keep the victim quiet.
2. Elevate his head somewhat if the face is red; keep it level if the face is pale.
3. Give the victim no stimulants.
4. Apply an ice cap, if available, to the head.

It is important to consider drunkenness in connection with head injuries. Often the drunkard is the victim of an accident and the injury is dismissed. The textbook discussion on this point is good.

Criticism has repeatedly been directed against various aspects of teaching on the topic of artificial respiration. Many misconceptions concerning theory are held. Henderson and Turner, in a recent issue of *The Journal*, consider physiology and methods, their article being based on much research work. This article should be read by all first aid instructors. Many instructors insist on meticulous observation of minor points in administering artificial respiration. Clearly, the following points should be emphasized:—

1. Get started at once.
2. Compress the chest and release twelve to fifteen times a minute.
3. Treat shock.
4. Keep the victim quiet after he starts breathing.

The student should know of the precious time interval between cessation of breathing and cessation of heart action. He should therefore know of the great need for starting artificial respiration at once. Though the prone pressure method is used ordinarily, it is occasionally impossible to straddle the victim. The student should understand the idea so that he will start artificial respiration in a boat or wherever he finds the victim.

The student should know when the method is useful. Occasionally instructors state that the

procedure should be followed any time a victim is not breathing. Hence first aiders are giving artificial respiration to victims of stroke, of concussion and even of infectious disease. The argument favouring such teaching is as follows: If a victim is not breathing, artificial respiration cannot be harmful, though it may be useless. One cannot expect the average person to remember a series of indications for its use; but if this person is taught to use the method any time a victim is not breathing, he will remember such a simple rule well.

The argument fails to consider the commonest mistake of the first aider. In his excitement he administers the prone pressure method to victims who are unconscious but breathing. Such cases often represent stroke, concussion or injury to the visceral system. The procedure of artificial respiration here may represent the finishing coup; it is definitely dangerous. During the past year I have seen two cases in which prone pressure method was being used on victims of stroke. These injuries are very common, and if the first aider gives artificial respiration to every victim of stroke or concussion he sees he may be responsible for more dire results than the good which follows use of the method wisely. Hence students must learn when artificial respiration is to be used.

The technique of the prone pressure method requires practice for good administration. The beginning instructor should be coached in the technique by an experienced operator. Otherwise, while he may get a good exchange of air, he may fail as a teacher in being awkward or singularly atypical in method.

In consideration of shock, the important thing is the prevention and the treatment. One may require the students to memorize thoroughly the symptoms and signs. Time devoted to one facet is obtained at the expense of time devoted elsewhere. Aside from modification of treatment with certain injuries, such as concussion and heat stroke, all accident victims should be treated through (1) heat, (2) position, (3) stimulants. The revised edition of the Red Cross textbook presents in improved fashion the first aid handling of burns. Perhaps one may look forward to better work on the part of graduates of the course in this type of accident.

The preceding paragraphs indicate the method of analysing the subject-matter in order to emphasize the heart of the topic, in order to gain emphasis. The main points should be clinched.

In order to apply methods learned, the first aider must have materials at the scene of the accident. Observation shows that in a proportion of cases graduates do not improvise material. The difficulties they feel are overbalanced by other factors. First aid kits provide a partial answer, but they are inadequate when the accident is a major one. They ought to be in each home and each automobile. But there should also be available in each automobile a few splints, at least six large triangular bandages, a flashlight and a jack knife. These can readily be provided and carried; certainly they can be provided more easily before than at the accident. If they are present, they will likely be used. If not present, the likelihood of transfer of the patient without splinting is greater. A film, sponsored by many medical societies and dealing with fracture care, has been widely shown to the public. This film demonstrates only the Thomas splint. But how often is the Thomas splint available at the scene of the accident? The real situation has again not been visualized. How may the situation be remedied? The answer is very simple: Have the pupils while enrolled in the course prepare the material for their own cars and homes. They can cut notches in the splints in such manner that traction splinting is possible. By teaching first aid, the teacher acknowledges its importance; he therefore is consistent when he insures application through providing necessary materials.

After the text work has been completed, a valuable teaching technique is to present hypothetical accident situations to the class, letting it work out procedures on designated victims. The pupils thus learn well the difficulties and factors to consider and also to organize

their efforts. Even medical students, segregated into groups of two or three, find difficulty in planning first aid procedures for such a simple matter as splinting an ankle.

Films ought to represent an exceptionally valuable teaching aid. From them students might visualize well the scene of the accident, the discouraging aspects for good first aid, the difficulty of going ahead in a planned way and the common mistakes made. Unfortunately,

available films omit particularly the aspects one would like to see. Sometimes significant omissions occur. Thus a film which suggests use of iodine on cuts ought to present some cautions when the lay public is being taught. Surgeons, when previewing films, commonly raise valid objections. However, better films will doubtless be prepared. The makers should have knowledge of the actual accident situation and experience in teaching first aid.

Reviews

TEXTBOOK OF MEDICAL TREATMENT.—By Various Authors. Edited by D. M. Dunlop, B.A. (Oxon.), M.D., F.R.C.P. (Edin.), L. S. P. Davidson, B.A. (Camb.), M.D., F.R.C.P. (Edin.), F.R.C.P. (Lond.), and J. W. McNee, D.S.O., D.Sc., M.D. (Glas.), F.R.C.P. (Lond.). Second Edition. 1942. E. and S. Livingstone, Edinburgh. Pp. xxiv plus 1179. Price, 25s.; postage, 9d.

It does not seem very long ago that the reviewer received the first edition of this book for review. Since then he has used it as a reference book and has seldom found it wanting. In the second edition, there has been a certain amount of addition in all the sections, but it does not in any way alter the character of the book. Many minor defects have also been remedied. The sections referring to tropical diseases are probably the best that have ever appeared in a book on general medicine. The accounts given of the treatment of sprue, cholera and dysenteries are excellent. The same can be said about the section on malaria which gives the names of all the more up-to-date synthetic substitutes for the German antimalarial drugs which were mentioned in the previous edition.

We had one or two criticisms to make on the first edition and there are still some that are applicable to this edition. Col. Gregg still remains loyal to his old colleague, and places thymol first as an anti-helminthic in the treatment of ancylostomiasis. It is quite true that some past helminthologists who had had vast experience recommended this drug, but time has moved on and I know no practising helminthologist of any reputation who would recommend its use now, except as an experiment to convince the die-hards. Loyalty to his country has also made this writer omit the most valuable antimony drug that has ever been used in the treatment of kala-azar, namely neostibosan; he has replaced it by anthiomaline, a drug which has been used in some half a dozen cases with apparently very indifferent results, but is marketed by a British firm. He has also mentioned the new drug, diamidino stilbene. His directions for dosage are not however very helpful. The total dosage which he recommends is 360 mgm. which is totally inadequate for an adult and the dose is recommended for a child in the publication from which he has obviously obtained this figure.

The student, and for that matter the practitioner, can purchase this book with confidence that he is getting almost the best possible value for his money.

A MONOGRAPH ON ADOLESCENT SPONDYLITIS OR ANKYLOSING SPONDYLITIS: THE EARLY DIAGNOSIS AND ITS TREATMENT BY WIDE-FIELD X-RAY IRRADIATION.—By S. Gilbert Scott, M.R.C.S., L.R.C.P., F.F.R., D.M.R.E. (Camb.). 1942. Oxford University Press, London. Humphrey Milford. Pp. xiv plus 132. Illustrated. Price, 5s. Obtainable from Oxford University Press, Bombay and Calcutta

HERE is an important work which should be read by all practitioners. It would appear from the author's investigation that what has hitherto been looked upon as an incurable and crippling disease can now be diagnosed in its early stages, provided the rule is observed that 'all patients under 25 years of age with

rheumatic symptoms should be referred to the x-ray department for an examination of the sacro-iliac joints'. If the patient is then submitted to the recommended form of treatment by 'wide-field x-ray therapy' there is nearly a 100 per cent chance of cure. Even in the more advanced stages of the disease some palliative effect is to be expected from this form of treatment.

The pathology of adolescent spondylitis needs further investigation as does the possibility of using wide-field x-ray therapy in other diseases where its principle of having 'a remarkable stimulating or constitutional influence on the whole body, the final result being a raising of the general resistance' whereby the patient is placed 'in a position to cure himself, irrespective of the disease from which he is suffering'.

This is an Oxford medical publication of 132 pages. While realizing the author's endeavour to stress the importance of his work one feels that the subject-matter could well have been reduced—thereby saving much repetition and paper. The book is well set up and the radiographic plates are excellent.

G. C. T.

THE AUTONOMIC NERVOUS SYSTEM: ANATOMY, PHYSIOLOGY AND SURGICAL APPLICATION.—By James C. White, M.D., and Reginald H. Smithwick, M.D. Second Edition. 1942. Henry Kimpton, London. Pp. xx plus 469. Illustrated. Price, 35s.

IN this book, the authors have succeeded in presenting a readable account of surgery applied to the autonomic nervous system as it stands to-day. Fact and theory regarding the subject are collected here in an orderly way and are critically reviewed in the light of the authors' extensive experience at the Massachusetts General Hospital. Professor Cannon and others of the Harvard School have been called on to collaborate in part I which deals with physiology and anatomy. Part II discusses the ways in which it is possible to modify abnormal activity of smooth muscle and glands by interference with their autonomic nerves. The conditions are indicated in which it is now known that sympathectomy is of value and those in which it is definitely not.

It is a pity that the authors confessedly did not make any special effort to discuss diagnosis and one feels that the 'medical' aspects could have been given more attention with advantage. The operative treatment, however, of hypertension is well done and one learns that 'significant effect has followed thoracico-lumbar sympathectomy in 65 per cent of cases in a short series of cases followed up for two years'. Part III describes details of operative technique. The illustrations make the points intended but the judicious use of colour would have improved them. This section is as good as one would expect from men who have done much to advance the subject. A large number of references are supplied up to and including part of 1941. One need look no further for a good up-to-date account of the autonomic nervous system for here it is predigested, palatable and easily assimilable.

E. D. M.

ACUTE INJURIES OF THE HEAD: THEIR DIAGNOSIS, TREATMENT, COMPLICATIONS AND SEQUELS.—By G. F. Rowbotham, B.Sc. (Manch.), F.R.C.S. (Eng.). 1942. E. and S. Livingstone, Edinburgh. Pp. xii plus 288, with 124 illustrations, 12 in full colour. Price, 25s.; postage, 7d.

In the space of under three hundred pages this book deals with a subject which at present is of extreme importance to all surgeons. Many will have felt the need of a handy textbook by a good man describing the essentials in the diagnosis and treatment of acute head injury in a clear and practical fashion. The author wrote this book primarily for those faced with acute cerebral trauma who had not had a special training in neurology or neurosurgery and he has been extremely successful in this object.

Every aspect is adequately described. Chapter 3 on the diagnosis and chapter 4 on the treatment of closed head injuries are right up-to-date and beyond criticism. The sequels of injuries of the head are well done in chapter 7 and it would be well if all young physicians and surgeons were to read this section as it is an excellent summary of conditions which are and will be so common in this war and afterwards. The author also shows considerable understanding of the problems in psychiatry, psychoneurosis and malingering associated with these cases.

The author tells us that the script was submitted to Dr. F. M. R. Walshe and Mr. Norman Dott. No doubt the helpful advice, acknowledged in the preface, of these men in the top flight of neurology and neurosurgery has been of value in producing a book which is of first class value in raising the general standard of treatment of these cases.

G. C. T.

THE ART OF LOVE AND SANE SEX LIVING (BASED ON ANCIENT PRECEPTS AND MODERN TEACHINGS).—By A. P. Pillay, O.B.E., M.B., B.S. D. B. Taraporevala Sons and Company, Bombay. Pp. xxiv plus 530, with 80 illustrations and 92 photographs (81 photos, specially taken for this book by Dr. S. H. Marathe, M.B., B.S.). Price, Rs. 10

This is notoriously a difficult chapter for any author to open, that upon sex relationships, marriage and marital relationships, and it may be said that Dr. Pillay is the first Indian author to offer so comprehensive a work to the 'educated layman' for whom, in the preface, it is stated that the book is designed.

The text covers a very wide field including the anatomy and physiology of the sex organs, disorders

of menstruation and pregnancy, sterility and control of conception. This last-mentioned subject is one of the best treated in the book and for those who are interested in it, the book is well worth buying on that account alone.

Chapter XII, which deals with the legal aspects of marriage and sex, offers new material of great interest to the Indian family, as also does the chapter on physical exercise for men and women which is illustrated by photographs.

Throughout, the book is clearly prepared for the Indian reader; there are profuse quotations from Sanskrit and Persian writings, as well as from modern authors such as Havelock Ellis, Freud and Dickinson.

The author states that, among his friends, opinion was divided upon whether the treatment of some aspects was not too frank. Perhaps the omission of chapter XI, which deals with the deviations of the normal sexual instinct much in the manner of German authors, would not have affected the book adversely.

L. G.

ILLUSTRATIONS OF BANDAGING AND FIRST-AID.—Compiled by Lois Oakes, S.R.N., D.N. (Leeds and London). Second Edition. 1942. E. and S. Livingstone, Edinburgh. Pp. vii plus 256. Illustrated with 300 photographs. Price—De Luxe Edition, 6s.; Cheap Papered Edition, 4s. 6d.; postage, 6d.

This book provides an easily comprehended and accurate guide to bandaging for both the 'first-aid' and the hospital worker. The practical photographs are supported by simple notes which are sufficient in themselves to render the intelligent learner proficient, even in the absence of a demonstrator.

D. E. C.

HANDBOOK OF HYGIENE FOR STUDENTS AND PRACTITIONERS OF MEDICINE.—By Joseph W. Bigger, M.D., Sc.D., F.R.C.P.I., M.R.C.P. (Lond.), D.P.H., M.R.I.A. Second Edition. 1941. Baillière, Tindall and Cox, London. Pp. xii plus 414 with 18 illustrations including one plate. Price, 12s. 6d.

This handbook provides in a small compass much useful and up-to-date information on hygiene and is very well written. It will be read with profit not only by the ordinary medical student but will also supply useful information to those who are specializing in public health. A second edition in four years shows that it has gained popularity which it certainly deserves.

Abstracts from Reports

ANNUAL REPORT OF THE CHEMICAL EXAMINER TO GOVERNMENT, UNITED PROVINCES AND CENTRAL PROVINCES, FOR THE YEAR 1941

The total number of cases examined during the year was 3,793 comprising 8,574 exhibits as compared with 3,569 cases consisting of 8,607 articles during the preceding year.

One thousand, four hundred and thirty medico-legal cases and 5,079 articles were examined during the year under report as against 1,514 cases and 5,510 articles in 1940.

The total number of cases of human poisoning examined was 316. Poison was detected in 70.2 per cent of cases as against 68.4 per cent in 1940. Dhatura was again the most commonly used poison. It was detected in 33.5 per cent of the detected cases.

In 2.6 per cent of cases, unidentifiable organic poisons were found. This shows the need for research on the indigenous vegetable poisons.

Bones and ashes of 2 persons were received and examined during the year. Arsenic was found in one of the cases.

Twenty-three cases of animal poisoning were examined as compared with 22 cases for the preceding year. The percentage of detection in these cases was 69.6. Arsenic was detected in 11 of the cases.

One thousand and ninety-one stain cases were examined under this section comprising 822 cases of blood stains and 269 cases of blood and semen stains. The percentage of detection in blood stain cases (murder or hurt by violence) was 96.5 as compared with 96.6 for the year 1940. Spermatozoa were detected in 92.2 per cent of cases of sexual offences as against 89.3 for 1940.

Five hundred and fifty-two samples of opium were received in connection with illicit traffic. Of these samples 394 were found to be contraband or adulterated. In addition to the usual examinations, all the samples of opium had to be assayed for prosecution purposes under the Excise Act.

ANNUAL REPORT OF THE PREMANANDA FREE CHARITABLE OUTDOOR LEPRO DIS-PENSARIES FOR THE YEAR 1941

The year 1941 has seen certain important changes in the personnel of the committee of management and the medical staff.

The war has affected our work in various ways. It has increased the working expenses owing to the enhanced cost of essential drugs and other medical material and apparatus.

Another result of war conditions is seen in the falling off of the number of patients attending the Manicktola dispensary during the latter part of the year, amounting to about 50 per cent, though at the time of writing the numbers are showing a tendency to rise.

In addition to the regular medical work of the dispensaries we have been able to co-operate with the School of Tropical Medicine in making a full investigation of some hundreds of cases as a preliminary to preparing a case for the establishment of a Home or Colony to serve the needs of Calcutta, with which to approach Government, the Corporation, and the public generally in order to procure the necessary funds required to bring into existence an institution comparable to the Lady Willingdon Leper Settlement at Chingleput, Madras. Without this it is impossible to deal at all adequately with this very urgent problem.

Our work in the Kalighat district is still hampered by the lack of a suitable building but we have some hope of a suitable site being made available before long through the generosity of a landowner in that neighbourhood.

The total number of patients who attended for treatment during the year 1941 was 1,912 at Manicktola, and 676 at Kalighat. Last year's figures were 1,888 at Manicktola and 613 at Kalighat. Altogether they put in 41,047 attendances at Manicktola and 15,969 at Kalighat totalling 57,016. They received the following treatment: 37,204 anti-leprosy injections, 3,848 general treatment at Manicktola and 14,194 and 1,775 respectively at Kalighat. The average daily attendances were 162.8 at Manicktola and 105 at Kalighat.

Of these patients, 1,234 at Manicktola and 487 at Kalighat attended sufficiently regularly to justify re-examination at the end of the year. The following results were obtained:—

	Manicktola	Kalighat
Disease arrested ..	59	41
Much improved ..	351	155
Slightly improved ..	414	195
Same, as on admission ..	410	96

One member of our staff regularly visits the homes of patients who have discontinued their treatment at their own discretion. His duty is to persuade them to return to our clinics for treatment, to explain the serious nature of the disease and to advise them about the precautionary measures to be taken against the spread of the disease in the family. Altogether 391 homes were visited; 59 cases only came back for treatment and 36 cases gave wrong addresses, so afraid are they of being known to be lepers. During these visits 5 contact cases were found.

REPORT ON THE ADMINISTRATION OF THE EXCISE DEPARTMENT IN THE PRESIDENCY OF BENGAL FOR THE YEAR 1940-41

The total consumption of country spirit in the province was 717,129 L.P. gallons as compared with 661,650 L.P. gallons in the preceding year. There was a general increase in the consumption of country spirit throughout the province, excepting the district of

Bogra which showed a slight decline in consumption. The most noticeable instance of increase in consumption occurred in the district of Calcutta.

The total quantities of potable foreign liquor sold to the public in Bengal by licensed dealers were 147,391 gallons of spirits, 16,849 gallons of wines and 687,608 gallons of beer. This does not include medicated wines.

The total quantity of ganja consumed in the province during the year of report was 905 maunds 7 seers against 866 maunds 31 seers in the preceding year showing a net increase of 38 maunds 16 seers or 4.4 per cent. During the year 1,120 seers were sent to French Chandernagore as against 1,470 seers in 1939-40.

Three maunds 11 seers of ganja were issued at the concession rate of duty of Rs. 15 per seer for the manufacture of medicinal preparations by chemists against 2 maunds 5 seers in the previous year.

The demand for bhang was mostly confined to the West Bengal districts. In some of the districts in East and North Bengal, bhang grows wild. It is suspected that the major portion of consumption of bhang that exists in those districts is met from the illicit drug of wild growth. There has been a considerable decline in the use of bhang by village kabirajes. The total quantity of bhang consumed in the presidency amounted to 229 maunds 15 seers against 222 maunds 38 seers in the previous year, showing an increase of 6 maunds 17 seers or 2.8 per cent.

The total quantity of charas imported by the wholesale dealers at Birbhum and Calcutta was 21 maunds 38 seers 1 chittak against 21 maunds 1 seer 13 chittaks in the previous year, showing an increase of 36 seers 4 chittaks. The actual consumption in Calcutta amounted to 15 maunds 33 seers against 14 maunds 15 seers in the previous year, showing an increase of 1 maund 18 seers.

The consumption of excise opium during the year under report was 670 maunds 5 seers as compared with 655 maunds 28 seers of the previous year showing an increase of 14 maunds 17 seers or 2 per cent. There was general increase in the consumption of opium throughout the province except in certain parts where there was distress. Noticeable increase in consumption occurred in Calcutta, Midnapore and Bakarganj. The increase in consumption in Calcutta was chiefly due to the prevention of smuggling of opium from outside the province as a result of detection of some very important cases of opium smuggling which broke up some organized gangs of smugglers of considerable inter-provincial notoriety. Stricter control of the licensed shops also to some extent accounted for the increase in the licit sale of the drug.

The manufacturing chemists of Calcutta imported from Ghazipore opium factory 1,000 pounds of opium powder and 50 pounds of opium in cake and 72 pounds 11 ounces of morphia hydrochloride. The import of opium powder showed an increase of 647 pounds and that in cake showed a decrease of 25 pounds in comparison with the last year's figures.

There was no evidence of the use of cocaine as an intoxicant and the habit was unknown in almost all the districts except that its existence in a limited extent was reported from the districts of Calcutta and Dacca and in the mill areas of the 24-Parganas.

Four ounces of confiscated cocaine which were in stock and certified to be fit for use by the chemical examiner, were issued to the charitable dispensaries during the year under report.

JUVENILE JAIL, BAREILLY: CORRECTIONAL AND REHABILITATION WORK (1939, 1940 AND 1941). BY LIEUT.-COLONEL A. H. SHAIKH, I.M.S., INSPECTOR-GENERAL OF PRISONS, UNITED PROVINCES

Annual report.—This jail receives convicted juveniles from the other jails. There are no direct admissions from the courts.

Our general correctional programme came into existence on 1st January, 1939. On admission we give

affection and considerate treatment to our boys as much as it is expected in a well adjusted home.

After the boy gets settled down and feels at home, we try to get him interested in games and scouting.

After the games, we get him interested in work such as tailoring, carpentry, etc.

He is given the work of his choice. If he does not like to take up any of the outlets we have, his aptitude is studied and interest created for one of the outlets we have in the jail.

Lastly we get him interested in studies. There we do not find so much keenness as for the games and the work.

Out of the population of 182 boys we found 8 incapable of being educated and 10 required extra time and special attention to get through their texts. This gives a total of 18 retarded and defectives out of 182 which comes to almost 10 per cent.

As an aid to our correctional programme, we introduced the experiment of granting leave to the desirous and deserving inmates of this jail, in order to enable them to go home and spend a few days with their parents and other relations.

The experiment covers a period of two years and three months. During this period 36 boys have been on home leave. They all returned punctually to the jail at the expiry of their leave. There was no escape nor even an overstayal.

The present system of *rehabilitation* started on 1st June, 1939, and covers a period of two years and a half. The object is to inculcate in the youngsters a sense of social responsibility and a habit of work, and to enable them to equip themselves for an honest and decent living upon leaving the prison. The method consists in apprenticing the young offenders, while

serving the sentence, in a factory or an institution or under an employer of labour. When at work, there is no surveillance by the jail and the offender works side by side with the free labourer; goes there on his own, and returns to the jail in the evening after the day's work is over. The wages he earns are credited to him after making necessary deduction for food, etc.

A note on sex deviation

Review.—This report records that enquiries indicate that 30 per cent of the male population in a certain district have indulged at one time or another in homosexual practices, but the number of police arrests and convictions is only a few every year.

The author describes the phase of homosexual feeling through which most persons pass before puberty, and attributes the high incidence of homosexual practices to the lack of free association of the sexes.

In spite of the fact that persons guilty of such offences were not eligible for admission, examination of the inmates of the juvenile jail in 1939 revealed that 22 per cent had played a passive rôle in such practices. The number playing an active rôle was not known.

With the rehabilitation work the proportion of passive agents fell in 1940 to 11.5 per cent and in 1941 to 7 per cent. The chief changes instituted were the full occupation of the inmates from 5 a.m. to 9 p.m. and the removal of control exercised by boys over other boys, all authority being vested in the staff.

The author emphasizes the rarity of any serious results of masturbation, and also the fact that these results are produced by shame and fear rather than by the act itself.

Service Notes

APPOINTMENTS AND TRANSFERS

THE VICEROY AND GOVERNOR-GENERAL has been pleased to make the following appointments on His Excellency's personal staff with effect from the dates stated :—

To be Honorary Surgeon

Colonel W. C. Spackman, *vice* Colonel H. E. Shortt, C.I.E., vacated, 23rd August, 1941.

On re-employment Colonel J. J. Harper Nelson, O.B.E., C.I.E., M.C., I.M.S. (Retd.), assumed charge of the office of Civil Surgeon, Lahore, on the 16th July, 1942.

Brevet-Colonel Sir R. N. Chopra, C.I.E., I.M.S. (Retd.), is appointed Emeritus Professor in the School of Tropical Medicine, Calcutta.

Major H. S. Waters, Professor of Midwifery and Gynaecology, Grant Medical College, and Specialist in Obstetrics with Gynaecology, Bai Motlibai and Sir D. M. Petit Hospitals, Bombay, is appointed to officiate as Superintendent, St. George's Hospital, Bombay, *vice* Lieutenant-Colonel S. R. Prall, granted leave.

Major W. S. Morgan, Agency Surgeon in Bundelkhand, resumed charge of his duties, with effect from the forenoon of the 14th July, 1942.

On transfer from Lahore Major G. J. Joyce assumed charge of the office of Civil Surgeon, Amritsar, on the 20th July, 1942.

The undermentioned officers (on probation) are confirmed in the Indian Medical Service, with effect from the dates specified, subject to His Majesty's approval :—

Margaret Ellen Mary Blanden. Dated 29th May, 1942, with seniority from 11th February, 1940.

Charles Sonick. Dated 10th January, 1942, with seniority from 22nd September, 1941.

Michael Joseph Barry. Dated 21st February, 1942, with seniority from 2nd November, 1938.

John Alexander Walton Bingham. Dated 21st February, 1942, with seniority from 1st May, 1937.

George Richard Butterfield. Dated 21st February, 1942, with seniority from 7th August, 1936.

Cawley Robert Kinsley Carroll. Dated 21st February, 1942, with seniority from 10th February, 1941.

Claud Conway. Dated 21st February, 1942, with seniority from 24th September, 1939.

Donald Currie. Dated 21st February, 1942, with seniority from 29th July, 1941.

Howell McIntyre Davies. Dated 21st February, 1942, with seniority from 19th June, 1941.

Alfred Charles Greene. Dated 21st February, 1942, with seniority from 25th November, 1939.

Francis Alleyne Hall Hall. Dated 21st February, 1942, with seniority from 26th February, 1941.

Roger Clement Hallam. Dated 21st February, 1942, with seniority from 8th May, 1941.

George Hannigan. Dated 21st February, 1942, with seniority from 9th May, 1941.

Frederick Hunter. Dated 21st February, 1942, with seniority from 22nd August, 1935.

Nicholas Nikolaevich Iovetry-Tereshchenko. Dated 21st February, 1942, with seniority from 29th March, 1941.

Hugh Vernon Knight. Dated 21st February, 1942, with seniority from 21st February, 1936.

Alastair Delmi Archibald Maconochie. Dated 21st February, 1942, with seniority from 5th August, 1941.

John William Magnier. Dated 21st February, 1942, with seniority from 22nd November, 1940.

John Michael Mungavin. Dated 21st February, 1942, with seniority from 11th December, 1940.

Brian John Niall. Dated 21st February, 1942, with seniority from 8th April, 1936.

Geoffrey Lewis Leslie Reynolds. Dated 21st February, 1942, with seniority from 18th June, 1940.

Louis Rich. Dated 21st February, 1942, with seniority from 2nd May, 1937.

John Lawton Roberts. Dated 21st February, 1942, with seniority from 14th June, 1941.
 Basil Rowlett. Dated 21st February, 1942, with seniority from 4th May, 1941.
 Charles Gordon Rennick Sell. Dated 21st February, 1942, with seniority from 4th August, 1941.
 Stanley Ernest Vincent. Dated 21st February, 1942, with seniority from 8th June, 1941.
 Gilbert Benjamin Rowland Walkley. Dated 21st February, 1942, with seniority from 27th March, 1941.

To be Lieutenants (on probation)

27th February, 1941.

Vishnu Narayan Khaana, with seniority from 27th February, 1940.
 Framroze Jehangir Bilimoria, with seniority from 27th February, 1940.

(DENTAL BRANCH)

(Emergency Commissions)

To be Lieutenants (on probation)

Minocheker Kaikhosbru Sanjana. Dated 9th October, 1941.

Satya Pal. Dated 8th December, 1941.

5th May, 1942

George Mathias.
 Lekh Raj Bhalla.
 Nariman Rustomji Vazifdar.
 Sorab Munchershaw Nicholson.
 Mohan Dev Mehra.

6th May, 1942

Hari Dayal Gupta.
 Keshab Chandra De.
 Harish Chandra Aurora. Dated 7th May, 1942.
 Parkash Chander Verman. Dated 5th March, 1942.
 S. Bratt. Dated 6th March, 1942.
 Hardasmal Jagatsing Kundanani. Dated 7th March, 1942.
 Sunil Kumar Gupta. Dated 8th March, 1942.
 Charles Mathew Rego. Dated 9th March, 1942.
 Henry Joseph Lobo. Dated 10th March, 1942.
 Gordhan Lal Narula. Dated 20th March, 1942.

To be Lieutenant (on probation)

Vasant Gopal Dabholkar. Dated 18th April, 1942.

Lieutenant Vasant Gopal Dabholkar is seconded for service with the Royal Indian Navy, with effect from the 18th April, 1942.

LAND FORCES

To be Lieutenant (on probation)

Gordon Arthur Ransome. Dated 11th April, 1942.

(Emergency Commissions)

Albert Francis Lasrado. Dated 15th April, 1942.
 Darashah Rustomji Bharucha. Dated 18th May, 1942.
 Mohammed Abdul Sami. Dated 4th June, 1942.
 Mohammad Ziz-Ullah. Dated 22nd June, 1942.

PROMOTIONS

Major F. R. W. K. Allen, Civil Surgeon, Raipur, has been promoted to the rank of 'Lieutenant-Colonel', with effect from 5th April, 1942.

Captains to be Majors

J. G. Stonham. Dated 1st February, 1942.

E. C. Hicks. Dated 7th June, 1942.

The undermentioned Captains are granted the local rank of Majors, whilst employed as Senior Medical Officers in Recruiting Areas, with effect from 18th February, 1942:—

B. R. Khinijo (A.I.R.O.).
 H. R. Kapoor (A.I.R.O.).
 Parduman Singh (A.I.R.O.).
 A. L. Khurana (A.I.R.O.).
 R. L. Soota.

S. K. Ghose (A.I.R.O.).
 A. K. Mallick (E.C.).
 K. C. Virmani (A.I.R.O.).
 S. D. Butt (E.C.).
 C. K. Patel (A.I.R.O.).
 B. L. Sahi (A.I.R.O.).

PROMOTIONS

The following promotions are made:—

INDIAN LAND FORCES

(Emergency Commissions)

Lieutenants to be Captains

Sardar Ahmad, Charanjit Shah Singh, Shushil Kumar Puri, Bishambhar Nath Kapur, Jyoti Ranjan Sen Gupta, Suchil Mohan Dass, Kazi Abdul Jabbar, Prabandham Rangachar, Anil Prasanna Banerjee, Wunnava Venkata Bapiah, Ali Akbar Shah, Manikkath Narayana Menon, Radha Raman Lal, Surendra Nath Chatterjee, Shiva Bhajan Prasad Tewari, Kali Shankar Bagchi, Kozhimannil Abraham, Jagdish Chandra Das Gupta, Rahatullah Khan, Govind Shamrad Vingle, Pratap Chand Badhwar, Madhab Chandra Bhattacharyya, Riaz-ud-Din Quraishy, Mukunda Seshagiri Prabh, Vaigalathur Sunderamier Ramaswami, Christopher Arumainayagam, Sita Ram Kaura, Nripendra Narayan, Nariman Kaikhosbru Shroff, Hirendra Mohan Gangopadhyaya, Velu Vaidyer Krishna Vaidyer, Amir Chand Narula, Mohammad Qasim Ali, Yashwant Dattatry Deshpande, Navroji Manckji Kalapesi, Thekevetil Ninan Chacko, John Pakiam, Gurmukh Das Agarwal, Gehi Wadhmal Keswani, Jitendra Chandra Chakrabarti, Abani Kumar Das Dastidar, Deva Prasad Ray, Sarat Chandra Srimani, Jiban Krishna Bose, Joseph Elmer Grieff Baker, Mahendra Vikram Singh, Chethalavada Sanjeevi Venkatasubramaniam, Velacheri Kuppaswami Sundaram, Bahadur Singh Nagra, Sri Krishna Suri, Jose Luciano Glennie Pinto, Mian Akbar Jan, Pundi Srinivasa Raghvan, Gurpur Damodar Shenoi, Chandulal Shiolal Tamboli, Palayathil Velandi Krishnan, Digambar Shivramsa Khatri, Nanabhai Framroze Lilauwala, Maduriah Chetti Muniswamy, Gajanan Dattatray Joglekar, Amulya Kumar Saha, Prabhas Kumar Sen, Ram Krishna Chettur, Ramamurti Arunachalam, Bisheshwar Dayal, Balkrishna Keshco Sheorcy, Bishamber Nath Baggan, Boddapati Amrit Rao, Hans Raj Nischol, Raman Sukumaran, Vasudeva Krishna Row, Ramesh Chandra Biswas, Jonnalagadda Surya Prakasa Rao, Brij Ballabh Parshad, Kundan Singh Gill, Jiban Krishna Sarkar, Gopal Ganesh Sahasrabudhe, Muddassir Khan, Rabindra Nath Sen, Shiv Dev Singh, Chhajju Ram Abrol, Gurditta Mal Diwan, Pargat Singh, Krishna Gopal Bhatia, Rustam Sohrab Tata, Nellorepalla Vankata Subrahmanyam, Revur Krishnamurti, Arumugam Pillai Thiagarajan, Cortielle Madhavan Nair, Iftakhar Jahan, Balai Lal Roy Chowdhury, Anil Kumar Bose, Yeshwant Govind Joshi, Mayaram Venkatarama Ramachandran, Chambathil Ramanunni Mannadiar, Dady Framji Vachha, Mukhai Subramania Mahadevan, Palathiruthi Aelutha Menon, Sardari Lal Bhandari, Pratibha Ranjan Dutt, Mohan Hatangdi, Gobinda Prasad Halder, Raghunath Singh Hoon, Mammen Mammen, Chirayath Francis Varied, Narayan Prasad Mahapatra, Guruswami Audikesavalu Naidu, Rishiyur Sundaram Thyaga Rajan, Phiroze Jehangirji Engineer, Panakkal Othuppu Ittooppunny, Thakar Das Narang, Sardari Lal Kalra, Bhag Singh, Vapa Purna Rao, Allen Arthur Rawat, Profulla Chandra Sen, Rai Sahib Lakshman Prasad Misra, Narayan Gangadhar Chitnis, Charu Bhavanishankar Bhargav, Vinay Bhavanishankar Bhargav, Fakir Chandra Mukherjee, Jal Harmajshaw Chibber, Gopal Laxman Chitale Bhajekar, Devki Nandan Mehta, Gursewak Singh Sidhu, Gauri Shankar Singh, Manmatha Nath Ghosh, Mafizuddin Talukdar, Lalgudi Annadurai Venkataraman, Balwant Singh Sachdev, Ashiq Hussain, Vadarangam Swaminadha Mahadevan, Jyotish Chandra Ghosh, Tattamagalum Subramanispattar Viswanathan, John John Eapen,

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

AFTER-HISTORIES OF TUBERCULOUS PATIENTS

By P. V. BENJAMIN, M.B., B.S., T.D.D. (Wales)
Medical Superintendent, Union Mission Tuberculosis Sanatorium, Arogyavaram, near Madanapalle

THE value of treatment of tuberculous patients in an institution can be judged in two ways:—

- (1) By the results of treatment up to the time of the patient's leaving the institution.
- (2) By the ability of the patient to survive after leaving the institution.

We know from sanatoria all over the world that the immediate results of treatment have improved considerably especially during the last two decades, and also since the wide adoption of various methods of collapse therapy. This improvement has extended to the later results of treatment, that is, after the patient has left the institution, but the improvement in this respect has not been so marked as was expected, although reports from different institutions vary. Hartley and his co-workers (1935) after analysing by statistical methods the figures for 8,766 cases treated in Frimley Sanatorium, England, draw the conclusion 'that the prognosis of an average case of pulmonary tuberculosis has not materially changed during the past thirty years, and that our patients of more recent years show an after-history very similar to those of cases treated in the earlier period'. They do however admit that patients who have been able to get a successful pneumothorax do definitely have a better expectation of life.

On the other hand, Midhurst Sanatorium, England, in a follow up of about thirty years, records in its Annual Report (1936), a decrease in mortality of 20 per cent in recent years compared with the period before 1920. Cheshire Joint Sanatorium in its Annual Report (1936) records a decrease of 30 per cent in mortality three years after discharge.

Looked at from another point of view, we see that the percentage of deaths for all tuberculous patients still remains very high even after good results of treatment. London County Council figures, reviewing about 4,000 patients each year from the years 1921-29, considering each patient five years after completion of treatment, record a survival percentage varying between 31.9 and 36.1; for the sputum-positive advanced cases the percentage of survival was between 3.7 and 6.9; for the sputum-positive moderately advanced cases between 28.4 and 35.2 per cent; and for the sputum-positive minimal cases between 60.1 and 72.1 per cent.

Figures from Trudeau Sanatorium, U. S. A., which takes mostly patients of good social status are rather better (Heise and Hennigar, 1933);

of 708 patients with minimal disease, 660 or 93 per cent are known to be alive five years later; of 2,192 patients with moderately advanced disease, 1,874 or 85 per cent; of 478 patients with far advanced disease, 253 or 53 per cent.

In Fort Qu'Appelle Sanatorium (Ferguson, 1926) of 407 stage I patients discharged between one and seven years previously, 90.4 per cent were alive; and 83 per cent of stage II patients, and 47.9 per cent of stage III patients were found alive.

In order to try to find out what is the position in India, the sanatorium at Arogyavaram has attempted to collect after-histories of all patients discharged from the institution, who have had at least one month's treatment (those who died while under treatment in the sanatorium are not included in the figures). These figures have been collected in 1925, 1930, 1935 and 1940 for patients who had completed a period of five years after leaving the sanatorium prior to those years.

Immediate results of treatment

During these years there has been a steady improvement in the immediate results of treatment as shown by the following table (table I).

In table I are shown those patients discharged as 'arrested' and 'much improved', who could be expected to have a fair prospect of doing well in after-life. Taken together in stage I good results have increased from 85.8 to 96.8 per cent during the several five-year periods, in stage II from 58.3 to 82.8, and in stage III from 21.2 to 40.9. Are these results carried over into the after-history?

After-histories of the patients

Enquiries were made about all the 3,945 patients of pulmonary tuberculosis discharged after treatment between the years 1916-35. In such an enquiry, it is at present impossible in India to get a really satisfactory number of replies. Answers were received concerning only 2,424, i.e., 61.4 per cent of all the cases. The distribution of these patients is shown in table II, where it will be seen that the traced and untraced cases are fairly evenly distributed over the different stages and different results of treatment in each stage.

It is recognized that it is very difficult to draw statistical conclusions when as many as 39 per cent of the cases are untraced. One method, which gives the most unfavourable picture, is to assume all the untraced cases as dead, but we believe that this would not give a correct picture. While it is possible that the majority of untraced stage III patients may have died, it is very unlikely that this is true for the stages I and II patients. Another way is to ignore the untraced cases and to deal only with the traced cases, realizing that possibly the figures for survival in stage III are an over-estimate, because probably most of the patients

		Untraced	3	27.3	302	41.1	169	37.2	264	33.6	738	37.2

in this stage and about whom information cannot be obtained, have died.

In table III are shown the percentages of survival calculated according to both these methods divided according to the stage of the disease on admission, and the result of treatment on discharge in each of the five-year groups.

From table III it will be seen that at the very lowest computation 56.3 per cent of the discharge cases of stage I were alive five years later; 38.0 per cent of stage II and 16.5 per cent of stage III, or taking all stages together 31.2 per cent. If we take only the traced cases we find that in stage I, 87.7 per cent are alive; in stage II

66.7 per cent and in stage III 26.3 per cent, but as we have already stated these figures especially for stage III may be too high.

If we add together the arrested and much improved, *i.e.*, those who could be expected to do well after discharge, and can be called 'clinically well', we find the following :—

TABLE IV
*After-histories of patients discharged as
'clinically well'*

Stage	Total number of patients	Number of patients traced	KNOWN TO BE LIVING, 5 YEARS LATER		Percentage of traced cases
			Number	Percentage of all patients	
I	809	523	473	58.5	90.6
II	790	464	364	45.5	78.4
III	746	441	261	34.9	59.2

From table IV it will be seen that at the very lowest estimate 34.9 per cent of the stage III cases discharged as 'clinically well' are alive five years later, 45.5 per cent of the stage II and 58.5 per cent of stage I.

A consideration of the after-histories for the various five-year periods (table III) does not show any marked and progressive improvement in results, except that the results for the years 1921-35 are better than for the first five-year period; collapse therapy was begun in 1921 and may have contributed to this improvement.

After-care and after-history

If only the 'traced' cases are taken into consideration, it will be seen (table IV) that 90.6 per cent of the cases of stage I discharged as 'clinically well', are alive at the end of five years, the percentages of such cases of the stages II and III being 78.4 and 59.2. Thus, at least 9.4, 21.6 and 40.8 per cent of such cases, in the 1st, 2nd and 3rd stages of the diseases, respectively, have died in five years. These figures are for all the patients discharged, irrespective of special after-care.

Similar figures for patients who have had special after-care are not easily available. In this sanatorium, 91 patients have had after-care after discharge either on the sanatorium staff or in the ex-patients' colony, for periods varying from one to twenty-six years. Of these, 38 out of such 53 stage III patients, *i.e.*, 71.7 per cent, are alive and working. The corresponding figure for such patients not receiving any special after-care, is 34.9 per cent if the untraced cases are considered as dead, or 59.2 if the untraced cases are omitted from the analyses. Although the number of patients receiving after-care is small, yet the results seem definitely to prove the value

of such after-care, even if a few of the ex-patients have not yet completed five years after discharge. The ex-patients in this group were not selected because they were specially well, but more often because they needed continued medical supervision.

Similar figures showing the value of after-care are available for the Rhode Island State Sanatorium in U. S. A., where Barnes (1919) states that only 55 per cent of patients who left the sanatorium as improved are alive two to twelve years later, while of 286 ex-patients who were employed on the staff of the sanatorium 69 per cent were alive after the same period.

The place of clinics in after-care

In India it will be many years before after-care centres, in places like colonies or institutions, can deal with more than a mere fraction of the discharged cases needing after-care. But the tuberculosis clinics that are now being established all over India, can do much if their functions are properly understood and carried out.

One of the things we have found in our ex-patients' colony is that the ex-patients frequently need close medical supervision and treatment, especially in the earlier years after discharge. The availability of this has contributed much to the higher survival rate. This type of supervision can be carried out by the clinic during the first years after discharge, but there must be co-operation between the clinic and the sanatorium or other institution in which the patient has been treated. Of recent years it has been possible to refer some of our cases on discharge to clinics, and the value of such subsequent supervision has been encouraging.

Further, the after-care committee, which should be a part of the clinic's organization, can help by arranging suitable work or living conditions for the ex-patients. In addition, co-operation between clinic and sanatorium will facilitate the tracing of patients so that we shall be able in course of time to get much more reliable figures for after-histories.

Conclusion

From the above study of the fate of discharged patients in India, it will be seen that the survival rate compares very favourably with those of other countries. The difficulty of tracing patients after discharge is very great, but in course of time with progress of education and with the increasing co-operation of clinics and general practitioners, this difficulty should decrease, and more reliable figures become available. As elsewhere, there is a fairly high percentage of deaths after discharge, specially in the patients who were suffering from advanced disease, but efficient after-care can help much in reducing the mortality.

THORACOPLASTY IN THE TREATMENT OF PULMONARY TUBERCULOSIS

AN ANALYSIS OF 150 CASES

By P. V. BENJAMIN, M.B., B.S., T.D.D. (Wales)

Medical Superintendent, Union Mission Tuberculosis Sanatorium, Arogyavaram. (near Madanapalle), (South India)

and

J. FRIMODT-MÖLLER, M.D. (Copenhagen)

Assistant Medical Superintendent

ONLY a few reports on thoracoplasty have appeared so far from India. From this sanatorium a review of the first seventeen patients operated on was published in 1937 (Benjamin). From the Wanless Sanatorium, Miraj, two reports, on 110 and 94 patients, respectively, have been given by Jones (1937 and 1939). As a wider knowledge of the value, possibilities and limitations of thoracoplasty in Indian patients is desirable, we are presenting the experience gained from our first 150 patients treated by thoracoplasty.

From 1932 to the end of July 1942, 194 patients have had a thoracoplasty with a total of 455 operations. For the purpose of this

(Continued from previous page)

Summary

(1) A review is made of the after-histories of 3,945 patients five years after treatment at Arogyavaram.

(2) Replies were received about only 2,424 patients, and the difficulty of drawing conclusions when 39 per cent of patients are untraced and unknown, is discussed.

(3) Survival figures have been calculated on two different principles: firstly, considering as dead all the untraced cases (the worst possible figure) and secondly, ignoring the untraced cases.

(4) While immediate results of treatment have shown definite improvement in all the five-year period since 1915, a corresponding improvement in after-histories is not observed except that all the five-year periods since 1920 show better results than the period 1915-20.

(5) The influence of after-care on survival is discussed and illustrated by figures from a group of ex-patients working in the sanatorium and ex-patients' colony.

(6) In the absence of colonies for ex-patients in India, the place of the tuberculosis clinic in after-care is discussed.

investigation we have taken the first 150 of these patients, the last being operated on in November 1941 and so having had an observation period of nine months. The 17 cases already reported by Benjamin in 1937 are included in this series. On these 150 patients, 347 operations were done, that is an average of two to three operations for each patient.

Before examining the results it should be understood that these cases constitute a group of tuberculous patients in whom all other forms of treatment had failed. All had tubercle bacilli in their sputum before the operation; all except a very few had definite cavities, often of considerable size. In all cases pneumothorax treatment had been attempted; in about one-third of the cases a pneumothorax had been induced, but had to be abandoned after some months when found to be ineffective. In the other cases no free pleural space was found, or, at the most, only very small pockets. Most of the patients had been a long time under institutional treatment, and it was very unlikely that further conservative treatment would be of any use. Without surgical treatment the majority would probably have succumbed to their disease, and, if sent home, all would certainly have been a constant source of infection to their surroundings. It should therefore be borne in mind that we here are dealing with a group of patients with serious forms of tuberculosis and for whom the prognosis was very unfavourable.

The material presented includes patients from all parts of India. The majority (125 patients) were Indians, mostly from South India, but many also from the central and northern provinces; the other patients were 14 Anglo-Indians, 4 Europeans, 4 Burmans, 2 Anglo-Burmans and 1 Chinese. It has been difficult to get information from all after discharge, as many, due to the present war situation, have moved from their homes on the East coast to the interior; from the patients living in Burma we have of course been cut off. The results of the operation are based upon the condition on discharge when no later information has been available. The period of observation therefore shows much variation ranging from six months up to nine years, in the earlier cases, the majority being between one and two years with an average of one year and five months.

Operative technique

During the first part of this series, nitrous-oxide was used as general anaesthesia, but as there was reason to suspect that ill effects were caused by this anaesthesia, in one case perhaps even death, it was given up in favour of ether. We now use a combination of local anaesthesia with procaine, and general ether anaesthesia with a little chloroform at the beginning.

All the operations, except one, were done by means of a posterior paravertebral incision. In the earlier years it was common to do the

Notes:—(1) Case of tuberculous empyema, operated in two stages.

(2) Operation incomplete, patient had to leave for family reasons.

(3) Sputum became TB-negative but patient died from extrapulmonary dissemination.

(4) Included a case of an antero-lateral thoracoplasty *ad modum* Ascoli.

(5) One patient refused the planned third stage.

(6) One of the two patients left against advice although operation incomplete (third stage intended).

(7, 8 and 9) Included a case operated on for tuberculous empyema with mixed infection.

operation in one stage, removing five to six ribs, but no attempt was made to remove long pieces of rib. In table I the first 16 cases, done by this method, are grouped under the heading 'Modified Brauer-Friedrich'. The majority of these patients had the predominantly fibrotic (chronic) type of disease, one of the criteria commonly accepted at that time for selecting patients for thoracoplasty. The collapse of the apex obtained by this operation was not always good, but these patients generally responded well. Later, when thoracoplasty was extended to patients with a more exudative type of disease, and when it was also found necessary to remove longer pieces of rib than in the earlier operations, the operation was divided into several stages, as the patients could not stand the more extensive operation so well. In table I these cases are grouped under the heading 'Modern Type'.

It is now our routine to remove only two or three ribs at a stage; the two upper ribs are radically removed during the first stage operation. The posterior ends of the ribs are resected medially as far as the transverse processes, sometimes including a portion of these also. In some cases in which the cavity has been situated anteriorly in the lung, and did not close because of remaining anterior stumps of the upper three ribs, we have had to supplement the posterior operations with an anterior one in order to remove these also.

Clinical results and the results of sputum examination are shown separately; the sputum results refer only to patients who are living. In table II the clinical results are correlated with the sputum results.

Clinical results.—By 'much improved' is understood that the patients were so well that they could stand normal life and were fit for work shortly after discharge, though some of them were still TB-positive. As seen from table II, 48 patients (32.1 per cent) were much improved and had negative sputum; as the period of observation is yet rather short, it is too early to call them 'arrested' or 'cured' although we expect most of them will be in course of time. On the other hand, some of the TB-negative patients could only be classified as 'improved', i.e., their general condition was still not sufficiently improved for them to be fit for work.

Almost half of the patients obtained very satisfactory results, 46.7 per cent being 'much improved'; in addition, 22.7 per cent were 'improved' making a total of 69.4 per cent positive results of the operation.

Sputum results.—Though the clinical improvement from the point of view of the patient's ability to return to work is important, yet the success of the operation has to be judged by the disappearance of tubercle bacilli from the sputum; this is important not only for the

TABLE II

Clinical results after thoracoplasty correlated with sputum results in 114 living patients
(Percentages calculated on basis of the material of 150 patients)

Clinical results	SPUTUM RESULTS			Total
	O TB	± TB	+ TB	
	%	%	%	%
Much improved	48 = 32.1	5 = 3.3	17 = 11.4	70 = 46.7
Improved	11 = 7.3	1 = 0.7	22 = 14.4	34 = 22.7
Stationary or worse ..	0	0	10 = 6.7	10 = 6.7
TOTAL ..	59 = 39.3	6 = 4.0	49 = 32.7	114 = 75.9

Generally a period of three to four weeks is allowed between the stages. Longer intervals are not desirable because of the rapid regeneration of the ribs, which sometimes takes place in spite of our treating the periosteum with 10 per cent formalin to delay this.

The post-operative treatment follows generally accepted lines, but we stress the importance of a sufficiently long sanatorium regime after the last operation, a minimum of four months, even if the patients' general condition could apparently make an earlier discharge possible.

Results

In table I, the patients are grouped according to the number of operations they have had.

patient's own sake but also for the sake of those with whom he has to live and work.

From the western countries statistics each dealing with more than 100 patients and published since 1930, show results of 'arrested' or 'TB-negative' varying from 20 to 75 per cent, the majority from 40 to 50 per cent, as shown by Hein *et al.* (1938) from a survey of the literature available up to 1937. Hein himself obtained 47.8 per cent TB-negative in 280 cases (1938). Since then Edwards, Leggat and Davies (1941) reported 68 per cent in 52 cases, and Meltzer (1941) reached 79 per cent among 143 patients. Jones (1939) from Indian material of 90 cases reported 56.7 per cent 'apparently arrested', all the operations however done

within two years of publication, and the standard for sputum examination is not mentioned.

In estimating the sputum results we have taken the latest information available. Three patients were classified as TB-negative although only negative by direct smear on eight examinations within the last two months before discharge; all the others were either sputum-negative by direct smear at least four months before discharge or had in addition one or more negative sputum cultures as can be seen from the following:—

Sputum was TB-negative by

direct smear only	13 patients
direct smear and also—		
one sputum culture	32 "
two sputum cultures	9 "
three sputum cultures	3 "
two sputum cultures and one		
stomach-wash culture	1 "
guinea-pig inoculation	1 "

In the '± TB' group are six patients who had shown a negative sputum over a long period after their operation but in whom a single examination by direct smear or culture had shown tubercle bacilli shortly before discharge: in none of these patients could a cavity be detected.

A few patients, who were TB-negative at the time of discharge, have since reported a positive sputum and are therefore grouped under '+ TB'.

The standard adopted in our investigation for sputum examination should be borne in mind when our results are compared with statistics of an earlier date, or from institutions where cultivation for tubercle bacilli is not carried out, or where the standard for negative sputum is not given.

From table I it can be seen that our thoracoplasty results have improved with the modern technique. Although in the earlier group (modified Brauer-Friedrich) 43.8 per cent were 'much improved' compared with 47.1 per cent of the 134 patients of the modern type operation, only 18.7 per cent became TB-negative against 41.8 per cent in the latter group. The number of patients in the first group is small but the difference in percentage is sufficiently large to be considered significant. The better sputum result after the modern type of operation may be explained by the much improved apical collapse obtained with a radical removal of the upper two ribs.

Operative mortality

As suggested in 1930 by Bull at the conference in Oslo of the International Association of Tuberculosis, we have considered deaths within two months after an operation as 'operative deaths'; in table I figures are also given for deaths during the first post-operative week showing the 'immediate operative mortality'.

Of the total number of operations the immediate operative mortality in the whole

material is 4.04 per cent; 14 in 347 operations, and 6.06 per cent for deaths within the first two months. As each patient has had an average of two to three operations, the operative mortality based on the number of patients is higher, namely, 9.3 per cent 'immediate operative' mortality and 14 per cent mortality within two months. Most of the immediate operative deaths occurred after a first stage operation, and most of these again happened during the period when we began to include the less resistant and more acute type of case and changed the technique to removing larger pieces of rib, although still taking as many as three to four ribs during the first stage; our present procedure is to remove only two ribs at the first stage, and those completely, and only in cases when there is no tendency to mediastinal flapping do we remove a portion of the third rib also. This change of technique has we believe contributed to the lower mortality in the later figures. Another contributing factor has been the use of pressure breathing immediately after operations and also during the first week if there is any distress in breathing or tendency to paradoxical respiration.

The decrease of operative mortality may be seen in the following table:—

	Died during first week	Died after first week within 2 months
First 50 cases ..	7	1
Second 50 cases ..	5	4
Third 50 cases ..	2	2

Subsequent to the 150 cases in this investigation, 44 more patients have been operated on, 10 were operated on within the last two months and 34 earlier; there have been no deaths either immediate or later.

Age

The patients have varied in age from 18 to 49 years, but the majority were between 20 and 30 years of age. An analysis of the results, judged by clinical improvement and disappearance of tubercle bacilli, shows no material difference in the various age groups.

Sex, and side of operation

In table III the patients are grouped according to sex and to the side of operation. The totals for men and women show no appreciable difference, nor do the totals for right and left sides, regardless of sex. But analysis of the results in women in relation to the side of operation, seems to give an indication that in women operation on the right side is less favourable than operation on the left. Bull (1930) noted a higher operative mortality for right than left side, especially in women, but Hein (1938) has not been able to substantiate this.

Although the difference observed by us is sufficiently large to be statistically significant, we feel that more material should be collected before we can come to a conclusion.

often the winner (Hein). In many cases we have had to wait until the progressive phase has subsided as shown by a clearing-up of the radiological shadows, the temperature reverting to

Suitability for operation

When considering indications and contraindications for thoracoplasty, it is important not only to select the proper type of case, but also to decide whether the patient is in a suitable phase to stand the operation. It is obvious that if the patient presents a rapid progression of the tuberculous lesion, the operation is risky. It has been said that if it is a question of a race between the disease and the surgeon, the former is most

normal or nearly normal, and a steady or increasing weight curve. These observations are borne out from table IV; the patients are here grouped according to a clinical estimation of their general condition at the time of their first stage.

The figures show in a striking manner how the patients in good general condition fared much better than those in only a fair condition and very much better than those in a poor condition.

TABLE IV

General condition before operation compared with the results in 150 thoracoplasty patients

Pre-operative condition	Total	CLINICAL RESULTS					Sputum results		
		Living			Died				
		Much improved	Improved	Stationary or worse	During first 2 months	After 2 months	O TB	± TB	+ TB
		%	%	%	%	%	%	%	%
Good ..	78	50 = 64.2	16 = 20.5	1 = 1.3	7 = 8.9	4 = 5.1	34 = 43.7	4 = 5.1	29 = 37.2
Fair ..	58	19 = 32.8	15 = 25.8	6 = 10.3	9 = 15.5	9 = 15.5	21 = 36.2	2 = 3.5	17 = 29.3
Poor ..	14	1 = 7.2	3 = 21.4	3 = 21.4	5 = 35.7	2 = 14.3	4 = 28.6	0	3 = 21.4

We have, rather to our surprise, found that the usual blood examinations such as the erythrocyte sedimentation rate and differential counts of the leucocytes with regard to immature forms (Schilling's method) offer very little guidance in prognosis. Whereas the sedimentation rate proved of no prognostic value at all, the ratio of immature neutrophile leucocytes (Schilling's 'stabkernige') proved to be of some value, but this only in certain cases. The value of these blood tests cannot be compared with the value of general clinical judgment.

Type of lesion

As previously stated, in the earlier period only patients with more fibrotic types of lesions were operated on. But the majority of the patients in the sanatorium had the exudative type, and since for many of these, other methods having failed, there seemed to be nothing left but to try a thoracoplasty. In table V we have grouped the

Cavity closure

One of the main objects of a thoracoplasty operation is to obtain a definite closure of cavities; all our cases, except seven, showed clear cavity shadows in the radiogram and by fluoroscopy before operation; the seven cases without demonstrable cavities had persistently positive sputum for years, and some had had repeated hæmoptysis; the cavities could perhaps have been found by tomography, a method not yet at our disposal. The cavities ranged in size from small ones less than 2.5 cm. to large ones of more than 7.5 cm. in diameter. In table VI we have grouped the cases according to whether the cavities were smaller or larger than 5 cm. in diameter.

From table VI it can be seen that, as would be expected, the smaller cavities are easier to close than the larger ones. In the group with cavities above 5 cm. in diameter are included six

TABLE V

TOTAL ..	146	67 = 45.9	34	10	21 = 14.4	14	57 = 39.1	6	48

Note.—Four empyema cases excluded.

patients according to the radiological appearance of their lesions; in the group 'predominantly productive' we have included patients who, as far as we could judge, had a definite tendency to form more chronic productive lesions but this does not exclude the presence of some exudative elements. Similarly, in the group of more fresh exudative cases there will be lesions with some productive elements, as practically in all cases both elements coexist.

Although there is some difference in the results between the three groups, this is by no means very large; the difference is reflected less in the sputum figures than in the clinical results. On the other hand it may be said that our figures show that thoracoplasty treatment for cases with predominantly exudative lesions certainly is justifiable, provided, as stated above, that their general condition is good and the operation is timed at the proper phase in the evolution of the disease.

cases with cavities measuring more than 7.5 cm. in diameter, and we obtained definite closure with negative sputum in two. A result of 31.4 per cent TB-negative in all cases with cavities of 5 cm. or more in diameter is definitely encouraging.

It might be argued that perhaps some of the cases with cavities might have obtained cavity closure without thoracoplasty, especially those with small cavities. As we have from time to time observed such spontaneous healing of cavities, it is our practice not to do a thoracoplasty before we are convinced the cavities will not close by conservative methods.

On the other hand there are cases in which the cavities do not close even with thoracoplasty. In the group with cavities smaller than 5 cm. in diameter (table VI), there are 26.4 per cent who still had a positive sputum after the operation, and in most of them the positive sputum was due to non-closure of the cavity. It is not

easy to predict what sort of cavities may close. Sometimes cavities show a quicker and easier closure than expected, while in other cases in which no difficulties were anticipated, it was not possible to get the cavities closed in spite of the most radical removal of ribs. These cases present a most difficult problem, one which we have in common with other workers.

One of the reasons why the cavities do not close may be the removal of too few ribs. In table VII 96 living patients are grouped according to the number of ribs removed, the position of the cavity being taken into account.

TABLE VII

The number of resected ribs in 96 thoracoplasty patients correlated with the position of the cavity as determined by the number of its nearest underlying rib (posterior end)*

Difference between the number of the rib just below the cavity and the number of ribs resected	Patients remaining TB-positive	Patients rendered TB-negative	
			%

0	17	18	51.3
+ 1	13	22	62.8
+ 2	6	4	..
+ 3	0	2	..
TOTAL ..	46	52	

* Following 52 patients are omitted: 16 'Brauer-Friedrich' cases, 3 empyema cases, 26 dead and 7 patients without definite radiological cavity shadows.

The figures (table VII) suggest that the best procedure to get the cavity closed is the removal of the ribs down to the one just below the cavity or the next lower rib. It is better to remove too many ribs than too few. Edwards, Leggat and Morriston Davies (1941) advocate as a matter of routine a ten-rib thoracoplasty regardless of the extent of the disease in the chronic type, and report very good results, but they suggest that a partial thoracoplasty may be preferable in cases they group as 'justifiable risk', the type of cases we most commonly find among our thoracoplasty patients. The partial thoracoplasty is in line with the modern principles of selective collapse, since it allows as much of the healthy lung as possible to function, thereby also reducing the strain on the contralateral lung which often shows some evidence of disease, either old or fresh.

Early regeneration of resected ribs may be another cause of failure in cavity closure. This is a consequence of the operation being done in stages. Therefore, it is important that the

TABLE VIII

Length of interval between first and second stage in 98 living patients who had the modern type of thoracoplasty in two stages or more

Length of interval between 1st and 2nd stages	Patients rendered TB-negative (- TB)	Patients remaining TB-positive (+ TB)
Less than 6 weeks	35 = 67.3%	20 = 43.5%
7 weeks or more	17 = 32.7%	26 = 56.5%
TOTAL ..	52 = 100	46 = 100

interval between the various stages should be as short as possible. That this is so may be seen from table VIII where the disappearance of

tubercle bacilli is considered in relation to the interval between the operations.

We have given only the length of interval between the first and second stages as in most cases it is the regrowth of the upper two or three ribs which prevents the cavity closure. Table VIII shows that the patients who became TB-negative generally had a shorter interval than those who remained TB-positive.

Another possible explanation of the failure of the cavities to close is the yielding of the mediastinum allowing the cavities to 'retreat' medially.

In other cases it may be that changes of a tuberculous origin in the wall of the draining bronchus may cause the bronchus to act as a check-valve to the cavity, allowing the air to be sucked in but preventing its escape. On the other hand, we have also obtained good results with cavities definitely inflated because of impeded bronchial drainage.

Other collapse measures

In 47 of the 150 cases, the thoracoplasty had been preceded by pneumothorax treatment on the same side for a period varying from some months to about a year. As the pneumothorax was contraselective and the sputum remained positive, it was abandoned in favour of a thoracoplasty; in some of the cases thoracoscopy had been tried but the adhesions were found uncauterizable. We find no appreciable difference in the results of thoracoplasty in this group compared with those who did not have a period of artificial pneumothorax treatment before the thoracoplasty.

whereas others have maintained that it is harmful. As our figures suggest that the operation has no influence on the results of subsequent thoracoplasty, we believe that a phrenic operation is unnecessary; moreover it goes against the principle of leaving as much as possible of the lung to function when the disease is confined to its upper part.

An extrapleural pneumothorax had been done in five patients but, as the result was not satisfactory, a thoracoplasty was done later, with a good result in four of the cases.

Thoracoplasty and contralateral disease

As will be seen from table X, over one-third of our cases operated on showed tuberculous changes in the contralateral lung, of varying degree. In some cases the lesions were of such a nature as to require collapse therapy. Five had pneumothorax treatment completed before the thoracoplasty on the other side, three had extrapleural pneumothorax and one a thoracoplasty; in fourteen the pneumothorax was kept up while the other side was operated upon. The results in bilateral cases are naturally less good than in the unilateral ones. They are, however, sufficiently encouraging for us to state that in many instances contralateral disease is not a contraindication if it is not too extensive and if it is amenable to collapse therapy.

Extrapleural complications

Twenty-one cases had laryngeal tuberculosis, diagnosed either by the symptoms or by routine

TABLE IX

Phrenic nerve operation (paralysis hemidiaphragmatica) as a preliminary to thoracoplasty

		CLINICAL RESULTS						Sputum results		
		Living			Died					
	Number of patients	Much improved	Improved	Stationary or worse	Within first week	During 2nd week to 2 months inclusive	After 2 months	O TB	± TB	+ TB

Controls (no phrenic nerve operation done).	107	50 = 46.7%	27 = 25.2%	6 = 5.6%	11 = 10.3%	5 = 4.7%	8 = 7.5%	42 = 39.3%	6 = 5.6%	35 = 32.7%

In 43 patients a phrenic nerve operation had preceded the thoracoplasty. This group also showed no difference from the rest of the 150 patients who had no phrenic operation.

Phrenic nerve operation has been advocated by some as a useful preliminary to thoracoplasty,

laryngoscopy. These patients showed practically the same results as the rest.

Eleven patients had moderately severe intestinal tuberculosis, three fistula-in-ano and three ischio-rectal abscess; the results in these seventeen patients were not so good as in the

* The patient died after a thoracoplasty on the left side, having previously had in another institution an incomplete thoracoplasty (three ribs only) for the right side.

other cases, but the number is too small to allow of any conclusions.

Conclusion

In order to obtain an unbiased estimation of the value of thoracoplasty treatment, a control group should be provided consisting of at least 150 patients who have had conservative treatment only but were in all other respects similar to those of the treated group. This has not been possible, and here we find ourselves in the same difficulty as practically all other workers who attempt to assess the value of any treatment of tuberculosis, whether it be pneumothorax, sanocrysin or thoracoplasty. One possibility would be to compare the thoracoplasty patients with a group of similar patients selected from an earlier period before thoracoplasty was used in the institution, but developments specially in the x-ray and laboratory work have influenced the diagnosis and assessment so that the two groups are not comparable. Another possibility would be to select patients for thoracoplasty and then operate only on alternate ones and treat the others by conservative methods. This is obviously impossible as we cannot withhold a

form of treatment just in order to secure a control, when we believe that this treatment is of real value. Since the patients operated on had already had conservative treatment without effect, and since we have seen satisfactory results in a large proportion after operation, we are left in no doubt as to the value of the operation.

As a result of experience gained from this series of patients treated by thoracoplasty, and experience covering a number of years, we should like in conclusion to emphasize a few points.

When using thoracoplasty it should be remembered that this treatment is only an adjuvant and not the whole treatment itself, and that both before and after the operation, the patient has to be treated on the general lines accepted for the treatment of tuberculosis.

A successful thoracoplasty depends not merely on technical perfection in performing the operation, but also on proper selection of the case, choice of the time for the operation, and planning the operation for the particular individual. This means considerable experience in treating tuberculous patients and a wide knowledge of the disease.

The operation should be performed in a place which provides facilities for major surgery and a trained staff of doctors and nurses. It is not advisable to carry out this operation in a place where only a very occasional thoracoplasty can be done. Therefore it would be best if the operation was confined to certain selected centres where specialized staff and equipment are available. If closer co-operation between various institutions, sanatoria, hospitals and clinics can be developed, it would be possible for these central institutions to take over the patients needing the special treatment, while the other institutions took mainly patients requiring the simpler forms of treatment or patients who still needed supervision by specialists, after the operation. In such a way it would be possible to make thoracoplasty available to a much larger number of patients than at present, patients for whom this treatment will perhaps provide the only hope of recovery.

Summary

(1) A series of 150 cases treated by thoracoplasty between 1932 and November 1941, the majority within the last three years, is analysed.

(2) Clinical results showed 46.7 per cent much improved and 22.7 per cent improved, a total of 69.4 per cent positive results.

(3) The sputum results showed 39.3 per cent cases with no tubercle bacilli.

(4) The operative mortality was 9.3 per cent for deaths within the first post-operative week, 14 per cent for deaths within the first two months.

(5) The results are examined with regard to age, sex, side operated on, general condition of the patient, blood examinations, type of lesion and size of cavities.

(6) Reasons for failure of cavities to close are discussed.

(7) Pneumothorax and phrenic operation preliminary to thoracoplasty showed no influence on the results.

(8) It is shown that contralateral disease need not be a contra-indication for thoracoplasty if the contralateral lesions are not too extensive or can be treated by collapse therapy.

(9) The need for closer co-operation between sanatoria, hospitals and clinics, and central institutions dealing with patients requiring thoracoplasty treatment is stressed.

Text to illustrations (figures 1 to 10)

Case 1, figures 1 and 2.—Mrs. A., married teacher, 29 years. Sick for 15 months. Upper half of right lung showed a process of predominantly productive type with a cavity, 2.4 × 4 cm. large, below right clavicle; trachea moderately displaced to right side (figure 1). Sputum + TB. Pneumothorax failed—thoracoplasty done in two stages, six ribs removed. Good selective collapse obtained with definite cavity closure (figure 2). Sputum became negative one month after last operation and remained negative the last four months before patient was discharged as much improved, fit for work.

Case 2, figures 3 and 4.—D. M. J., doctor, 39 years. Sick for 2 years and 4 months. Had previously been treated with pneumothorax on the left side for more than a year, developed effusion and a temporary empyema. Figure 3 shows left lung re-expanded but a huge cavity, 4 × 10 cm. large, remaining in left upper lobe; mediastinum displaced markedly to the left side. Sputum + TB. Had thoracoplasty in three stages, seven ribs removed. Collapse very good, cavity closed (figure 4). Sputum negative for more than two years after the operation, patient doing full work.

Case 3, figures 5 to 7.—Mr. D. D., 24 years. Ill for three years, had repeated hæmoptysis. Admitted with a contra-selective pneumothorax; left apex showed a large cavity (figure 5). As extensive adhesions were found uncauterizable at two thoracoscopies, the pneumothorax was stopped. When the lung had re-expanded, the cavity occupied the whole of left apex, measuring 3.5 × 5 cm., trachea pulled to the left (figure 6). Sputum + TB, advanced laryngeal tuberculosis. Thoracoplasty done in three posterior and one anterior stages, six ribs in all removed, resulting in a good collapse and cavity closure (figure 7). Sputum TB-negative for seven months. Patient much improved and fit for work; larynx healed.

Case 4, figures 8 to 10.—Miss I. B., 23 years. Had been treated here previously from October 1935 to January 1937 with pneumothorax for a fresh process with cavity in the right lung's upper lobe, pneumothorax continued another year at home, and patient was well with negative sputum until February 1941 when she got a relapse. Re-admitted May 1941, had now bilateral disease. Right lung: fairly chronic apical process with an infraclavicular cavity, 2.5 cm. in diameter, and in left lung, a fresh cavity at the centre. This fresh process was first treated with pneumothorax on the left side, supplemented with cauterization of adhesions. When the lesion in left lung appeared well under control, bacilli persisting, thoracoplasty was carried out for the right side after an attempt to re-induce artificial pneumothorax on this side had failed. Six ribs were removed on the right side through three posterior and one anterior stages (October 1941 to January 1942), the artificial pneumothorax on the left side being maintained at the same time. Figure 9 shows condition after second operation (four ribs removed), left lung partially collapsed by the artificial pneumothorax. Figure 10 shows condition on discharge on 23rd May, 1942. Right side, a good selective collapse, no cavity; left side, lung re-expanded, clear, and without cavity. Sputum was negative from January 1942 until discharge except for a single positive smear in May (classified under '± TB'). Patient much improved.

THORACOPLASTY

By S. K. SEN, F.R.C.S.E.

Honorary Surgeon, Irwin Hospital, New Delhi
Honorary Surgeon, S. J. Tuberculosis Hospital, Delhi

In America, as recently as fifteen years ago, surgery for tuberculosis of the lung was practically unknown, and was only occasionally used by a few pioneers. It is, therefore, not surprising that in Delhi thoracoplasty for tuberculosis of the lung has only just been inaugurated. I have examined very carefully all the records of the various hospitals in Delhi and have come to the conclusion that before 1940 no organized attempt was made to use thoracoplasty for treatment of tuberculosis of the lung. In January 1939 Lieut.-Colonel R. H. Candy (now Major-General Candy), the then chief medical officer, Delhi, created the post of honorary visiting surgeon in the Silver Jubilee Tuberculosis Hospital, Delhi, with a view to starting major surgical treatment for tuberculosis of the lung. On the strength of my apprenticeship to Professor Sauerbruch of Berlin and Professor Kunz of Vienna in the years 1935-37, Colonel Candy very kindly gave me the opportunity of starting this work.

In spite of an indifferently equipped operation theatre and the complete lack of any special instruments, I endeavoured to start the work with whatever I had at my disposal. It was more than a year before I was able to attempt my first thoracoplasty. My difficulties were an utter lack of surgical-mindedness among the public, and the failure of physicians in general to advocate surgery for tuberculosis of the lung, beyond the minor operations for collapse therapy.

Lieut.-Colonel M. M. Cruickshank, the present chief medical officer of Delhi, has taken a very keen interest in this matter and has procured all the special instruments necessary and, by his influence, has finally brought about the acceptance of major surgery by the leading tuberculosis specialists of Delhi. He also very kindly agreed to collaborate with me in all cases of thoracoplasty, and thus gave me the necessary encouragement to proceed with the work. We have so far done twenty-two cases since December 1940—all of them having been operated on in the Irwin Hospital. These cases were selected from patients of the New Delhi tuberculosis clinic, from sanatoria outside Delhi, from the Silver Jubilee Tuberculosis Hospital and from the Ramakrishna Mission clinic, the former two groups of patients being under Colonel Cruickshank, and the latter two under me.

The subject of collapse therapy is a very complex one and there should be perfect co-operation between the physician, the surgeon, and the roentgenologist. There is a paucity of competent thoracic surgeons in India, and the great distance between them and the rural sanatoria further handicaps thoracic surgery.

We in Delhi are general surgeons, performing thoracoplasties without adequate facilities for suitable pre-operative and post-operative care and management. We have to work without the aid of specially trained nurses and assistants, whose intimate acquaintance with tuberculosis, detailed knowledge of thoracic physiology and pathology and the special problems that arise in such cases, as well as a broad experience in the minute details of pre- and post-operative care of the phthisical patient are an essential addition to the equipment of a general hospital which undertakes the surgery of pulmonary tuberculosis. The margin of safety for the patient in our cases is therefore narrowed.

It appears to be the idea of some physicians that the ability to resect ribs and find the phrenic nerve is the foundation of thoracic surgery. I have seen well-known physicians undertaking surgery for collapse in which they clearly showed their fundamental lack of surgical training in their floundering technique and repeated violation of general surgical principles. It is true that it is possible for anyone with a little knowledge of anatomy and with brief or no surgical training, to find the phrenic nerve, but the number of serious, or even fatal, complications on record following this minor operation in the hands of unskilled operators is appalling. The small incision, for example, may meet an exceptionally large vessel, or the operation may at times become difficult and dangerous enough to require the utmost resourcefulness of an experienced surgeon.

The question of whether the operation of thoracoplasty should be undertaken in a sanatorium or in a general hospital is still a vexed one. American opinion seems to be unanimous that it is unjustifiable for a surgeon to perform a thoracoplasty in a sanatorium if he is unable to make daily visits to the patient during the important post-operative period.

In my opinion, although a surgeon dislikes to operate on a case which he is unable to follow closely, it is not essential for him to visit the patient daily if a suitably trained resident assistant is available.

The plan of transferring the patient to the general hospital has obvious disadvantages. These include problems of transport, the change of the patient to an unaccustomed environment, the lack of separate accommodation for open cases of pulmonary tuberculosis, and the use of attendants and nurses who are not trained in the regime of a sanatorium. A properly equipped sanatorium should, I believe, have on its visiting staff a surgeon who is able to visit the sanatorium as often as once a week for purposes of consultation and operation.

The evolution of thoracoplasty

The study of the evolution of thoracoplasty is a very interesting one. In 1885 De Cernville of Lausanne first realized the need of breaking the continuity of the rigid thoracic wall in order

to collapse the lung effectively. The idea first occurred to him after studying the work of Simon (1869) and Estlander (1879) and his own work on empyema (1877). He performed four operations for apical tuberculosis where he removed 3.5 cm. of the 2nd and 3rd ribs, or as many ribs as necessary according to the extent of the cavity. This pioneer work is the beginning of the evolution of modern postero-lateral thoracoplasty operations. In 1888, and later in 1896, Quincke advocated small costal resections for cavernous and non-cavernous lesions. In 1890 Karl Spengle advocated the removal of greater lengths of rib through a para-scapular incision. Until 1903 Garre, Bier, and Landerer practised thoracoplasty but were dissatisfied with the resulting incomplete collapse. Brauer, in 1906, argued that clinical success could only be attained when the collapse of the lung affected by operation was similar to that attained by pneumothorax, and he felt the need of the removal of the entire length of the ribs from the 2nd to the 9th to obtain actual compression rather than mere relaxation.

Friedrich, on 17th December, 1907, undertook this heroic operation for him and performed it on M. Cordier who survived the operation and who, fourteen months later, was labelled as an arrested case. He performed the operation under a local anæsthetic, supplemented by a light general one. These two surgeons quickly improved their technique, and suggested a two-stage operation, sub-periosteal resection of ribs, the limited resection of the upper ribs to avoid flutter, and positive pressure breathing, and also suggested cough-resisting drugs. In 1911 Friedrich further modified this operation and performed the para-vertebral thoracoplasty. Brauer differed from Friedrich and developed his subscapular para-vertebral thoracoplasty. Wilms, of Heidelberg, in 1911 developed his own technique and included the 1st rib. Sauerbruch of Marburg, later of Zurich and Munich, and now of Berlin, devised in 1909 his famous operation of para-vertebral thoracoplasty, using a long vertical incision through the skin and muscles to the ribs. This was the first real para-vertebral operation ever performed for pulmonary tuberculosis. In the beginning he was not satisfied and used a variety of new operations, finally perfecting his technique in 1924. He insisted that the lower ribs should be first removed to prevent aspiration, and he initiated the two-stage operation as advocated, but not practised, by Brauer. It was he who first realized the importance and significance of the removal of the 1st rib, and declared in his unique manner that, whatever else is done, the 1st rib must be removed under all circumstances.

The modern operation consists of the removal of the postero-lateral parts of ribs and varying lengths of the anterior portions of the ribs in several, not one or two, operative stages. The majority of patients require the removal of

seven or eight ribs. Experience shows that Sauerbruch's and Brauer's operations left too much of the antero-lateral portion of the ribs. Alexander, of Michigan, perfected the modern postero-lateral operation in 1928 and began to remove still greater lengths of the upper ribs. O'Brien and Alexander showed that by the postero-lateral incision the costal cartilage, and even the sternum, can be removed. The modern operation involves the removal over the diseased lung of the transverse processes of the corresponding vertebræ as well as the ribs, the upper ribs being removed first.

Physiology of thoracoplasty

The alteration of the physiology of respiration in collapse therapy takes place in two ways: firstly, by reduction in the size of the thoracic cavity and, secondly, by restricting the movement. With this reduction of the thoracic space there is a reduction in the pulmonary volume and increase in intra-pleural pressure similar to that of pneumothorax.

I have noticed that some authors use the terms atelectasis and collapse vaguely, confusing their readers. The pathogenesis of the two conditions are quite distinct and should not be confused with one another. Collapse is a mechanical diminution in the volume of air in the lung, while atelectasis is caused by occlusion of the arterial blood supply or the airways, followed by absorption of the air from the parenchyma. Atelectasis cannot be produced by external pressure, so that, if a lung becomes atelectatic after collapse therapy, then endobronchial obstruction or bronchial kinking should be suspected. It has been conclusively proved by extensive experiments carried out by Alexander, that the following pathological changes occur after collapse of the lung: (1) In the early stage a slight histiocytic reaction in the septa and in the perivascular and peribronchial spaces, terminating in slight increase of connective tissue. (2) Thickening of pleura to a slight degree without evident inflammatory changes, probably due to slowing of lymphatic flow. (3) Relative local anæmia. (4) Slight dilatation of lymphatics. (5) Alveolar cells may in part become cuboidal, resembling the embryonal state. (6) There is neither atelectasis nor diffuse fibrosis, this point being the most important one.

The outstanding effect on the tuberculous focus after collapse is, of course, fibrosis, which causes encapsulation of the diseased tissue, fibrotic organization of the lesion, and an increase of perivascular, peribronchial and septal connective tissue. The way in which healing takes place under collapse therapy is far from settled, but it is possible to enumerate the factors which contribute towards the process of healing. They are: (1) Elastic relaxation which eliminates strain on diseased tissue, thus enhancing scar contraction and collapse of cavities. (2) Relative or absolute rest secured by the decrease

in thoracic movements. (3) Actual compression of pulmonary tissue. (4) Restriction of respiratory amplitude, hindering bronchogenic spread. (5) Relative anæmia hinders blood-borne spread. (6) Lymph stasis diminishing toxæmia.

Type of operation.—It was my impression that, apart from the modern postero-lateral operations, other types of thoracoplasties are now obsolete, although as late as 1937 I saw Professor Sauerbruch in Berlin and Professor Kunz in Vienna performing the Wilms-Sauerbruch type of operation, beginning with the lower ribs and doing the whole operation in either one or two stages. They also removed the transverse processes of the corresponding vertebræ. The research carried on by Walter, Graf, Balle, and Alexander had improved the technique so greatly that the other types of operation were rendered obsolete. I was surprised to note that in the book *The Operations of Surgery*, published as late as 1936, Rowlands and Turner make no mention of the modern postero-lateral operation or the removal of the transverse processes, but, instead, give a detailed description of Sauerbruch's operation, the author stating: 'if the operation is performed in two stages the lower ribs, usually 5th to 11th, should be excised at the first operation, the upper 4th and 5th ribs at the second'. In *Post Graduate Surgery*, edited by Rodney Maingot and published in 1937, in which the chapter on thoracic surgery is contributed by Holmes Sellers, there is also no mention of Alexander's operation, neither is there any mention of the special instruments. He describes in great detail the total paravertebral operation in (1) single stage and (2) two or more stages, and remarks: 'only a short length of the 11th rib must be taken, if that rib is touched at all, and increasing lengths of ribs are removed until 6 to 8 inches are resected about the level of the 8th rib. From this point there is a reduction until at the 2nd or 3rd rib only 3 or 4 inches are excised'. Further, he says: 'It has been emphasized that rib must be removed as close to the transverse process as possible, and if a projecting stump is left, powerful punch forceps are used to remedy the defect...excision of transverse processes is sometimes practised to enhance the posterior collapse'. *Pulmonary Tuberculosis* by Kayne, Paget, and O'Shaughnessy, published in 1939, also recommends the paravertebral operation as the operation of choice, and further recommends the carrying out of the lower stage first—in order to avoid the danger of aspiration...the extreme posterior end of the rib, up to, or even including, the tip of the transverse process, is excised'. This book, however, mentions the modern postero-lateral operation, but does not advocate its general adoption. I am not aware of the position in Great Britain to-day, but in America all operations, with the exception of the modern postero-lateral operation, are now regarded as

obsolete. In Calcutta, one surgeon is still doing the Sauerbruch type of operation, without removing the transverse process, but others are doing the modern postero-lateral type of operation. In the Madanapalli Centre also this is the type of operation performed. Mirajkar of Lahore usually removes the first seven or eight ribs, with their transverse processes, in one or two stages, and removes a large portion of the posterior angle of the scapula, after the American surgeons. We, however, have only done the modern postero-lateral type.

The modern postero-lateral operation

The patient.—Although the general condition of the patient should be the main consideration in determining whether a thoracoplasty can be performed with reasonable safety, we are faced with many problems, as already noted, the unwillingness on the part of the patient in general, in Delhi, to submit to a major operation being the chief handicap. Otherwise, the number of suitable patients in the Silver Jubilee Tuberculosis Hospital is enormous. It has been my practice to give to the patients a general picture of the whole operation and to explain to them that the chance of complete recovery is good, and then leave it to the patient to decide. I have been disappointed to find that the majority dread the operation so much that they choose instead an almost certain death from tuberculosis, which, because it is not immediate, is to a great extent unrealized.

On broad principles we prefer patients (1) who are in the third or fourth decade, although we have a case on our records of a boy of 6, on whom a thoracoplasty was done with excellent results; (2) as a rule we do not take cases unless the cardio-circulatory functional reserve is satisfactory. We are guided in this by the blood pressure readings and pulse and respiratory rates taken during strict rest, two to five minutes after mild exercise; (3) if the daily morning temperature on the chart shows a horizontal line, we consider this as a point in the patient's favour; and (4) we have so far selected only unilateral cases.

In conclusion we chose patients in a fairly good general condition, who have had no recent exacerbation of the disease, whose cardiac and respiratory reserves are adequate, and who are apparently unilateral cases whose lesion is predominantly cavernous and exudative in nature, and in whom other revocable operations have failed to arrest the lesion.

Pre-operative management.—I have already expressed the view that major surgery for pulmonary tuberculosis is best undertaken in a sanatorium which is equipped for the purpose. In order to emphasize the importance of suitable nursing facilities and the psychological effect of environment on the patient, I am repeating these points. As we transfer the patient to the Irwin Hospital we defer the operation for several days in order to give the patient rest,

both physical and mental, after his journey. Before the operation we take a fresh roentgenogram to verify the exact condition of both the lungs. We daily measure the amount of sputum for two reasons: (1) comparison with the post-operative amount, and (2) for guidance in the choice of anæsthetic. Carter has recommended routine digitalization of patients before operation and I have done it in two cases, but gave it up on the advice of our cardiologist, who was of the opinion that the digitalization of an essentially normal heart is more likely to be detrimental than beneficial. During the pre-operative resting period we carefully avoid increasing the patient's apprehension of the operation by telling him that the operation has been postponed on account of pressure of other work, so that he may not feel that extra precautions are being taken presumably because he presents a poor risk. The night before the operation a mild purgative is given. We do not as a rule give any sedative, but half an hour before the operation 1/6 gr. of morphia is given. A sedative might prevent free evacuation of sputum and atrophine makes the sputum sticky and difficult to expectorate, causing stasis of secretions. Finally, a few hours before operation the patient is advised to cough out as much sputum as possible, to procure an emptying of the lung.

Anæsthesia.—Theoretically, the ideal anæsthetic should: (1) give a wide margin of safety; (2) be non-irritating to the lung; (3) be able to maintain quiet respiration and retain the cough reflex during complete analgesia; (4) allow a rapid recovery from narcosis in order to enable the patient to cough and expectorate voluntarily immediately after the operation; (5) not cause acidosis; and (6) not cause vomiting. Probably nitrous oxide and O_2 come nearest to the ideal. Local and regional anæsthesia meet all the requirements. In America there is a preference for gas and O_2 , but in the British Isles, chloroform, with or without local anæsthesia, was in favour at least until recently. On the Continent in general and in most clinics in India, local anæsthesia is preferred. Sauerbruch's anæsthetic of choice is ether. The general opinion to-day is that either chloroform or basal narcotics are more dangerous than gas or local anæsthesia, from the point of view of pulmonary complications.

Gas has the advantage of quick induction, and maintains the cough reflex. There is rapid recovery and other obvious advantages, but gas anæsthesia requires a preliminary opiate and frequently ether, or avertin, has to be added as anæsthesia cannot be maintained with gas alone without a dangerous degree of cyanosis. It requires a very skilled anæsthetist who can administer the correct proportion of gas and oxygen to maintain the cough reflexes and keep the patient quiet, and, at the same time, anæsthetize without sub-oxidation. Although we possess a very up-to-date gas and oxygen

apparatus we do not have, at present, the advantage of an anæsthetist highly experienced in gas and oxygen administration. Nitrous oxide further causes a large amount of fluid loss due to perspiration, and is often followed by vomiting. Ethylene has a very disagreeable odour and is highly inflammable. We have no experience of cyclopropane. Lastly, all gases are neither easily available nor sufficiently cheap for use on a large scale in India.

Theoretically, local anæsthetics should be an ideal form of anæsthesia. The greatest disadvantage in my opinion is that an operation of such magnitude as thoracoplasty is an insupportable ordeal for the average patient. I have done several major abdominal cases under local anæsthesia, but patients have invariably been faced with such a great psychological shock that from the very beginning I felt a great diffidence in using it for thoracoplasty. It is not always possible to produce a satisfactory anæsthesia with non-toxic amounts of the drug and it is also more difficult to produce for the subsequent postero-lateral stages, because of the difficulty of free dissemination of the solution. In the presence of extensive scarring it becomes quite impossible.

Although the fact that local anæsthesia demands extreme gentleness on the part of the surgeon might be considered an advantage, yet it does not permit of the rapid completion of the operation. Also, though the initial bleeding may be less, there is a greater tendency to bleed after the completion of the operation, on account of the passing off of the effect of adrenalin (if used) and the pressure of the injected fluid on the tissues.

The chances of poisoning, apart from individual susceptibility, are also great in the use of a local anæsthetic. In mild novocain poisoning there can be pallor, light cyanosis, a slow and then fast pulse, hiccough, and vomiting and this condition may be indistinguishable from surgical shock. There are sometimes delirium, collapse, and convulsions, due to small quantities of the local anæsthetic entering a vein or nerve sheath.

We, therefore, use pure ether, at times inducing with a little open ethyl chloride. I follow Sauerbruch in this respect and believe that ether has no unfavourable action on the lungs. We have used this anæsthetic in all our cases of thoracoplasty, and so far have never regretted it. Our anæsthetist is experienced enough to be able to maintain a slight cough reflex and at the same time produce a good anæsthesia. We have not had a single case of aspiration pneumonia, or any other post-operative pulmonary complication, even when the sputum was more than 30 c.cm. in 24 hours. We do not favour the induction of anæsthesia in an ante-room, but begin in the operation theatre, as this permits of the painting of the skin and draping of the patient before he is fully anæsthetized, thereby shortening the administration of the anæsthetic to the patient by five or ten minutes—which we believe to be of considerable importance to the patient. We keep

the patient at 15 to 20° Trendelenburg position throughout the operation, to assist the flow of the cavernous and bronchial secretions into the mouth by gravity, and so prevent their aspiration into the lung.

I have already said that the modern postero-lateral operation is the only operation done by us, because I consider the para-vertebral and other types of operation are nowadays, if not obsolete, at least rapidly becoming so. Statistics show that the best results in all respects are obtained by this type of operation, performed in two or more stages. We differ from Alexander and others in removing the first four ribs completely. This procedure does away with the risk of having to do a supplementary anterior thoracoplasty for incomplete closure. We have not, so far, regretted having taken this attitude. We remove the transverse processes as routine, and rarely remove more than three ribs at a time.

The modern operation is virtually the same in extent as the original Brauer-Friedrich operation, except that the former is performed with far greater safety in multiple stages and includes the removal of much greater lengths of the upper ribs as well as the transverse processes.

The dogmatic insistence of Sauerbruch, and others, resulted in the acceptance of removal of the lower ribs before the upper ones. They believe that the early collapse of the lower lung prevents aspiration from the diseased upper area to the lower area when the upper lung is collapsed later. Sauerbruch considers this point so important that he strongly opposes selective thoracoplasty of the upper ribs. The available evidence does not entirely justify Sauerbruch. Alexander studied this question and came to the conclusion that aspiration pneumonia can and does occur after the primary resection of the upper ribs, but the risk is considerably less than when the lower ribs are resected first. Aspiration pneumonia is rare in extra-pleural pneumolysis with paraffin filling. This is probably because the function of expectoration is very little impaired after operation. The abdominal muscles and the lower thoracic muscles are not interfered with, hence coughing is comparatively painless. There is no evidence to prove that a thoracoplastic collapse of the lungs prevents gravitation or even aspiration of secretion into the collapsed lung. It is probable that the bronchial secretions are frequently aspirated or they gravitate to the uninfected portion, but coughing and ciliary action removes them before they can do any damage. Interference, therefore, with the efficiency of coughing is the most important cause of aspiration pneumonia. The lower thoracic walls and the abdominal muscles play the most important rôle in the function of coughing and expectoration. The resection of the lower ribs in the first instance necessarily weakens the lower thoracic wall and makes the abdominal muscles painful. The abdominal muscles and the lower thoracic wall are not interfered with in the primary resection of the upper

ribs. The patient is unable to control the act of coughing so as to restrict it to one side of the chest, and the pain and paradoxical movements following a lower thoracoplasty tend to prevent efficient coughing. These facts together with the fact that the lung on the other side is somewhat more liable to inhale infectious secretions, account for the higher percentage of post-operative pneumonia in the uncollapsed lung. The importance of doing the upper ribs first in the presence of a large amount of secretion is more obvious. Further, it is more convenient to control the more extensive area first, which is usually in the upper lobe. The diminution in the amount of sputum following the first stage makes the more dangerous second stage safer. Finally, if the operation has to be suspended on account of unforeseen circumstances the performance of an upper first stage will have produced at least a partial effect. Nowadays it is rarely necessary to remove more than six, seven, or eight ribs. Incidentally it is no longer necessary to paralyse the diaphragm before starting a modern postero-lateral operation. The resection of the upper ribs collapses only that part of the lung which lies under those ribs, but when the resection of the lower ribs is performed, the upper ribs maintain a suspensory and hoop-like effect on the rest of the lung. And when, finally, the upper ribs are reached, there is a sudden great collapse of the whole lung, not only that portion of it immediately underlying the last resected rib, but of the more extensive portion that had been suspended and held open by the uppermost ribs. Consequently the patient is exposed to the danger of too sudden a collapse of a tuberculous lung.

The number of stages to be performed in a modern operation depends on the vertical extent of the lesion. Alexander has rarely removed more than six or seven ribs. In our experience, however, in almost all cases we had to remove nine ribs, excepting in one case out of twenty-one, in which we were satisfied with a six-rib resection. The reason probably is that our patients come to the surgeon a little too late. Alexander's usual procedure is two and a half, two and a half, and two ribs, whereas we resect three ribs at one stage. The extent of thoracoplasty to be performed is decided by us before undertaking the operation, and the apparent clinical arrest of the disease after having performed two stages does not deter us from performing the third stage. If we find that the lesion is sufficiently high to require the resection of only five or six ribs we usually do an eight-rib operation so that the lower end of the scapula will not remain posterior to the unresected ribs, because the permanent pulmonary collapse is much better when the entire scapula has fallen into the costal defect than when only the upper portion of the scapula has tilted into it. In such circumstances Mirajkar of Lahore resects the inferior end of the scapula which he believes causes

sudden pain by slipping over the upper end of the uppermost unresected rib. We have so far had no occasion to do a supplementary anterior thoracoplasty because, in order to avoid this possibility, we have removed the entire length of the first four or five ribs. Although Sauerbruch prefers a one-stage operation, I have seen him performing his operations in two or more stages. The chief advantage of multiple stages is that they unquestionably reduce the mortality as well as permit the removal of a greater length of rib, and consequently give a high percentage of closure of cavities.

We make an effort to keep the time interval between stages at three or four weeks but we are handicapped by various factors, chief amongst them being the reluctance of the patient to undergo the second stage at such a short interval. Our average interval has been six weeks, the minimum being three weeks and the maximum four months.

Modern thoracoplasty closes more than twice as many cavities as does the Wilms-Sauerbruch operation. This is entirely due to the removal of greater lengths of the ribs. If sufficiently great lengths of the ribs over the lesion are removed without too great a delay between the stages, few cavities resist closure. We do not deny that the para-vertebral operation does close a certain number of cavities, but decision as to the relative value of para-vertebral and the modern operation must depend upon the basis of the results in a large series of cases of both the types. The conclusion is inescapable that the surest way of producing a great collapse is by removing greater lengths rather than a greater number of ribs. Many textbooks emphasize the fact that the number of ribs resected and the length of a resection depend on the nature of the lesion. It is obvious that some cavities are more stiff-walled than others. It is true that soft-walled cavities will collapse by the removal of small portions of the ribs, but it is not possible clinically to assess entirely the degree of stiffness of the wall. Hence, while performing thoracoplasty, I believe that the maximum benefit should be offered to the patient by the removal of maximum lengths of rib. The risk in removing large portions of two or three ribs in one stage is very small. In the presence of very large cavities we remove not only the rib at the costochondrial junction, but also make an effort to remove bits of the cartilage of the first three ribs. We have, so far, not regretted having done so, and have come to the conclusion that the paradoxical movement is probably less after an extensive resection than after a limited resection because of the greater descent of the collapsed upper lung. Alexander has great fears about such a step by which the collapse is sudden and extensive. The mortality in cases where he has performed this technique has been very high and he has uttered a warning against the complete removal of the first four or five ribs, strongly advocating the performance of a supple-

mentary anterior thoracoplasty if required. In our series of twenty-one cases we have been fortunate in that we have not lost a single case after the first stage. We have, however, had three deaths out of the twenty-one cases in the second stage and have come to fear this stage.

We have procured for our thoracoplasty operations a few special instruments. We have Alexander's periosteum raspatories, square and round ended, Brewster's appendicectomy retractor for sacrospinalis muscle, a costotome, Sauerbruch's large square-nosed double-action rongeur, and a small rongeur.

Operation.—We place the patient on his side in 15° Trendelenburg, placing a rubber air ring beneath the patient's dependent shoulder to prevent the formation of a decubitus. The uppermost arm is hung over the edge of the table to assist in the forward displacement of the scapula. The dependent arm is thus anterior to the axis of the body preventing the patient's rolling forwards. We use sandbags instead of the Tudor Edwards anterior chest support. A strap is adjusted over the crest of the ileum tangentially to prevent the patient's sliding towards the head. The surgeon who makes the skin incision stands at the back of the patient and resects the costal end of the rib, while the first assistant performs the resection of the vertebral end including the transverse process. We have a second assistant to retract the sacrospinalis muscle. All our cases have been done by Colonel Cruickshank and myself together, the incision being made by the person under whose charge the case has been.

The incision is begun 5 cm. inferior and posterior to the anterior border of the trapezius muscle and is carried downwards several centimetres medial to the vertebral border of the scapula; it then curves laterally below the inferior angle of the scapula and is continued to the mid-axillary line. We incise the skin and the subcutaneous tissues and then identify the auscultatory triangle (figure 1). We consider it important to divide the entire thickness of the muscles at once, so that the immediate retraction of the muscles seals many of the small vessels. The larger vessels can be quickly clamped by two of the surgeons while the second assistant keeps on mopping. Carter has devised an excellent technique of dividing the muscle, but I have seen several surgeons performing thoracoplasty completely disregarding Carter's technique. (An incision that passes through only a part of the trapezius muscle at the first stroke of the scalpel is apt to result in so much bleeding as to invite the clamping of the vessels before the incision through the muscle is completed. The blood loss is enormous and the sight ghastly.) The surgeon and the assistant on the opposite side each introduces his index finger or thumb into the auscultatory triangle and then upwards between the ribs and the rhomboideus muscles. Each pinches the muscles between the forefinger and

thumb, or merely presses upwards with the forefinger while one of them divides the pinched section with seissors. Then each in turn elamps the large vessels whose position is indicated by

Fig. 1.—Showing the auscultatory triangle.

Fig. 2—A. The surgeon and an assistant have introduced a forefinger and a thumb in the auscultatory triangle and then upwards deep to the rhomboides major muscle.

(From Carter—Surgery, Gynaecology and Obstetrics.)

the spurt of blood when the compression is momentarily relaxed. After the vessels have been secured, the fingers are advanced to the next section of the muscle (figure 2). The process is repeated until the vertical and eurved sections have been completed. When we have had difficulty in finding the triangle, we have resorted to splitting the fat over the probable site and pushing the fingers through to reach the under surface of the muscle. I have seen some surgeons controlling the hæmorrhage by doubly elamping with long slender clamps section by section before dividing them, and at the end of the operation suturing the muscle over the elamps before removing them. Theoretically this is an excellent procedure, but the crushing of so much muscle invites infection and there is a greater danger of secondary hæmorrhage. After the skin and muscles are excised, the vessels ligated, and the skin towels placed, the vertebral border of the scapula is lifted posteriorly and laterally and the loose areolar tissue between the scapula and the ribs is divided by several sweeps of the fingers covered with gauze. The digitations of the origin of the serratus magnus are clearly visible upon the ribs. The digitation on the second rib is more posterior than the others and projects backwards as a crest when the scapula is retracted (figure 3). This crest serves as a

Fig. 3.—Digitation on second rib standing out as a crest when scapula is retracted.
(From Alexander.)

convenient identification mark for the second rib. Beginning from the second digitation the muscle is raised from the upper five or six ribs. Care must be taken while separating the first digitation from the first rib to avoid danger to the braehial plexus and great vessels. We do not apply clamps on the divided edge of the muscle for fear of injury to the long thoracic nerve: we have found that hot mops are sufficient to stop hæmorrhage from one or two vessels in the muscle. The separation of the

serratus magnus origin has not so far interfered with the return of the function of the shoulder girdle in any of our cases, probably on account of the rapid adhesion of the muscle to the decostalized thoracic wall. We start by removing the second rib. In one of our cases we found the identification of the second rib difficult. In that case the radius of curvature of the first rib was simulating the second rib. We realized our error after we had seen the brachial plexus. The postero-lateral portion of the first rib has upper and lower surfaces and inner and outer borders, whereas all the other ribs have inner and outer surfaces and upper and lower borders. After removing the second rib, the removal of the first rib becomes easier. We remove the first rib after the second because of the possibility of having to suspend the operation after removing two ribs. If the third rib were removed before the first and the patient's subsequent condition did not permit the continuation of the operation, the first rib could, of course, be removed at a second operation, but its presence would interfere with the collapse between the operations. I believe that the first rib keeps the lungs suspended and expanded.

The subperiosteal resection of the ribs, excepting the first, is begun by separating the sacrospinalis muscle which extends to the costal angle. Retraction of the muscle is easier if the separation is carried two or three ribs above or below the rib to be resected.

We do not divide any perforating vessel from the intercostal space to the muscle medially to the tip of the transverse process, because the posterior rami of the thoracic nerves accompany them. The horizontal division of the sacrospinalis should be avoided because it leads to scoliosis. We strip the ribs bare of the periosteum with Alexander's periosteum raspatories. Then we divide a large central bit of the rib with the help of the costotome, after which the surgeon who is standing behind the patient frees the stump of the rib up to the sternum and removes it with or without the cartilage. The surgeon standing in front of the patient removes the posterior end and the transverse process. Here we have devised a technique which we consider very useful. With a pair of blunt-pointed curved scissors we deliberately divide the superior costo-transverse ligament on either side; then we divide the lateral and inferior costo-transverse ligaments. By this means we are able to depress the posterior end of the rib and then dislocate the whole rib together with the head by touches of scissors cutting the intra-articular ligaments (figures 4 and 5). This procedure exposes the under surface of the transverse process to view completely. Now the retraction of the sacrospinalis muscle exposes the transverse process in such a manner as to permit its complete removal under direct vision, by means of a Sauerbruch's rongeur (figure 6). Sometimes this procedure causes bleeding from the posterior external plexus of veins. This is

easily controlled by small hot mops. After dislocating the rib, if we find that the oozing from the posterior plexus is troublesome, we place a hot piece of mop at the site and postpone the removal of the transverse process till the next rib is removed, when the removal of the mop leaves a dry area.

Fig. 4.—A. Infra-articular ligament.
B. Superior costo-transverse ligament—cut.
C. Lateral costo-transverse ligament.
D. Inferior costo-transverse ligament.

The original method of removing the transverse process and the posterior end of the rib together with the rongeur has been found by us to be unsatisfactory. The transverse process has not been sufficiently removed and the head and part of the neck of the corresponding rib have been left behind, and the rongeur is used more

Fig. 5.—A. Superior costo-transverse ligament.
B. Infra-articular ligament.
C. Radiate ligament.

or less blindly (figure 7). We also make a point of removing the transverse process of the first rib because we dislike seeing the transverse process of the first rib standing out grotesquely in the x-ray picture. The first rib is more difficult and dangerous to remove. The first

step in freeing the first rib is to push off the periosteum and muscles from the outer border of the rib. The abducted position of the arm carries the brachial plexus and great vessels away from the upper surface, but they are in

Fig. 6.—Showing how when the rib is disarticulated from the articular surface, the transverse process becomes visible.

danger of being injured where they cross the inner border. When the upper border is being freed, if the index finger is placed under the lower surface of the rib so that the tip of the finger lies against the inner border, the danger

Fig. 7.—When the rib is not disarticulated the head, a portion of the neck and a portion of transverse processes are left behind.

of the instruments plunging over the inner border and injuring the vessels and nerves or the pleura is prevented. The end of the instrument and the tip of the finger should be held

close against one another, while the former rapidly separates the Sibson's fascia and muscular attachments. When the rib has been freed, the cartilage is divided with a costotome and the rib is removed. Then the extreme anterior end of the cartilage is removed with rongeurs, leaving only a little piece of the cartilage beneath the sterno-clavicular joint.

After the rib and transverse processes have been resected, the muscles are closed in one layer with continuous or interrupted catgut, and the skin is closed with interrupted silkworm gut. We insert a long drainage tube for thirty-six hours. A voluminous dressing is placed over the wound and bandaged in position. We fix the arm to the side because in our first case there was some gaping of the wound due to sudden violent movements by the patient. The weather conditions in Delhi, especially in summer, do not permit vaseline dressing or elaborate elastoplast. We perform the second stage through the same incision after excising the scar of the first operation. We sometimes do the third stage through the lower three-fourth of the same incision, but usually prefer a separate incision.

Post-operative management.—The surgeon who undertakes to perform a thoracoplasty assumes the heavy responsibility of supervising the entire post-operative care. There are few operations which demand as much expenditure of the time and attention to detail as does thoracoplasty for phthisis. In the absence of a trained team of nurses, I delegate to my house surgeon the constant attendance upon the patient during the first day and night after each stage and I tell the nurse to help him if the patient vomits. As soon as the patient is returned to the ward, I give either CO_2 inhalation for five minutes every hour or make the patient inhale smelling salts until he comes round. As the patient comes round the nurse is instructed to stand by him and insist upon his coughing and expectorating at frequent intervals. She assists in this at hourly intervals by gently and firmly pressing with her open hand on the antero-lateral portion of the decostalized segment during coughing. She should wipe away the sputum from the lips rather than have him expectorate into a cup. Warm sodium bicarbonate solution or lemonade, or the inhalation of steam helps to raise tenacious sputum. Coughing is best encouraged by insisting upon the taking of several deep breaths. To assist this, hourly CO_2 inhalations for five minutes are useful. Atropine is not given as a routine, but if the sputum is too abundant atropine may be given. Morphia or omnopon is useful when the cough reflex is present, but painful. We record the pulse rate and systolic and diastolic blood pressures every fifteen minutes during the first hour, every thirty minutes during the next two hours, and three-hourly during the next forty-eight hours. External heat is applied if the patient's rectal temperature is below 97° . We

begin intravenous saline in the operation theatre and continue it in the ward until 3,000 c.cm. are given in six hours. We use 5 per cent glucose saline. As the nausea disappears small amounts of water, fruit juice or weak tea are given at fifteen-minute intervals. If rectal fluid is to be given we prefer tap water. An enema is given three days after the operation and a solid diet of high calorific value is started as soon as the patient is able to take it.

The patient is returned from the theatre on his own bed of which the foot is raised 40 cm. to combat low blood pressure or prevent stasis of secretions. The foot of the bed is kept raised until the condition of the pulse and blood pressure is wholly satisfactory, and until the patient is able to expectorate freely, i.e., for the first two or three days. The head of the bed is not raised, the only exception being when the patient is dyspnoic. If the patient is tired of lying flat on his back he may be allowed to turn on the side operated on twenty-four hours after the operation, but not on the sound side for a week, for the reason that the secretion would gravitate into the sound lung. I place a sandbag on the side of operation below the clavicle, to increase the collapse (after 24 hours) and to control paradoxical movements. If paradoxical movement is present from the beginning a 2-lb. bag is placed in position immediately after the operation. If symptoms of early shock appear, the foot of the bed should be further raised and an injection of ephedrine and morphia given. It is best to continue the intravenous saline or gum acacia solution. Transfusion of whole blood or serum is given if necessary. To combat severe paradoxical movement and mediastinal flutter, inhalation of oxygen is useful, although in Sauerbruch's opinion positive pressure breathing is the only suitable treatment. Oxygen by funnel is considered useless. It should be given by intranasal catheter at 4 to 8 litres per minute. It is surprising how slight the post-operative pain is. Pain is only experienced during coughing and this can be lessened by the nurse's aid. It can be controlled by omnopon or morphia, but a too frequent use of morphia is to be avoided as it abolishes the cough reflex. If the patient complains of pain, the loosening or tightening of the bandage, or the direct inspection of the wound for the presence of a stiff suture sticking out, or of a too-tight skin suture, and attention to them will often alleviate pain. Pain in the arm in one of our cases was very severe, probably on account of injury to the first thoracic nerve, but it disappeared, without any ulnar paralysis.

Complications are dyspnoea, auto-tuberculinization, hiccough, and vomiting. Dyspnoea is best controlled with oxygen, hiccough is usually stopped by CO_2 , and vomiting is best treated by giving no fluids by mouth and adding sodium chloride to the intravenous transfusion fluid.

For some time after the thoracoplasty, a patient requires a support for the thoracic wall

which has been extensively decostalized, but he must be made to understand that the support is only a temporary one. Otherwise I have seen patients wearing the support for months together, for they are usually reluctant to discard the chest support. The brace should be discarded when after its removal there is no increase in sputum, no rales and no appearance of fever. We have used a modification of Woodruff's brace.

The surgical supervision of the patient is begun by us a few days before the operation when we transfer the cases from the various institutions into our wards. We continue to maintain charge of the patient until two or three weeks after the last stage has been performed. Between stages I send my patients back to the Silver Jubilee Tuberculosis Hospital or the Rama-krishna Mission Clinic after removal of the stitches, but the cases that come from outside Delhi are kept in the hospital until all the stages have been finished. When patients are sent back after a stage they still remain under my supervision. The period of sanatorium supervision is decided by the physician.

It is surprising how slight is the visible change which occurs in the shape of the thorax after such extensive decostalization. There are depressions above and below the clavicle, the scapula is less prominent, the shoulder is probably a little higher than the normal side, and one or two long scars are visible in the back. There is usually a slight upper thoracic scoliosis (figure 8), but if the patient is clothed, it is often difficult to tell upon which side the operation has been performed. In one of our cases we encountered 'snapping scapula' because the patient refused further operation after having undergone a two-stage six-rib resection. He has merely a disagreeable sensation of jumping of the scapula. The full range of movement of the shoulder joint has always been maintained in all our cases.

We have so far completed thoracoplasty operation in only 21 cases for tuberculosis of the lung and one Schede's thoracoplasty has been performed by us for tuberculous empyema. The latter patient died from shock after the operation. Out of our 21 cases there have been three deaths—a mortality rate of 14.25 per cent. All the three deaths occurred after the second stage. Two of them, both men, came from outside Delhi and were not under our observation for a sufficiently long time before the operation. The third case was a woman, suffering from Jacksonian epilepsy for which no cause could be found. She stood the first stage very well, although she had several fits in the ward. We were much encouraged by this and performed the second stage after four weeks. She had no post-operative paradoxical movements, nor was the shock too severe. On the eighth day, about an hour after the stitches had been removed, she went into a fit and never recovered from it. No post mortem could be performed as the relatives did not give us the necessary permission. One

case, as already mentioned, refused a third stage and his sputum is still positive and the cavity did not collapse sufficiently, although he apparently is better as his temperature never rises above 99.4°F. and he has less sputum.

Seventeen of our cases show no bacilli in the sputum and are afebrile; also the E. S. rates are considerably diminished. Eight of them

Acknowledgments

I wish to express my gratitude to Colonel Cruickshank who has given me whole-hearted encouragement and help and has collaborated with me in all the cases. My thanks are also due to Dr. R. Krishna, internist at the Silver Jubilee Tuberculosis Hospital, Dr. A. Roy Chowdhry of the Ramakrishna Mission and

have returned to their daily routine of life and are earning a livelihood or doing housework. Although the remaining nine cases have been allowed to go home as arrested cases, they are still under our observation as the E. S. rates are higher than normal and expectoration is still present. They have been advised not to start work yet. The eight 'cured' cases visit us once in three months.

Dr. Sikand of the New Delhi Tuberculosis Clinic for their constant advice and co-operation in selecting cases and persuading them to undergo the operation. My thanks are also due to my past and present house surgeons who have been of such great assistance to me. I also express my special gratitude to my wife, Dr. Sita Sen, who has kept all my records, arranged them for me and helped me in preparing this paper.

BILATERAL THORACOPLASTY : REPORT ON 10 PATIENTS TREATED IN THE WANLESS TUBERCULOSIS SANATORIUM

By G. SAMUEL, M.B., B.S., F.A.S.C.

Medical Superintendent, Wanless Tuberculosis Sanatorium, Wanlesswadi, District Satara

THE efficiency of thoracoplasty in the treatment of pulmonary tuberculosis is universally admitted today. This surgical treatment of bilateral caseo-pneumonic affection with cavitation and with much fibrotic changes in the lesion situated in the apical and sub-clavicular region was done by Graveson as far back as 1931. Since then several European thoracic surgeons have done bilateral thoracoplasty. In the year 1936, Coryllos and Ornstein gave an illustrated report on 7 bilateral thoracoplasty cases done in Sea View Hospital.

Ten such patients were treated by bilateral thoracoplasty in the Wanless Tuberculosis Sanatorium during 1938 to 1941, a period of three years.

In all cases a fair trial of artificial pneumothorax treatment was given. In most of the cases artificial pneumothorax could not be induced and in some it was contra-selective. All cases were operated on with the procedure of paravertebral extra-pleural thoracoplasty as described by Sauerbruch and O'Shaughnessy (1937) with slight changes. The ribs generally resected at the first stage were, first, second and third; in the second stage fourth and fifth and in the third stage, the anterior stumps of first, second and third ribs by anterior approach. In all these cases the operation was done under local anaesthetic. Half per cent procaine was used and a basal anaesthesia with morphine and atropine and, in certain cases, nembutol. There are several advantages in performing the operation under local anaesthetic. One of them is that there is a good co-operation between the patient and the surgeon. If the patient feels dyspnoeic due to mediastinal flutter (if the rigidity of mediastinum is not sufficient which happens in some cases) or respiratory embarrassment, the surgeon is informed of these symptoms and uses his discretion and stops the operation for the time being, continuing after an interval of three weeks to a month. Hence, sometimes the resection of only one rib is done, sometimes two; sometimes the ribs are resected as far as the midaxillary line, sometimes only a few inches are removed. Another advantage of this procedure is that post-operative complications, such as excessive vomiting, aspiration-pneumonia and non-tuberculous broncho-pneumonia, can possibly be avoided.

The interval between the thoracoplasty on one side and on the other is three to six months and the interval between the stages is three weeks to six weeks.

The following indications and contra-indications were strictly followed.

Indications :—

1. Bilateral apical and sub-clavicular infiltration with much productive element in the lesion.
2. Good respiratory reserve.
3. The general condition of the patient both physical and mental is good.

Contra-indications :—

1. Exudative lesions without much productive element.
2. Vital capacity decidedly low, below 1,000 c.cm.
3. Respiratory embarrassment even during moderate exercise.
4. If the cavities are inferior to the level of the posterior ends of the 4th or 5th ribs.
5. Extra-pulmonary focus of infection in kidneys, and gastro-intestinal tract.
6. Valvular disease of the heart.
7. Myocarditis.

The following five illustrated cases are given :—

Case 1.—Female, aged 36 years, was admitted on 12th July, 1940, for bilateral caseo-pneumonic infiltration with much fibrosis, the apices and sub-clavicular regions being affected. Artificial pneumothorax was tried on both sides but failed due to thickened pleura. Therefore, first stage posterior paravertebral extra-pleural thoracoplasty operation was performed on the left side on 18th July with resection of first, second, and third ribs. After an interval of nearly three months and a half, first stage thoracoplasty operation on the right side was performed, with resection of first, second and third ribs with good collapse of lung. The patient was discharged in an excellent state of health as an arrested case. (Arrested according to the report of the sub-committee on classification of tuberculosis 1941.)

Case 2.—Male, aged 24 years, was admitted on 3rd August, 1938, with bilateral caseo-pneumonic affection with much fibrotic changes on both apices. Artificial pneumothorax was tried on the left side but failed; artificial pneumothorax on the right side was tried and was successful, and the patient had selective artificial pneumothorax. When his general condition improved after nearly six months, left side thoracoplasty operation was done on 29th April, 1939. The patient was discharged as a much improved case with good selective artificial pneumothorax on the right side and a negative sputum. The patient promised to continue his right artificial pneumothorax after discharge from the sanatorium. He was readmitted on 2nd May, 1941, with a positive sputum. He did not continue his artificial pneumothorax and the cavity reopened on the right apex. Artificial pneumothorax could not be induced again, therefore, first stage thoracoplasty on the right side was done resecting first, second and third ribs. The patient did very well and was discharged as an arrested case.

Case 3.—Male, aged 38 years, was admitted on 4th April, 1940, for bilateral caseo-pneumonic infiltration with much fibrotic changes. Artificial pneumothorax was tried on both sides but failed because of thickened pleura. First stage thoracoplasty operation was performed on the right side on 15th April, first, second and third ribs being resected with good collapse. Then, after a period of nearly five months when the general health of the patient improved, left first stage thoracoplasty was done on 7th September, first, second and third ribs being resected. Later an anterior stage was done on the same side with removal of the anterior stumps of first and the second ribs. The patient was

EXTRA-PLEURAL PNEUMOTHORAX POCKETS WITH SINUSES

By G. SAMUEL, M.B., B.S., F.A.S.C.

Medical Superintendent, The Sir William Wanless
Tuberculosis Sanatorium, Wanlesswadi

THE value of extra-pleural pneumothorax in the treatment of certain cases of pulmonary tuberculosis was established by the work of

(Continued from previous page)

discharged in an excellent state of health as an arrested case.

Case 4.—Male, aged 32 years, was admitted on 13th August, 1938, for bilateral caseo-pneumonic infiltration with much fibrotic change in the lesions. Artificial pneumothorax was tried on both sides but failed because of pleural symphysis; therefore left first stage thoracoplasty was done on 13th January, 1939, first, second and third ribs being resected. Within one month second stage on the same side was done fifth and sixth ribs being resected. A month later a third anterior stage was done the anterior stumps of first, second and third ribs being resected with a good collapse. The patient was discharged at his own wish after a further period of six months, as much improved (quiescent) case. Patient was readmitted eight months later with signs and symptoms of tuberculosis with positive sputum. The right lung showed active lesions. The right side thoracoplasty was done in two stages, five ribs being resected. The patient was later discharged as an arrested case.

Case 5.—Male, aged 45 years, admitted on 30th August, 1938, for bilateral caseo-pneumonic infiltration with much fibrosis. Artificial pneumothorax was tried on both sides but failed. Therefore, first stage thoracoplasty operation was done on the left side small lengths of the first four ribs being resected. Second stage was done nearly a month later, the fifth rib and the anterior stumps of second, third and fourth ribs being resected. After an interval of nearly three months first stage thoracoplasty was performed on the right side, the first five ribs being resected. This was done because there was little collapse after the removal of the first three ribs. The patient was later discharged as an arrested case.

Discussion

A report is made of ten patients on whom bilateral thoracoplasty operation was performed. Notes on five cases are presented.

The mortality is nil and the results of the operations are very encouraging. The patients were discharged as arrested cases and are to this day keeping good health and doing their regular work. Indications and contra-indications were strictly observed. Local anæsthesia was used. There were no post-operative complications. The operations were performed in several small stages at suitable intervals.

Graf and Schmidt. A number of papers have appeared explaining the indications and contra-indications of the operation, and several others assessing the results of the operation.

In this operation the stripping of the two layers of pleura from the wall of the chest must be done very carefully. When the pleura is separated from the chest wall an extra-pleural space or pocket is created, which is maintained by occasional re-fills with air as is done in artificial pneumothorax treatment. The procedure keeps the lung collapsed and thus the underlying disease of the lung may be brought under control. If the operation is too extensive, there is the risk of hæmorrhage into the space and consequent infection; and, if the operation takes a long time (as it always does), the resistance of the tissues is lowered and infection often takes place.

It is difficult for the thoracic surgeons to solve the problem of infection that takes place in the extra-pleural space, which is one of the grave complications of this operation. It is extremely difficult to avoid infection because, in all these cases, the general condition of the patient is poor and the operation is extensive and prolonged.

If infection occurs, pus forms in the extra-pleural space, and several sinuses are formed at the site of the opening made in the thoracic wall and also at other places. The extra-pleural pocket resembles an abscess cavity with the difference that, while in an ordinary abscess cavity the walls are elastic, in this space the walls are rigid, consisting of ribs, etc. Therefore this cavity is not obliterated spontaneously as are other abscess cavities, when the pus is drained. Further, the obliteration of the cavity does not take place, since the collapsed lung does not re-expand to fill up the cavity created by the operation. Therefore the treatment consists in collapsing the rigid walls to obliterate infected space. This is achieved by doing a paravertebral extra-pleural thoracoplasty operation.

In this sanatorium extra-pleural pneumothorax was done in sixteen cases; in nine, i.e., 56 per cent of the cases, this pneumothorax was maintained and the patients were discharged as much improved. One patient died of shock after the operation. Two patients were discharged as hopeless cases because of the bilateral infiltration of the lungs and poor general condition. In four cases the extra-pleural pneumothorax pocket became infected. Of these four patients two died without a thoracoplasty operation being performed and the other two patients, on whom thoracoplasty was performed, were later discharged as arrested cases.

These two illustrative cases are given below :—

Case 1.—Mrs. R. S. was admitted on 27th July, 1941, with sinus on the right side due to infected extra-pleural pocket, after operation. After nearly a year and a half, the sinus had not closed. Her sputum was negative. First stage thoracoplasty operation was

BEHAVIOUR OF THE CONTRALATERAL LUNG IN AMBULATORY CASES UNDER UNILATERAL PNEUMOTHORAX TREATMENT

(A RECORD OF 500 CASES)

By P. K. SEN, M.B. (Cal.), T.D.D. (Wales),
M.D. (Berlin), Ph.D. (Wales)

Junior Visiting Physician

and

K. N. DE, B.Sc., M.B.

Research Assistant

(From the Department of Chest Diseases, Medical College Hospitals, Calcutta)

THE number of tuberculosis cases found suitable for artificial pneumothorax treatment at the out-patient's section of the chest department, Medical College Hospitals, is always far in excess of the bed capacity of the hospital. Due to this extreme dearth of beds it was decided that, after the first refill, cases would be treated as out-patients. Such ambulant treatment is likely to be risky in various ways. Fresh spread or extension of the disease in the contralateral lung is an important risk among them. As the force of circumstances made us introduce this line of treatment in 1930 and as sufficient data have accumulated by this time, it is important that an assessment of this risk should now be made. This paper has been strictly restricted to the observations on the behaviour of the contralateral lung under this ambulant unilateral pneumothorax treatment.

In unilateral collapse, the other lung is subjected to influences both for and against the formation of new lesions or exacerbation of pre-existing lesions. The factors for it are strain for compensating function, increased chance of aspiration of pressed-out infective material, and sudden and heightened auto-tuberculization (as reported by Alexander, 1937). The factors against it are ultimate diminution of toxæmia, closure of main infective foci or cavities, congestion (Bier's effect) and relaxation, to a slight extent, produced in the contralateral lung, as shown by Ascoli (1929) and Simon (1921).

Rist (1927) in his series of 759 cases recorded 75 per cent of the deaths as due to contralateral

spread. Matson *et al.* (1924), on the other hand, recorded serious extension of contralateral disease in 7.9 per cent in a series of 480 cases. Simon (1921) showed that pneumothorax had no bad effect on the lesions of the contralateral lung of rabbits in which the lesions had been produced by intravenous injection of tubercle bacilli. Burrell and Macnalty (1922) had noted that 'a small lesion in the better lung disappears or becomes much improved when the other lung has been collapsed'. Their question 'what effect do you consider a pneumothorax has upon the other lung?' put to medical superintendents of sanatoria brought out the following information; in 67 cases of Carling, the better lung 'lit up' in 5 cases. Morriston Davis noted improvement in the secondary lesions but no effect on the healthy or primarily infected lung. Felkin, Fernandez, Lillingston, Lucas, Pearson, and Woodcock saw good results, and Riviere, Rolleston, Sutherland, Tattersall, Walker and Wingfield saw good or no ill effect with certain reservations.

Most workers to-day believe that collapse of one lung, if produced gradually, not only entails no great hazard for the other lung, but actually acts beneficially on the lesions in it, or diminishes the chance of formation of new lesions in it. Almost all the investigations done on this subject related to sanatorium patients. Such patients were generally well-controlled, and pneumothorax therapy was conducted non-ambulant for the first few months at least.

The present series of patients were in quite a different category. After the initial artificial pneumothorax, they were hospitalized for only 24 or 48 hours. Thereafter the patients had to travel from home for refills. Our patients are generally of the poor class and, Calcutta being a large city, most of them had to travel 4 to 6 miles in public conveyances. Many came from neighbouring places 20 to 25 miles away from the town. Besides this exertion of the journey, many of them continued to work or began work much too soon, or could have no adequate rest at home, chiefly for financial reasons. It will therefore be realized that the likelihood of contralateral spread or exacerbation was likely to be much more in this series than in the sanatorium group of patients. We believe that the conditions of administering artificial pneumothorax are almost the same everywhere in India. It should, therefore, be worth while recording our findings, in order to try to improve our judgment in the selection and control of such artificial pneumothorax cases in future.

Method of collection of data and some general information

All the records of artificial pneumothorax cases from 1930 to 1940, whose treatment had been concluded or abandoned, were examined. Cases with incomplete records or in which the duration of artificial pneumothorax was less than 6 weeks were excluded from this series.

(Continued from previous page)

done on 15th August; this closed the extra-pleural pocket, the sinus healed and the patient was discharged in an excellent condition on 4th September, 1941.

Case 2.—Mr. V. C. was admitted on 8th April, 1940, for bilateral caseo-pneumonic infiltration. As his general condition was poor extra-pleural pneumothorax was done on the left side on 31st October under local anaesthesia. The cavity closed and the sputum became negative. The contra-lateral spread improved but the extra-pleural pocket became infected and developed a sinus. The patient was slowly getting worse because of the infection. On 24th January, 1941, the sinus was enlarged and packed with iodoform gauze, with no effect. Therefore thoracoplasty was undertaken in four stages with the result that the pocket closed.

The numbers of completely recorded cases included each year from 1930 to 1940 were as follows:—1, 1, 4, 18, 45, 53, 62, 88, 106, 78, and 44. The records of the earlier period were not so complete as those of later years; this accounts for the small numbers of cases quoted from the earlier years.

The causes of abandonment of artificial pneumothorax at the out-patients' section of the chest department and their numbers in each group were as follows:—patients' inability to continue—277, obliterative pleurisy—83, ineffective collapse—35, hospitalized—19, contralateral spread—32, and termination after optimum conduction—54 = total 500.

It is evident that artificial pneumothorax had to be abandoned prematurely at varying periods

affected contralateral lung, (c) the lesions improved, (d) the lesions remained stationary, and (e) the lesions progressed.

Tables are made to show the above-mentioned groups in relation to (1) some epidemiological factors, (2) the types of lesions and complications, and (3) some special factors connected with the conduct of artificial pneumothorax. A general table, without any special consideration of any factor, comparing the condition of the contralateral lung before and at the termination of artificial pneumothorax, has also been included. Conclusions were drawn whenever the findings on statistical analysis possessed a sufficiently significant value.

(A) *Behaviour of the contralateral lung in relation to some epidemiological factors.*

in many cases due to the inability of patients to come for treatment. These cases had been included in this series to get a true cross-section of results as they occur in an out-door dispensary.

The information about each case was collected in a specially prepared statistical schedule, punched and tabulated at the statistics department of the All-India Institute of Hygiene and Public Health. For dearth of space the general schedule and many other tables could not be incorporated in this paper.

The condition of the contralateral lung previous to the induction of artificial pneumothorax was recorded in four main groups: (1) normal; (2) minimal lesion, when its extent was less than half a lung zone; (3) moderate lesion, when its extent was from half to one zone; and (4) lesion with cavity. In order to assess the effect at the abandonment of artificial pneumothorax, the changes were observed and recorded in the following manner: (a) contralateral lung remained normal, (b) the normal contralateral lung was affected, and in previously

The above table produces comparable data in the 15 to 24 years and 25 to 39 years groups, the other two groups being small. The data clearly show that the danger of contralateral spread or exacerbation is much greater in the 15 to 24 years or young adult group than in the 25 to 39 years or adult group. The previously normal lung of the former group was affected in 30.9 per cent and of the latter only in 17.7 per cent; pre-existing minimal lesions of the former group, 35.2 per cent and of the latter, only 19.9 per cent, progressed; of 'moderate lesion' and in 'lesions with cavity' groups, the corresponding figures are 33.3 per cent and 31 per cent and 40 per cent and 16.7 per cent. It is also noticeable from a comparison of all the groups that with the advancement in age, the chance of contralateral spread becomes less.

It will be seen that the previously normal lung was affected more in males than in females; whereas the pre-existing lesions progressed more in females than in males. This difference in behaviour is interesting, showing more potentiality of a lesion in females but no more

or even less likelihood of developing fresh lesions.

The Hindus and Moslems show comparable data, other groups are rather small. The

figures tend to show that the contralateral lung of the Moslems fared worse than that of the Hindus both in the previously normal and pre-existing lesion groups.

TABLE II
Sex and behaviour of contralateral lung

The figures indicate that the normal contralateral lung was affected and pre-existing contralateral lesions were exacerbated in greater number in those with a history of contact than in those without it.

(B) *Behaviour of the contralateral lung in relation to the types of the lung lesions, complications, etc.*

(1) *Stage of the disease (according to Turban-Gerhardt classification).*

classification committee of the Tuberculosis Association of India.

Exudative and productive were those where the lesions were predominantly so. Intermediate was a mixture of the above two in almost equal proportions. Each of the above types were divided into 'with' and 'without' cavity. As there were only 9 cases in the 'productive' class, they are not shown in the table. All the three types of the pre-existing lesion in the contralateral lung are shown together to avoid too much subdivision of the numbers.

TABLE VI
Stage of disease and behaviour of contralateral lung

State of contralateral lung before artificial pneumothorax	Normal		Minimal lesion			Moderate lesion			Moderate lesion with cavity			Total
Behaviour after artificial pneumothorax	Normal	Affected	Improved	Stationary	Progressed	Improved	Stationary	Progressed	Improved	Stationary	Progressed

The figures in the table show that a normal contralateral lung before artificial pneumothorax has a much greater chance of remaining unaffected if the treatment is started at an earlier stage of the disease. The general trend in pre-existing lesions also shows that the progress of contralateral lesions is less when the treatment is begun at an earlier stage of the disease.

It will be seen that in both types of cases, with or without lesions in the contralateral lung before artificial pneumothorax, the type of lesion, exudative or intermediate, in the collapsed side exerted no remarkable influence on the fresh spread or exacerbation of the lesions in the contralateral lung. It will however be clearly seen that lesions with cavity, both exudative and

TABLE VII

Lesions on the artificial and pneumothorax side and behaviour of the contralateral lung

TOTAL ..		201	62	77	90	61	491

intermediate, on the artificial pneumothorax side exerted a harmful influence on the contralateral lung. Cases with such lesions showed more frequent involvement in the previously normal lung, and also more frequent progression of already existing lesions in the contralateral lung.

(3) *Character of lesions in the contralateral lung*

TABLE VIII

Character and behaviour of the contralateral lung lesions

Character		Improved	Stationary	Progressed	Total
Exudative	With cavity	1 10.0%	5 50.0%	4 40.0%	10
	Without cavity	60 35.3%	66 38.8%	45 24.9%	171
Intermediate	With cavity	3 75.0%	..	1 25.0%	4
	Without cavity	11 35.5%	16 29.0%	12 35.5%	39
Productive	With cavity
	Without cavity	2 33.3%	3 50.0%	1 16.7%	6
TOTAL ..		77	90	63	230

Out of 230 cases in the 'contralateral lung lesions' group, 171 were of the 'exudative without cavity' type. Other groups are not large enough to serve the purposes of comparison. However, when the two largest groups, 'exudative' and 'intermediate without cavity', are compared they showed progression of lesion in

24.9 per cent and 35.5 per cent respectively. This seems to indicate that the prognosis of the exudative contralateral lung lesion is better than that of the intermediate type. This finding may be due to the greater chances of retrogression of lesions of the exudative type than of the intermediate one.

(4) *Cases with positive and negative sputum (by ordinary smear and concentration tests only).*

Sputum condition was unknown in 6, so they are not included in the table.

The figures definitely show that in the 'sputum positive' group a large number showed affection of the normal contralateral lung and a large number of already existing lesions in the contralateral lung progressed. It can, therefore, be said that the prognosis of the contralateral lung is better in the sputum negative cases than in the sputum positive ones.

In the series, 429 had no complication, 7 had pregnancy, 14 had glandular involvement, 31 had laryngeal and 8 had intestinal tuberculosis, 3 had effusion and 8 had other complications. As each group with one complication is small, they are all shown together in a table in contrast to the 'no complication' group.

Cases without any complication or with it show in almost equal proportions involvement of a previously normal contralateral lung, but in the 'pre-existing contralateral lesion' group the lesions progressed in far greater number in the group with complications (54.3 per cent) than in the group without it (23 per cent). It seems, therefore, that the presence of complications has no remarkable effect on a normal contralateral lung but has a definitely harmful influence on the pre-existing contralateral lesion.

(C) *The behaviour of the contralateral lung in relation to some special factors connected with the conduct of artificial pneumothorax.*

after the induction of artificial pneumothorax. Thereafter it does not show this tendency to any marked degree. The findings regarding progression of the pre-existing contralateral lesion are similar. Thus it seems that the maximum hazard for the involvement of or spread of lesion in the contralateral lung exists during the first year of conduction of artificial pneumothorax. Improvement of the contralateral lesion, on the other hand, shows no such time demarcation. The longer the treatment, the greater is the incidence of improvement in contralateral lesions.

per cent, 23.6 per cent and 19.3 per cent). This tendency is also seen in moderate lesions and lesions with cavity in the contralateral lung, though the numbers are small and are not comparable. The improvement in the contralateral lesion is seen in greater numbers in the 'effective collapse' group (51 per cent) than in the 'partial' (37.6 per cent) and 'ineffective' (14.2 per cent) groups.

It, therefore, appears that the danger of contralateral lung involvement or spread of lesion diminishes according to the effectiveness of the collapse; least in effective collapse, more

TABLE XII

Nature of collapse of the artificial pneumothorax side and behaviour of contralateral lung

State of contralateral lung before artificial pneumothorax	Normal		Minimal lesion			Moderate lesion			Moderate lesion with cavity			Total
	Normal	Affected	Improved	Stationary	Progressed	Improved	Stationary	Progressed	Improved	Stationary	Progressed	
Effective collapse ..	79 85.9%	13 14.1%	24 51.0%	14 29.7%	9 19.3%	12 66.6%	5 28.0%	1 6.4%	1 100%	158

TOTAL ..	206	64	60	59	41	13	26	17	4	5	5	500

(2) *Nature of collapse and contralateral lung.*

It is evident that with 'effective collapse', the chances (14.1 per cent) of formation of new lesions in the previously normal contralateral lung are much less than with partial (28.8 per cent) and ineffective (28.1 per cent) collapse. As is seen, the danger of new lesions in cases with partial and ineffective collapse is almost the same.

The chance of progression of pre-existing contralateral minimal lesions diminishes with the increase in effectiveness of the collapse (42.9

with partial collapse and most in ineffective collapse.

(3) *Mobility of the mediastinum and contralateral lung.*

The groups, as shown in the table, are not of comparable size, yet they tend to show that the involvement of a previously normal contralateral lung is little influenced by the mobility of the mediastinum; but that pre-existing contralateral lesions more frequently progress in those with a definitely mobile mediastinum (47.8 per cent) than in those with almost fixed mediastinum (25.2 per cent).

TABLE XIII

Mobility of the mediastinum and behaviour of the contralateral lung

State of contralateral lung before artificial pneumothorax	NORMAL		PRE-EXISTING LESION			Total

TOTAL ..	206	64	77	90	63	500

A general consideration of the condition of the contralateral lung before and at the termination of artificial pneumothorax.

The table below shows that out of 500 cases, the contralateral lung before artificial pneumothorax was apparently normal in 270 and was affected in 230. Among the 'normal' groups, 64

or the extension of pre-existing lesions, in the other lung.

Summary

1. An attempt has been made to find out the behaviour of the contralateral lung during ambulant unilateral artificial pneumothorax treatment.

TABLE XIV

Condition of the contralateral lung before artificial pneumothorax	CONDITION OF THE CONTRALATERAL LUNG AT THE TERMINATION OF ARTIFICIAL PNEUMOTHORAX					
	Normal	Affected	Improved	Stationary	Progressed	Total
Normal	206 76.3%	64 23.7%	270
Minimal lesion	60 37.5%	59 36.9%	41 25.6%	160
Moderate lesion	13 23.2%	26 46.4%	17 30.4%	56
Moderate lesion with cavity	4 28.5%	5 35.7%	5 35.7%	14
TOTAL ..	206 76.3%	64 23.7%	77 33.5%	90 39.1%	63 27.4%	500

(or 23 per cent) cases developed lesions in the contralateral lung during the course of treatment. In those cases in which a contralateral lesion existed before the induction of artificial pneumothorax such lesions improved in 77 or 33.5 per cent, remained stationary in 90 or 39.1 per cent, and progressed in 63 or 27.4 per cent cases. It will, therefore, be seen that during the conduct of artificial pneumothorax treatment, a previously normal contralateral lung was less frequently affected (23.7 per cent) than the lesion in previously affected lung progressed (27.4 per cent). Nevertheless, the difference is slight and the danger not greatly increased. The results appear to justify the use of ambulatory pneumothorax treatment in bilateral cases, if the other lung is not severely affected.

The table also shows that, the more severe a contralateral lesion is, the greater is its chance of progression. Out of 160 cases with minimal contralateral lesion, 41 or 25.6 per cent progressed, 60 or 37.5 per cent retrogressed; in the moderate lesion group of 56 cases, 17 or 30.4 per cent progressed and 13 or 23.2 per cent retrogressed and in the lesions with cavity group of 14 cases, 5 or 35.7 per cent progressed and 4 or 28.5 per cent retrogressed during the period of artificial pneumothorax treatment. These findings suggest, generally, that the progression or retrogression of a lesion in the contralateral lung is mainly dependent on the inherent nature of such a lesion.

In the absence of a control group not treated by pneumothorax no attempt is made to determine whether collapse of one lung either encourages or prevents the formation of fresh lesion,

2. For this purpose, details of 500 cases are given.

3. The effect in unilateral conduct of artificial pneumothorax on the contralateral lung has been shown generally and in relation to (a) some epidemiological factors, (b) the types of the lung lesions and complications, and (c) some special factors connected with the conduct of artificial pneumothorax.

(a) Epidemiological factors :—

The danger of the contralateral spread (development of a lesion in a previously normal lung) or exacerbation of the pre-existing lesion was greater in the young adults (15 to 24 years) than in the adults (25 to 39 years), in Moslems than in Hindus and in those cases with a history of contact than in those without it. The frequency of exacerbation of the pre-existing lesions was greater in females than in males and habitation showed no significant influence.

(b) Types of lung lesions and complications :—

The danger of contralateral spread or exacerbation of the pre-existing lesions was found to be greater in cases with cavity in the artificial pneumothorax side than in those without it and in cases with positive sputum than in those with negative sputum. Exudative lesions in the contralateral lung retrogressed in greater number than with intermediate lesions. In cases with complication the pre-existing lesion progressed in greater number than in those without it.

(c) Some special factors connected with the conduction of artificial pneumothorax :—

(Concluded on opposite page)

EARLY DIAGNOSIS AND TREATMENT OF INTESTINAL TUBERCULOSIS

By A. C. UKIL

(From the Department of Chest Diseases, Medical College Hospitals, Calcutta)

Pathology

TUBERCULOUS lesions in the intestines are strictly comparable to such lesions elsewhere in

(Continued from previous page)

The maximum hazard for the contralateral spread or exacerbation of the pre-existing lesions was noticed during the first year of the treatment, whereas with longer treatment the improvement of the contralateral lesions was found to be more frequent.

The danger of contralateral spread or exacerbation of the pre-existing lesions was found to vary inversely with the degree of collapse; the more effective the collapse the lesser was the danger.

A definitely mobile mediastinum was associated with more frequent progression of the pre-existing lesions than was an almost fixed mediastinum. Mobility of the mediastinum had no appreciable effect on a healthy contralateral lung.

4. A general consideration, without taking any special factors into account, showed that the lesions in a previously affected contralateral lung progressed slightly more frequently than a previously normal lung developed lesions. The results justified the use of ambulatory A.P. treatment in suitable bilateral cases. It also showed that the progression or retrogression of the contralateral lesions was mainly dependent on the potentiality or intrinsic nature of such lesions.

Acknowledgment

We are grateful to Dr. A. C. Ukil, senior visiting physician, Chest Department, Medical College Hospitals, Calcutta. This work would never have been possible without his continued interest, help and guidance.

Our thanks are due to the Vital Statistics Department of the All-India Institute of Hygiene and Public Health for facilities for statistical analysis given to us and to Mr. N. K. Basu, statistical clerk of the Bengal Tuberculosis Association, for his help in sorting out cards and in tabulation.

the body. There is initial swelling, with hyperæmia, and it is possible that some early lesions may subside at this stage. As a rule, however, the disease advances and the next stage is one of caseation, after the formation of small tuberculous nodules. The superficial epithelium is next shed and the typical tuberculous ulcer results. Progression and retrogression of different lesions take place side by side, as in pulmonary tuberculosis, and the behaviour of the lesions depends on the bacillary insemination, or toxic action, in the area, which bring about varying degrees of hypersensitiveness of the tissues to tuberculo-toxin with consequent necrosis or hyperplasia, as the case may be.

There are three possible routes by which tubercle bacilli reach the bowel: direct contact, the blood stream and the lymphatics. The tubercle bacillus is prone to attack lymphoid structures. There is very little lymphoid tissue in the upper part of the digestive system and the main collection is found exactly in those parts in which tuberculous ulceration is found to be most common and with which swallowed sputum remains longest in contact, owing to its comparatively slow movement. It seems most likely that the bacillus attacks the bowel through the lymphoid tissue of the Peyer's patches and from there it may spread by lymphatics to the regional glands which are commonly involved. Microscopic examination at first shows a diffuse hyperæmia and round-celled infiltration of the whole intestinal wall, and both the nerve plexuses are as a rule affected, thereby disturbing the nervous control of the bowel, which may account for such symptoms as pain and diarrhoea. The lesions occur anywhere in the small intestine or colon, but in most patients the lesions first develop in the ileo-cæcal region and may remain confined to that region for quite a long time.

The data collected from 1,000 consecutive autopsies performed in the Calcutta Medical College Hospitals, and analysed by me in 1930, indicated that 12.8 per cent of the cases had died of tuberculosis, and that in another 4.8 per cent tuberculosis was found to complicate other diseases. Thus, there were 176 cases of tuberculosis in the above series. In 51.1 per cent of the cases tuberculous ulceration of the intestines was secondary to pulmonary tuberculosis but in 5.1 per cent no demonstrable tuberculous lesions were present in the lung or any other organ. The appendix was involved in 3.9 per cent and the peritoneum in 13.0 per cent of the 176 cases.

In children, there is a predilection for the involvement of the lymph nodes and peritoneum. Tuberculous peritonitis may give rise to adhesions, effusions, or caseous collections between adherent coils of intestine. Tuberculous adenitis may be the principal feature in a case in childhood or adolescence. In adults, the stress of the disease falls on the intestines and is seen in two distinct pathological forms—(a) destructive or ulcero-caseous, and (b) productive or hyperplastic.

Tribedi and Gupta (1941) have recently analysed the evidence obtained in 4,000 consecutive autopsies done between 1905-1940 in the same institution, and have supplied us with extremely interesting figures on the localization and types of intestinal tuberculosis found at autopsy. 45.8 per cent of the cases of tuberculosis in their series showed intestinal lesions, 41 per cent secondary pulmonary tuberculosis, and 4.8 per cent were without any demonstrable pulmonary lesions, as compared with 7 per cent in Viswanathan's series of cases at Vizagapatam (Viswanathan, 1940). Although no part of the intestines was exempt from lesions, the most frequently involved part was the ileum (86.7 per cent), the ileo-cæcal region coming next in order (65 per cent), and the jejunum third (34.5 per cent). Lesions were limited to the small intestines in 31.5 per cent and to the large intestine in 12.3 per cent, and were found in both the small and the large intestines in 56.1 per cent of cases. In Europe and America (Brown and Sampson, 1926) the ileo-cæcal region was found to be involved in 86.7 per cent of cases of intestinal tuberculosis, in contrast to 65 per cent in Tribedi's series. Mesenteric lymphadenitis was present in 80.7 per cent of Tribedi's cases; thus in nearly 20 per cent of the cases of intestinal tuberculosis no glandular involvement was present. In 1 per cent of the cases showed some collection of fluid in the peritoneal cavity. The incidence of appendicular involvement in Europe and America (32-41.7 per cent) is higher than in Calcutta (cf. my figures—3.9 per cent quoted previously). Though the appendix was found to be so frequently involved in Europe and America, acute appendicitis was very rarely noticed in these cases.

Regarding the types of lesions in the intestines, Tribedi found that ulcerations were present in 95 per cent, tubercle formation without ulcers in 3 per cent, and that the lesions in the remaining 2 per cent showed the hypertrophic or hyperplastic form. The *ulcerative type* of lesion is caused by an invasion of the submucous lymphoid tissues. These cases showed little fibrous tissue production. This finding was in close correlation with the types of pulmonary lesions found in a majority of phthisis cases in this country. Although intestinal perforations are expected to be common in these cases, they were noticed only in 7 cases (or 1.2 per cent).

In three of the cases with tuberculous ulcers in the small intestines, Tribedi found in some places in the large intestine fringe-like processes projecting from the mucous membrane due to hyperplastic proliferation of mucous glands, with evidence of tuberculous tissue in the submucous region. These *polypoid* changes, as he calls them, might be due to irritation of the tissues by tuberculo-toxin absorbed from lesions in the neighbourhood.

In three of the cases with the *hypertrophic* or *hyperplastic type* of the disease, the lesions were

limited to the ileo-cæcal region, there was no ulceration and no attendant pulmonary lesions were noticed. Owing to the productive changes and hyperplasia in these cases, a thickened mass was present, which was likely to be confused with neoplasm, producing a boggy swelling, some tenderness on palpation, visible peristaltic waves and, in the later phases, even nausea, colicky pains and obstructive vomiting. In the other two cases of the hypertrophic type, productive changes were less marked and ulceration of the granulation tissue was present. These cases are thought to be due to tubercle bacilli of low virulence.

Most of these cases must have been in adults, as there are few beds for children in the Medical College Hospitals.

The question might arise as to how far bovine tubercle bacilli might be concerned in the production of some of the forms of intestinal and abdominal gland tuberculosis in India. It may be of interest to mention that out of nearly 250 strains of tubercle bacilli isolated from tuberculous lesions in many parts of the body at all ages, we have not yet been able to obtain a bovine type of bacillus (Ukil, 1933; Ukil and Guha Thakurta, 1936). All the twelve strains isolated from mesenteric glands of autopsy cases have been found by us to belong to the *human type*.

Symptoms

Tuberculosis is notorious for the diversity of its symptoms and the symptoms in intestinal tuberculosis are no exception to this rule. There may be little or no abdominal symptoms even in the presence of advanced disease; or there may be symptoms referable to the intestinal tract in cases in which no demonstrable lesions in any part of the bowel are found by barium meal demonstration and at post mortem. Walsh (1909) did not notice any symptoms in 26 out of 76 cases of intestinal tuberculosis. It has been noticed in the present series of cases, that with active exudative forms of pulmonary tuberculosis the abdominal symptoms usually appear eight to twelve months after the onset of the disease, or even earlier, and that in chronic cases, this period may be much longer. We have had cases of phthisis of five years' duration with no evidence of involvement of the gut, either clinical or radiological.

It must be borne in mind that intestinal lesions are not confined to the advanced stages of phthisis. The importance of early diagnosis of tuberculous enterocolitis arises from the fact that, if detected in its early stages, it can be cured by a combination of various methods, including radiation and vitamin therapy.

It should be borne in mind that the symptoms of intestinal tuberculosis, in the early stages, may be as slight and as indefinite as those of early pulmonary tuberculosis.

In the early stages there are usually slight digestive disturbances. Some degree of anorexia, a feeling of fullness and discomfort after meals which may be accompanied by gas formation and heartburn, unexplained loss of weight, a feeling of malaise, or brief attacks of diarrhoea which readily yield to simple remedies, are commonly present. But these symptoms are often so slight and of such short duration that their significance is apt to be overlooked. If in a known case of pulmonary tuberculosis, slight digestive symptoms are present, and particularly if the patient does not continue to improve, or gets worse, the possibility of the existence of intestinal tuberculosis should be considered, and a careful study made to confirm or exclude its presence, even if the lung lesions are improving or stationary.

As the disease progresses, the symptoms usually increase and vary with the location of the ulcers, the extent of irritation of the nerves, the condition of the mucous membrane, and the involvement of the peritoneum. Pain and diarrhoea are two of the commonest symptoms of intestinal tuberculosis.

Pain is by no means always present, but may be an early symptom. It usually commences in the centre of the abdomen, but later radiates towards the right iliac fossa. Occasionally it is referred to the epigastrium and it may have such a definite relation to meals that the presence of a gastric ulcer may be suspected. It is usually most marked in the afternoon, and it may be accentuated by food. The pain is at first transient and then gradually persists for a longer period. It may be cramp-like or stabbing or colicky in nature, and is aggravated by pressure over the ileo-cæcal region; the pain is probably due either to hypermotility and spasm of the intestinal muscles arising from local irritation of the nerve endings of Meissner's plexus, or to stenosis or to localized peritonitis. A throbbing or burning sensation in the abdomen is said to be associated with the involvement of enlarged mesenteric glands. Pain at the time of or after meals is usually due to reflex peristalsis in the ileum or colon.

Diarrhoea, although often regarded as a classical symptom, is by no means invariably present. Instead of diarrhoea there may be marked constipation, due to muscular spasm. Diarrhoea may be transient, with a perfectly normal bowel action in the intervening periods, or there may be alternate constipation and diarrhoea. Ultimately the diarrhoea becomes frequent, and continuous. The diarrhoea is possibly caused either by increased peristaltic movements or by diminished absorption of water, owing to interference with blood and lymph drainage. It is thought that while ulceration in the small intestine may be associated with diarrhoea or constipation, ulceration in the colon produces, as a rule, diarrhoea, and ulceration at the hepatic flexure of the colon is more commonly accompanied by constipation. The

number and situation of the ulcers have no clear relation to the severity of the symptoms, which may, in fact, be very marked when the only visible post-mortem change appears to be a simple catarrh of the mucous membrane. Tenesmus is present only in cases in which the rectum is involved. Although gross hæmorrhage is rare, intermittent passage of small quantities of blood is common. There is often an associated secondary anaemia. The involvement of the appendix seems to increase the severity of symptoms.

A rise in temperature may or may not be a prominent feature. In cases secondary to pulmonary tuberculosis it is commonly seen that when the pulmonary lesions show retrogression and the patient has remained afebrile for some time, with the involvement of the intestine, the temperature begins to rise again and remains raised, and there is often a steady loss in weight. Any patient with chronic pulmonary tuberculosis, therefore, who fails to gain weight or to make satisfactory progress, should be studied for the existence of tuberculous enteritis, no matter how slight the abdominal symptoms are.

Many of the above symptoms may, however, be present without any demonstrable disease in the intestines. They are then believed to be toxic in origin, and to be the result of functional disturbance in the mechanism of the bowel.

Physical examination, apart from the suspicion aroused by the pulmonary condition and the symptoms, may not reveal anything except localized tenderness in the right iliac fossa. Glandular masses are sometimes palpable. Muscular rigidity is present only when the peritoneum is involved, and when the infection is acute; it is also present in cases with perforation and localized peritonitis. Thus it appears that the presence of tuberculous entero-colitis is first suspected by an alert examiner and then confirmed by certain laboratory and radiological investigations, although the latter may not yield conclusive evidence in some cases. In a few cases, a diagnostic laparotomy and biopsy may be needed to settle the diagnosis.

For differential diagnosis, one has to take into consideration mucous colitis, chronic appendicitis, malignant neoplasms of the intestine, amoebic dysentery, sprue, pellagra, ulcerative (non-tuberculous) colitis, diverticulitis, achylia gastrica, hyperthyroidism and spastic colitis.

The following methods of diagnosis will be found to be useful:—

(a) Laboratory methods

Fæces.—The fæces in early cases are usually normal in appearance. As the disease progresses, they become at first mushy, then soft and finally liquid with a foetid odour due to the presence of albumin, pus and peptone. The liquid stool may be pale, due to excess of fat and fatty soap, or dark in colour and frothy, and may contain, besides particles of undigested food, mucus,

blood, pus or even small shreds of mucous membrane due to rapid peristalsis and extensive ulceration. A large majority of the cases in our series showed red blood corpuscles and also occult blood in the faeces. The faeces should invariably be examined for pus and red blood cells, intestinal parasites and occult blood. In examining stools for occult blood, precautions should be taken to exclude meat in the diet.

Twenty-five per cent of our phthisis cases, in which symptoms suggestive of intestinal tuberculosis were present, amebic infection was found and no evidence of intestinal tuberculosis by fluoroscopy and radiography. One interesting feature of these cases was the absence of loss of weight, which is so common in cases of tuberculous enteritis.

In cases of pulmonary tuberculosis with positive sputum, an examination of the faeces for the presence of tubercle bacilli, by ordinary or by one of the concentration methods, gives little assistance in determining the source of the bacilli. It should, however, be done as a routine procedure in all cases.

It has been thought that the presence in the bowel of large quantities of water-soluble serum proteins, derived from tuberculous ulcers, points to the presence of intestinal lesions. Triboulet devised a test for these proteins, which involves the addition of mercuric chloride and acetic acid to faecal extract and he claims to have obtained 99 per cent of results corresponding to the radiological appearance in these cases. We regret we have not been able to corroborate these claims.

Blood.—In most cases there is a relative increase of neutrophils and monocytes. The blood should always be periodically examined for total red cell count, haemoglobin, leucocyte count, sedimentation rate of red blood corpuscles and Houghton's or Frimodt-Møller and Barton's index. Any production of anaemia (as anaemia is generally present in these cases) or rise in sedimentation index should indicate active trouble in some area, and should lead us to investigate the condition of the intestinal tract, if no other detectable cause is found elsewhere. The sedimentation rate of blood usually rises, but this is not a constant feature. A certain amount of anaemia is almost always present.

(b) Roentgenological investigation

X-ray examination constitutes the best single means of diagnosis. The methods used are by no means infallible, and much experience is required to interpret the results.

Tuberculous enteritis involves most commonly the last 18 inches of the ileum, the ileo-caecal valve and the ascending colon. Non-tuberculous intestinal disturbances of slight degree rarely confine themselves to these regions. Localized spasm and hypermotility of the bowel occur in the region of the ulcers. These can be elicited by making the intestinal wall radio-opaque by an opaque meal (barium sulphate, sold under various commercial names such as

cyto-barium, neo-barium meal, x-ray shadow food, etc.) introduced from above by the mouth or in the form of an enema (barium sulphate or thorium oxide).

The preparation of the patient for the barium meal examination consists in giving a light purgative (such as pulv. glycyrrhizae co.—2 drachms) 48 hours before examination, followed by a high soap and water or saline enema 24 hours later. The diet should be light. On the morning of examination, he may have a light breakfast with as little milk as possible. Two hours after this, the barium meal, suspended in about 16 ounces of water, is given. The stomach and duodenum are first examined on the screen. The patient is again examined after four to five hours and at nine hours by which time the barium should have arrived at the caecum. If so, the patient is examined under the screen by palpating the ileo-caecal region, and this examination may reveal both tenderness and what is called the 'spastic filling defect,' which is due to the retention of the barium in the caecum though it is rarely filled. This is shortly followed by hypermotility. This spastic filling defect and tenderness of the ileo-caecal region are characteristic of the ulcerative type of intestinal tuberculosis. In the presence of the above findings, the dyspeptic disturbances, even though mild, in a patient with definite evidence of tuberculosis in the lungs or elsewhere, should be considered as caused by tuberculous disease of the intestine, unless proved otherwise.

Case.—Ileo-caecal tuberculosis (ulcerative type).

M. R., Hindu, male, 24 years, urban. Was in England for five years and while there he was once in hospital for chest complaints for a short period in 1933. Came with a history of fever (maximum daily oral 102°F.) for six months, moderate loss of weight, no cough or sputum; marked pain and tenderness in right iliac fossa for two months; poor appetite and constipation.

Physical signs.—Chest—nothing abnormal detected; skiagraph—no active lesions found; irregular diaphragmatic margin; a few peribronchial healed foci in left upper lobe. Abdomen—tender and palpable mass in ileo-caecal area. Stool—no amœba, ova or cysts found. Blood—no eosinophilia; sedimentation rate = 49.25 minutes mean; von Bonsdorff's count = 213, lympho-monocyte ratio = 3:1.

X-rays chest (figure 12). Chest skiagraph showing no active tuberculous focus in lungs.

Results of barium meal investigation.—1 four hours after barium meal shows at A—hypermotility in last inch of terminal segment of ileum with spasticity above; at B—same condition at caecum; at C—same condition in caeco-colic area.

2 and 3 taken at intervals of 5 seconds.

4—taken 10 seconds after no. 3, marked distension of the terminal end of ileum due to spasticity is well seen.

5 and 6 taken at intervals of 15 seconds—spasm has now given way, permitting the meal to enter the lowest segment of ileum and caecum.

7 to 11 taken at intervals of a minute: 7 to 9 the irregularity of the mucosal surface due to ulceration is clearly visible; 10 and 11—the passage of the meal through the ileo-caecal valve into caecum is clearly seen.

Fluoroscopic examination.—Five hours after barium meal showed presence of meal head in sigmoid (showing general hypermotility of the large gut) with a small quantity still present (due to spastic stasis) in ileum.

Fig. 9.

Fig. 10.

Fig. 11.

Fig. 12.

The patient made an uneventful recovery under hygiene-dietetic regime and the judicious application of ultra-violet radiation. The improvement has been maintained for two years and he has remained free from symptoms and physical findings of disease.

A barium enema, when introduced 24 hours after the barium meal, gives an outline of the colon and may reveal some phase of the defects in movements. The old barium enema has now been superseded by the barium-air three-stage enema. After the ordinary barium meal examination is made, the patient empties the bowel. A photograph is taken to show the mucosal pattern, if evacuation has been sufficiently complete. The colon is then inflated with a Higginson's syringe under radioscopic control. If too much barium remains, the patient is sent to stool and the process repeated. After final inflation, further photos are taken, preferably stereoscopic.

Recent work has shown (Maingot and others, 1934) that a labile colloidal aqueous suspension of thorium oxide, which has a greater tendency to deposit itself on the mucosa, gives a better outline than barium. The preliminary preparation of the patient is important, however, as the type of flocculation depends on the pH of the contents of the colon.

In considering various diagnostic procedures, it is well to remember that the presence of an associated tuberculous pulmonary lesion is only presumptive, and not conclusive, evidence of an intestinal lesion being tuberculous; and that tuberculous entero-colitis cannot be ruled out in the absence of a tuberculous pulmonary lesion, either clinically or radiologically.

In the rarer type of the hyperplastic form of ileo-cæcal tuberculosis, diagnostic problems vary with the stage of the disease. In the early stages, the symptoms usually simulate those of chronic appendicitis. In the intermediate stages, alternate constipation and diarrhoea, and perhaps a swelling in the right iliac fossa, may be the only features present, giving rise to difficulties of diagnosis from chronic dysentery, regional ileitis (Crohn's disease), carcinoma or unresolved appendical abscess. In the final stages, symptoms of chronic obstruction, becoming acute at times, are evident. Fluoroscopy four to six hours after a barium meal followed by radiography, carefully interpreted, often helps in diagnosis but in many cases biopsy finally solves it.

Findings in our cases

We had an opportunity to investigate only 50 cases of pulmonary tuberculosis irrespective of their abdominal symptoms, until the war interrupted our work. The following findings may be found to be of interest:—

Age.—16-25 years	30 cases
26-35 years	15 "
Above 35 years	5 "
Sex.—Male	25 "
Female	25 "

Initial pulmonary lesions.—

Exudative type of infiltration	..	20 cases
Intermediate type of infiltration	..	30 "
Unilateral lesions	..	25 "
Bilateral lesions	..	25 "
Under collapse therapy	..	40 "
Lesions in lung showed retrogressive changes in 80 per cent cases.		

Sputum examination (by smear method).—

Initially positive	..	30 cases
Positive sputum subsequently became negative on treatment	..	20 "
Total period of positive sputum—		
3 to 6 months	..	25 "
6 months to 2 years	..	5 "
Throughout negative	..	20 "

Suggestive symptoms and signs.—

Pain and tenderness in cæcal region	30 cases
Vague dyspeptic symptoms such as acidity, flatulence, etc.	10 "
Diarrhoea	15 "
Alternate constipation and diarrhoea	15 "
Constipation	5 "
Duration of symptoms—3 months to 2 years.	
Slight to moderate anæmia	.. 15 cases
Changes in weight—	
Progressive loss	.. 20 "
Stationary	.. 15 "
Gain	.. 15 "

Examination of stool

Cysts of *Entamoeba histolytica* found—10 cases. Red blood corpuscle and occult blood positive—30 cases.

Sedimentation rate of red blood corpuscle

Varied between 25 mm. to 130 mm. at end of one hour.

Barium meal investigation.—

Apparently normal appearances	..	20 cases
Irritability of ileo-cæcal region	..	20 "
Spasm without irritability	..	10 "

In the ten apparently chronic amoebic cases—some cæcal spasm was present in five cases and no abnormal appearances were noticeable in the remaining five cases.

Complications and sequelæ

The frequency of complications depends on the nature and duration of the disease. The following have been noticed in ulcerative intestinal tuberculosis:—

1. Secondary infection.
Perforation and abscess formation are more likely to occur in these cases.
2. Intestinal hæmorrhage.
Occult blood is noticed in many early cases but frank hæmorrhage is comparatively uncommon.
3. Stenosis.
Attempts at healing of the tuberculous ulcers may result in the formation of much connective tissue, which may contract and narrow the lumen of the gut. The condition is much more common in primary intestinal tuberculosis. Strictures occur most frequently in the

ileo-cæcal region, ileum and jejunum, but can occur elsewhere. Intussusception has been reported in a few cases.

4. Localized tuberculous peritonitis, leading to adhesions, localized effusions, localized abscess or formation of fistulæ.
5. Generalized tuberculous peritonitis.
6. Perforation. Perforation may result in general peritonitis or fæcal fistula.
7. Generalized miliary tuberculosis.
8. Amyloid disease.

Prognosis

The prognosis of intestinal tuberculosis is extremely bad unless the disease is diagnosed in the early stages. As most of the cases are secondary to pulmonary tuberculosis, attempts at prophylaxis should be made by teaching the patients not to swallow their sputum, by giving them a high vitamin diet and a little hydrochloric acid after meals, and by keeping a watch on the earliest symptoms.

If the general condition is good, if the pulmonary condition is in only a moderately advanced stage, if the intestinal lesions are apparently not extensive, and, finally, if the patient can be placed under proper conditions of rest, diet, light therapy and other measures for a sufficient length of time (for it should be remembered that such tuberculous lesions take, on an average, two to three years to heal as in the case of tuberculous lesions elsewhere), the prognosis is not bad. In advanced pulmonary tuberculosis, and with patients in poor condition, the existence of intestinal tuberculosis hastens the inevitable end.

General principles in treatment

1. *Rest in bed.*—The rest should mean both physical and psychological rest. The patient should be nursed flat and kept as still as possible. A cotton-wool pad over the abdomen is of value in relieving discomfort. Chills must be avoided.

2. *Diet.*—The patient should be given a high caloric, high vitamin, and low-residue diet. A suitable diet in the beginning would be milk diluted with rice water, or gruel, to which 5 per cent glucose and 20 per cent cream are added. Fruit juices, puffed rice, toasted white bread, lightly boiled eggs, jelly, chocolate and weak tea, coffee, or cocoa may be given. If milk does not agree, it should be replaced by whey, *Sprulac* or *Eldon*, or even entirely eliminated. As the clinical condition improves, thick soup, boiled fish, chicken, lean meat, unsalted butter, potatoes, purées, custards and stewed fruits may be added. It is a good plan to give cod-liver oil in full doses in orange, carrot or tomato juice thrice daily. If cod-liver oil does not agree, viosterol 20 drops thrice daily may be tried.

3. *Heliotherapy.*—The work of Rollier and Sir Henry Gauvain has demonstrated the value of natural sunlight in cases of non-pulmonary tuberculous disease. This, however, requires

the study of solar radiation (Ghosh *et al.*, 1936; Ukil and Guha Thakurta, 1938) in the area where it is proposed to carry it out, and a considerable experience in its application. Where natural heliotherapy is not possible, ultra-violet light, from either a mercury vapour or a carbon arc lamp, is the best substitute. Ultra-violet radiation has been extensively used in the United States, and in a few centres in India, with encouraging results.

The results depend upon several factors, such as the general condition of the patient, the condition and extent of disease in the intestines, the response to light therapy in general, the reaction of the skin, etc. Favourable results cannot be expected in cases with far advanced pulmonary and intestinal disease, with very little powers of resistance. With heliotherapy or with artificial light, favourable results are obtained in over 60 per cent of suitable cases; most of these showing improvement within three months. Pain, nausea, and vomiting are quickly relieved, but diarrhoea, general digestive disturbances and general systemic disturbances, disappear more slowly. It should be borne in mind, however, that the ultimate results depend not only on the intestinal lesions but also on the condition of the lungs.

In applying ultra-violet radiation, care should be taken that the erythema produced by exposure is slight and that it fades quickly. The exposure, if it is to be beneficial, should give a sense of comfort to the patient. Even when the erythema causes only slight discomfort, the exposures should be stopped for a day or two.

The following scheme of dosage is followed by us, with modifications according to the nature of the case:—

The first course.—Place the lamp at a distance of thirty-six inches from the patient. For the first three days, expose the body from the feet to the middle of the calves, for three minutes over the front, and three minutes over the back. On the fourth day, expose for the same period from the feet to the middle of the thigh. On the fifth day, expose for the same period up to the waist. On the sixth day, expose for the same period the whole body, protecting the eyes with goggles, and if the lung lesions are in a markedly hypersensitive state, covering the upper part of the chest from the clavicle to the nipples in front, and a corresponding area at the back.

The lamp-distance remaining the same, the time of exposure is increased by one minute a day over the front and one minute a day over the back, until the back and front are each exposed for 20 minutes. Stick to this for three days and then have a week's rest.

The second course.—Lower the lamp by nine inches and proceed in the same way as for the first course. And then again have a week's gap.

The third course.—Lower the lamp by another three inches, i.e., place it at a distance of two feet from the patient, and proceed as in the first

course. When this has been tolerated, gradually lower the lamp by a further six inches, and continue as above for a total of three to six months; avoiding peeling of skin or burns and toxic reactions or fatigue. By this time a steady and marked improvement should be noticeable. In cases of intolerance, the interval of exposures might have to be lengthened, the lamp might have to be raised, or fractional doses might have to be applied over fractional areas, until the patient can tolerate the standard dosage. In determining the dosage, the clinical picture, hypersensitiveness of the lesions, the skin-reactions, sense of fatigue and rise of temperature have all to be borne in mind. Periodical blood and x-ray examinations may be undertaken to assess the position.

4. *Roentgen-ray treatment.*—Benefit has also been claimed from x-ray treatment, but this method has so far been comparatively little used. Where ultra-violet ray therapy alone does not give satisfactory results, it might be combined with roentgen therapy. If heliotherapy and x-ray exposures are simultaneously employed, the dosage of x-ray must be cut down. An average dose is 5 milliamperè minutes (90 kilo-volts, 2.5 to 3 milliamperes, filtered through 3 mm. of aluminium, with the tube at a distance of 35 cm.).

5. *Pneumo- or oxygen peritoneum.*—In view of the good results which have been obtained in the treatment of tuberculous ascites by means of pneumo-peritoneum, injections of oxygen have been employed in cases of tuberculous enteritis and some success is claimed for this method. We have not, however, been happy with the results in the few cases in which we have employed this method. The results, of course, depend on the stage of disease in which the method is employed. Most early cases improve without the use of this method, while advanced cases do not seem to obtain a lasting benefit with any method.

6. *Surgical treatment.*—Except for the hyperplastic form of ileo-cæcal tuberculosis, in which pulmonary involvement is often not present, the results of surgical treatment in tuberculous enteritis have not been very encouraging. Not only is the operative mortality high, but also the after-results are often not satisfactory. Results are somewhat better in cases without, or with very slight, pulmonary involvement. Heliotherapy and ultra-violet ray therapy, however, have given much better results.

In cases of localized intestinal disease, where a small part of the bowel is involved, a local excision may be undertaken. Anderson (1940) thinks that in hyperplastic intestinal tuberculosis involving the ileo-cæcal region, the operation of choice is excision with anastomosis of the ileum to the proximal third of the transverse colon. If the patient's condition does not admit of such an extensive operative procedure, a short circuit of the ileum to the transverse colon can be performed, leaving the diseased portion undisturbed.

In cases of acute obstruction, ileostomy is all that can be done.

In *ulcero-caseous enteritis*, the choice of operation depends on the amount of bowel involved and on the extent and nature of pulmonary disease. In case of stricture or obstructive symptoms due to adhesions, a short-circuit operation gives rest to the affected part, removes obstructive symptoms and may promote healing. Archibald (1920) thinks that there are two chief contra-indications to operation, viz, extensive and progressive pulmonary involvement, and extensive disease of the small bowel; he thinks that it is unwise to attempt operation if more than three feet of the small bowel above the ileo-cæcal spincter are involved. Resection should not be attempted unless the condition of the lungs is satisfactory.

7. *Medicinal treatment.*—Drugs are only useful in the treatment of symptoms. For loss of appetite, pale tongue and sense of weight after meals, either mineral acids or alkalies, with bitters, before meals may be tried.

For the relief of pain, the following procedures may be adopted:—

(1) Rub the abdomen with an ointment containing 1 drachm each of methyl salicylas and menthol in 4 drachms of lanolin, and cover with flannel, or apply a turpentine stupe after meals.

(2) Heliotherapy or ultra-violet ray therapy often quickly relieves pain.

(3) Calcium chloride, given intravenously as a 10 per cent solution, is of considerable value not only in controlling the diarrhoea, but also in relieving the pain which results from intestinal spasm. K. S. Ray (verbal communication) thinks that irrigation of the colon with 1 in 5,000 solution of acriflavine relieves pain when the lesions are chiefly confined to the ileo-colic region.

To control diarrhoea, first adjust the diet. Then try $\frac{1}{2}$ to 1 oz. of castor oil once a week, or $\frac{1}{2}$ to 1 drachm in tomato or orange juice twice daily after meals, followed by astringents like kaolin, bismuth, kino, coto, lead acetate, zinc oxide, etc., and in extreme cases a combination of opium and belladonna with astringents.

Gold, in small doses, may be tried with benefit in early cases.

The results of intensive treatment of tuberculous disease of the bowel, especially in its early stages, are sufficiently good to encourage the hope that better results may be achieved in the future. In the present position of therapy, therefore, every effort should be made to prevent the onset of tuberculous enteritis; if it cannot be prevented, it should be diagnosed in the early stages. In order to achieve this, the physician must be well informed and alert.

TYPES OF PULMONARY TUBERCULOSIS FOUND IN DIFFERENT COMMUNITIES, WITH SOME OBSERVATIONS MADE IN NORTHERN INDIA

By RIAZ ALI SHAH, K.S., M.B. (Pb.), D.T.M. (L'pool),
D.P.H. (Eng.)

Medical Officer in Charge, R. B. Amar Nath Tuberculosis Institute, Mayo Hospital, Lahore, and
Provincial Tuberculosis Officer, Punjab

Our conception of tuberculosis has undergone great changes since Koch revealed the causal organism and later showed that sensitization of tissue cells plays a significant part in the disease.

We now appreciate the unity of all tuberculous processes. We are able to define the pathological changes which take place at the site of first infection as the simple reaction of the tissues to the presence of the tubercle bacillus and its products, similar to the reaction of tissues to any foreign substance. We now consider the different types of reactions of the tissues of previously infected individuals, on again coming in contact with bacilli, as being evidence of a specific defensive mechanism.

The reaction to tuberculous reinfection is different in different individuals. If it were possible for us to know the particular factors which determine these diverse manifestations, we would thereby greatly increase our understanding of the disease, and improve our chances of finding a satisfactory cure for it.

The real understanding of tuberculosis and its diverse manifestations, and the ability to predict the course a given infection will take, seem to depend upon facts of immunologic nature which, if they were known to us, would explain many of the mysteries which at present surround the disease. However, intrinsic variations in susceptibility and resistance are exceedingly difficult to understand and evaluate, for they are

obscured by inconstant and complicated hereditary and environmental differences.

The reactions of the tissues to the tubercle bacilli produce a combination of cell proliferation and exudation, with or without tissue destruction. While these reactions are not distinctive but are found in one and the same lesion, yet the fact that one or the other almost always predominates goes to show that a different combination of forces is responsible for the different reactions. Anything that will enable us to explain these differences will help us to a better understanding of the specific protective mechanism which the body brings into play in combating tuberculous infection.

We have already made some headway, and in our present partial understanding of this disease we have, in the classification of the disease, discarded the purely descriptive pathology of the past for an interpretative outlook, based on certain recently-acquired knowledge in the field of immunology. The 'primary phase' and the 're-infection phase' of tuberculosis are now generally recognized, although the present views on the pathological character and seriousness of first infection are still divergent (Israel and Long, 1941).

The most common familiar form of pulmonary tuberculosis is the chronic, cavity-forming type. One fact about this chronic form which seems thoroughly established is that it is not a primary manifestation of tuberculous infection, but a late one, preceded by a first infection, often contracted years before.

Chronic tuberculosis may be mainly proliferative or mainly exudative. The former is mild in degree and usually not inconsistent with long life, while the latter is more acute, and there is more danger of the disease spreading quickly and also more danger of tissue destruction.

The two types of manifestations of the disease are, thus, widely different. It is, therefore, important to learn the factors that are responsible for chronicity of the disease in one case and for a fulminant course in another. For proper evaluation of factors responsible for these peculiarities, a basic analysis of the types of disease existing in different communities is necessary.

Furthermore, there are other advantages in undertaking such a study. Chronicity swells the morbidity lists, both through the accumulation of long-lived patients, ultimately dying of other diseases, and the continued widespread dissemination of tubercle bacilli. Investigations such as those conducted in Framingham and Cattaraugus Counties in the United States of America set useful standards for morbidity and necessary hospital accommodation in communities of white people among whom the chronic form of the disease predominates, but these figures probably do not hold for communities where the disease is more acute and of shorter

duration, as may be the case with the inhabitants of this country (Shah, 1940).

In this connection the figures of Opie and McPhedran (1926) are significant. Opie compared the duration of illness from tuberculosis in the white patients attending the dispensary of the Henry Phipps Institute in Philadelphia with the duration in negroes attending a similar clinic in Kingston, Jamaica, and found that the length of the disease in the whites was approximately three times that in the negroes. In a later paper, McPhedran and Opie have called attention to the rapid character of the disease in many negro families, the whole course from onset to fatal termination sometimes lasting only four months, and several members of the family dying of the disease within one year. In negroes of Jamaica, the ratio of existing cases of clinically manifest tuberculosis to deaths was 2.9. It was 4.3 for negroes and 12.2 for white persons of Philadelphia (Opie *et al.*, 1941).

It is important, therefore, that we gather data on the type of disease prevalent as well as on the spread of tuberculosis in different parts of this sub-continent, and establish standards for hospital accommodation and other control measures on the ratio of infection, morbidity and mortality.

Numerous statistical studies of the types of disease have been undertaken in Europe and in America. Observations made in the United States of America, where the white and the coloured races exist side by side, are of special interest.

Generally speaking, the white race shows a greater resistance to tuberculosis than the negro race. A larger proportion of whites shows a tendency to chronic disease with localization of lesions and marked fibrosis. The tuberculosis of the negro is generally more acute, with more tendency to caseous pneumonia and to generalization by both blood- and lymph-streams.

In this paper an attempt has been made to analyse and discuss the type of disease found in the patients who were treated in the out-patient and in-patient departments of the R. B. Amarnath Tuberculosis Institute, Mayo Hospital, Lahore, from 1st January, 1940 to 30th June, 1942. Altogether, 2,019 patients were skia-graphed. In this study are considered 973 cases skia-graphed and diagnosed as tuberculous.

In the determination of type, reliance has to be placed on x-ray observations. Unfortunately necropsy findings are not available. The same criteria have been observed as were laid down by Benjamin (1937, 1938), *viz*: the amount of fibrosis, evidence of previously healed lesions, tendency to dissemination, involvement of one or both lungs, the amount of cavitation, all as shown in x-ray films. Unfortunately the evidence of resistance to the disease as shown by the length of time between onset of symptoms and the time of observations, and the activity of the disease as shown by blood examination

(sedimentation test and Schilling count), could not be considered, as the records in these respects are incomplete.

The results of the study are tabulated below:—

TABLE

Analysis in percentage of findings in 973 cases together with findings in Benjamin's 2,021 cases.

	PRESENT SERIES		BENJAMIN'S SERIES	
	Number 973	Percentage	Number 2,021	Percentage
Exudative	633	65.0	1,879	93.0
Fibrotic	216	22.2	108	5.3
Miliary	18	1.9
Pleurisy	106	10.9	34	1.7
Previously healed lesions	212	21.8	321	15.9
Localized	211	21.7	397	19.6
Moderately disseminated	371	38.1	783	38.7
Markedly disseminated	391	40.1	841	41.6
Unilateral	305	31.3	581	28.7
Bilateral	668	68.6	1,440	71.3
With cavities	390	40.1	1,482	73.3
Cavities with soft walls	310	79.4	1,395	94.1
Cavities with moderately hard walls.	80	20.6	87	5.9
With single cavity ..	215	55.1	704	47.5
With two or three cavities	107	27.4	385	26.0
With multiple cavities	68	17.5	393	26.5

From the above table it will be seen that among 973 patients, 633, or 65 per cent, showed predominantly exudative lesions, while 216, or 22.2 per cent, showed predominantly proliferative lesions. Miliary spread in the lungs was demonstrable in 18, or 1.9 per cent; 106, or 10.9 per cent, showed involvement of the pleura only.

Previously healed lesions were found in 212, or 21.8 per cent. Only 211, or 21.7 per cent, showed any tendency to localization, while 391, or 40.1 per cent, showed marked dissemination.

Unilateral disease was found in 305, or 31.3 per cent, while in 668, or 68.6 per cent, both the lungs were involved.

40.1 per cent of the patients showed cavitation, 55.1 per cent of these showing a single cavity and 44.9 per cent showing more than one cavity. Of patients with cavities, 80 or 20.6 had moderately hard-walled cavities, while 310 or 79.4 per cent had soft-walled cavities.

Benjamin, in his study of 2,021 cases, found much more acute types of disease than the present study has revealed. He found evidence of marked fibrosis in only 5.3 per cent, while 93.0 per cent of his cases showed a predominantly exudative type of lesion. In his series, 73.3 per cent showed cavities, half of this number showing multiple cavities. X-ray showed only 5.9 per cent of patients to have moderately hard-walled cavities.

Sanjivi (1939) reported the results of a study made by him at the Government Tuberculosis

Hospital, Madras. Unfortunately his tabulation of results is on a basis different from that of Benjamin; therefore, in many respects, the results are not comparable.

Sanjivi found cavities present in 42.9 per cent, the walls of the cavities were hard and fibrous in 20 per cent of these. Mid-zone lesions were found by him in 26.6 to 28.7 per cent, while Benjamin found them in 71.2 to 73.1 per cent. In the present series, mid-zone lesions were found in 40.5 to 42.8 per cent.

Benjamin's results led him to the conclusion that in 'Indian patients the disease is of a very serious type; it is acute, rapidly developing, with little tendency to show a natural resistance and healing'. That the disease prevailing among our people is predominantly acute in type seems to be well established. The present study confirms it. But the very serious view that Benjamin has taken does not seem to be justified in the population of India generally.

The reasons for the extraordinary acuteness of Benjamin's series of cases are not far to seek. His results are based on a study of in-patients of the Union Mission Tuberculosis Sanatorium, Arogyavaram. Only selected cases are referred to the sanatorium by doctors from different parts of the country. A very large majority of patients in our country prefer to get an occasional treatment, either from private practitioners who are usually untrained in the modern methods of diagnosis and treatment of pulmonary tuberculosis, or from the out-patient department of a hospital or clinic. The practitioners usually advise their patients to join an institution only when they find that the disease is advanced or advancing. For this reason, an institution that, for selection of cases, depends upon references from private practitioners and not upon an 'out-door' closely linked with it is likely to get a high percentage of advanced cases.

The present study is based mainly on the out-patient attendance of the tuberculosis institute where not only are the patients given advice and treatment but those who are suitable are admitted to the wards of the institute, while at the same time efforts are made to bring in their 'contacts' in order to discover early cases. In this study, as many as 27.2 per cent were in stage I of the disease. Nevertheless, this also is a selected group, although less selected than Benjamin's. A true picture can only be obtained by conducting extensive surveys among unselected groups.

Discussion

At one time the acute course and high mortality of tuberculosis among certain communities was explained on the ground that the disease in such communities was essentially first-infection tuberculosis of rapidly progressive type occurring in adult life, the cause being the general failure of these communities to receive in childhood the mild immunizing infection. This

concept seems inapplicable to the people of this country.

The few tuberculin surveys that have been carried out show that our people are fairly heavily infected during their childhood years. Furthermore, the fact that no less than 21.8 per cent have demonstrable calcified nodes and nodules in the chest, shows that Indians display good resistance to childhood primary infection.

The factors responsible for high mortality and acute course of the disease must, therefore, be sought elsewhere.

Among our people economic conditions and hygienic standards are low. Ignorance and over-crowding lead to intense exposure to infection. On the basis of exogenous adult-type infection, the widespread infection and high mortality are easily understood. Nevertheless the chronicity of the disease seen in 22.2 per cent is notable.

In this connection the experiments of Lurie (1941) on families of rabbits with different genetic constitution are illuminating. He studied the type of disease developed by several rabbit families of different genetic constitution when exposed to tuberculosis in a manner simulating closely that obtaining in human life. The localized, ulcerative, pulmonary disease characteristic of white adults was acquired by the most resistant families of rabbits. Primary, rapidly progressive, generalized tuberculosis, as found in the Senegalese troops in the Great War, was characteristic of the most susceptible families of rabbits. The mixed type of tuberculosis intermediate between these extremes, as found in the American negroes, was typical of the tuberculosis developed by the families of intermediate resistance. Lurie concludes that 'it is likely, therefore, that the varying susceptibility to tuberculosis of the different human groups depends to a large extent on varying genetic rather than environmental factors'.

In more recent years have been published two important reports on the tuberculosis of African negroes that should help us to an understanding of our own problem. One is by Borrel (1920) who observed tuberculosis among the Senegalese troops during the last World War. A large number of them arrived in France, meeting what was for most of them their first contact with tuberculosis. On arrival, only 4 or 5 per cent reacted positively to tuberculin. A fulminant epidemic of tuberculosis developed among them. The disease was characterized by caseation, tracheo-bronchial lymph nodes, caseous pneumonia, extensive serositis and miliary tuberculosis. Mortality was high and rapid. This was typical tuberculosis of 'virgin soil'. It is not the type from which the people of India are suffering to-day.

The other of the two reports to which I have made reference, is that of the Tuberculosis Research Committee of the South African

Institute of Medical Research (1932). It is an exhaustive inquiry into the reasons for high tuberculosis mortality of the negroes employed in the mines in the Rand. In this case the native labourers were already heavily tuberculized on arrival, 70 per cent or more reacting positively to tuberculin. Furthermore, fully 50 per cent of 'healthy natives react to 1 : 1,000,000 dilution of tuberculin. These natives are, therefore, not 'virgin soil' for tuberculosis. Yet, if they remain in their kraals, the disease is found quiescent. It is only when they are exposed to the heavy labour of the Rand, coupled with under-nourishment and frequent super-infection due to living conditions, that there is activation of the disease. Their tuberculosis, while frequently fulminant in character, was not as massive as that of the Senegalese troops.

This is more nearly comparable to the situation in India to-day. Unfortunately, the tuberculosis mortality and morbidity figures in this country are very incomplete. But a few figures are on record which indicate that, in urban areas at least, it must be four to six times as high as the tuberculosis death rate among Western communities.

The high death rate in Indians cannot be explained by massive infection of 'virgin soil'. The writings of early Hindu physicians indicate that Indians have been tuberculized for many centuries. Racial stocks of this country have passed through long periods of survival of the most fit, and yet the disease is more fulminant than in the whites.

It may well be assumed, therefore, that environmental factors are involved. In general, the Western people have the advantage over Indians in economic status, hygienic standards, housing and dietary habits.

Whether the differences are due largely to true genotypic inherited variations in native susceptibility and capacity for immunization, or are chiefly the result of environmental variations, need much further investigation.

I am grateful to Dr Shabbar Hussain, M.B., B.S., my house physician, for kind assistance in tabulation of statistical data.

AN INVESTIGATION INTO THE TYPES OF TUBERCLE BACILLI CAUSING EXTRA-PULMONARY TUBERCULOUS LESIONS IN THE PUNJAB*

By S. M. K. MALLICK
 MAJOR, I.M.S.

Principal, Medical School, Amritsar

RAI SAHEB HET RAM AGGARWAL, M.D.,

Lecturer in Pathology, Medical School, Amritsar
 and

RAM LAL DUA, M.B., B.S.

Demonstrator in Pathology, Medical School, Amritsar

EVER since the discovery of the tubercle bacillus attempts have been made to determine the types of tubercle bacillus which produce lesions in man and other animals. Bovine strains of the bacillus have been isolated by Fraser (1912), Griffith, Munro (1930), Cumming, Blacklock, Wang and other workers in Great Britain in 27 to 70 per cent of human cases of osteo-articular and glandular tuberculosis, particularly in children. It has been encountered in 19 to 40 per cent of cases of cerebro-spinal meningitis examined by Blacklock, Griffith, Macgregor *et al.* (1934), Jensen (1932) and other workers. The incidence of the bovine type of bacillus isolated from extra-pulmonary lesions in the U.S.A. seems to be less (7.7 per cent according to Gosling and Mantoux) than in the north-European countries. Recent work by Lange (1932), Munro (1930), (Cumming, Foster, Girdwood, and Griffith, 1933), Smith, Jensen (1932) and other workers indicates that a varying percentage (3 to 8 per cent) of pulmonary tuberculosis cases in these countries is caused by the bovine type of tubercle bacillus. Investigations have shown that a high incidence of infection and disease in cattle is related to a higher incidence of the bovine infection in man, particularly among children, and dairymen who attend to cattle.

In India the earliest work available in this connection was that of Soparkar who isolated bovine strains from two cases of glandular tuberculosis and an avian strain from another. Whilst investigating the source of tuberculosis in the animals in the zoological gardens of Bombay, he demonstrated the presence of bovine strains in some of these animals. Soparkar also reported the presence of tuberculosis in 14 per cent of cattle at Ferozepur and Lahore. Taylor, however, showed that tuberculosis in cattle in India is much less than in the West.

More recently Ukil (1933) investigated the problem in Calcutta. He could not report a single case of bovine infection from cases of non-pulmonary tuberculosis.

We conducted this enquiry on lines similar to those of Ukil. We have so far been able to

* This article has been condensed by Dr. Ukil, at the Editor's request.

cultivate tubercle bacilli from 39 cases, out of which 37 have been completely investigated.

Material was collected from some of the hospitals in Amritsar and Lahore, as well as from private surgeries.

The sources of the material investigated were as follows: cervical glands 21, inguinal glands 1, pus from cold abscesses 10, and peritoneal fluid 7.

After experimenting with several media, Petroff's medium was chosen for routine use in making primary cultures from materials, some of which were sent from out-stations, preserved in 5 per cent glycerine saline with or without the addition of malachite green in the same strength as is present in Lowenstein's medium.

The following technique was adopted by us in culturing tubercle bacilli from pathological materials, with all possible aseptic precautions:—

The material, except in the case of pus when freshly obtained, was triturated with 6 per cent sulphuric acid in a mortar containing a small quantity of sterile sand, poured into a wide-mouthed tube and kept in the incubator at 37°C. for an hour. The acid is then neutralized with normal NaOH and about 0.5 c.cm. of the neutralized material put on to each of a few slopes of Petroff's medium. The tubes were then incubated and inspected every 4 or 5 days up to a period of two months, at the end of which the negative growth tubes were rejected. In case of positive cultures, the strains were subcultured on glycerinated and non-glycerinated media. The character of the growth on the tubes was noted. In addition to direct culture, 1 c.cm. of the neutralized emulsion of pathological material was inoculated subcutaneously into two guinea-pigs, with a view to obtaining primary cultures from any lesions produced in the guinea-pigs. In the case of pus uncontaminated with secondary organisms, a direct culture was made. In contaminated samples, the sulphuric acid method of treatment was adopted.

From the cultures obtained, a homogeneous emulsion of a weighed quantity of tubercle bacilli was made, and 0.01 mgm. of the dry weight of the bacilli was introduced intravenously into rabbits. In some cases, a subcutaneous dose of 10 mgm. was preferred. The animals were killed and autopsied at the end of 8 weeks, if they did not die earlier.

Findings

Cultural characters.—All the strains isolated are *eugonic* in growth and glycerophilic except two. One of these on subculturing is now giving fairly abundant growth on glycerinated medium also. The growth was generally dry, irregular, tough and tenacious. It was ivory coloured to start with and later on a little bit more yellowishness. All eight strains that have given a definite human type of reaction gave a growth which was slightly moist and glistening, but the growth was adherent in all these cases and

showed on the surface of the usual dry type of growth.

Animal inoculation tests

In all we have so far inoculated 107 rabbits for differentiation of the type in 39 strains of tubercle bacilli. We have been using two animals for each of the strains. Actually 78 should have been required but because of intercurrent infections, we had to repeat the inoculation test in some cases. When an animal died earlier than six weeks, the experiment was repeated.

None of the animals lost much in weight. Thirty-seven showed no change and in 10 it was actually increased. All the animals inoculated with 10 mgm. subcutaneously had to be killed. None of them died between 6 to 8 weeks after inoculation, and the autopsy always showed the disease limited to a localized abscess which contained acid-fast bacilli. Of the 90 animals inoculated intravenously 35 showed no tubercle lesions in 6 to 8 weeks after inoculation. The animals that showed disease were always ill from progressive lesions.

It is very important to know the incidence of the bovine infections amongst our people, since the institution of preventive measures depends to a very large extent on our knowledge of the type of bacillus causing infection in this country. Soparkar's findings were to the effect that infection is present in our cattle and the percentage of the infected cattle is likely to increase with overcrowding and bad housing conditions of the animals in the cities.

Tuberculosis in the animals is very uncommon in this country. In the beginning of this enquiry we examined specimens of milk from 25 milk sellers in the city. We used the technique of Cowan and Maddocks to demonstrate the presence of acid-fast bacilli in milk. None of the specimens showed acid-fast bacilli. This matter needs further investigation. It is said that tubercle bacilli in milk be ignored in this country because milk is boiled before use by the people. One who knows the dirty and careless habits of the milk sellers and the habits of the country people who take fresh and unboiled milk of buffaloes, will certainly not feel like dismissing the problem so lightly. We cannot say that the problem of the type of the bacillus has been thoroughly investigated as long as we have not investigated the diseased tissues from a large number of country and urban people. If it is not a problem for the public health worker, it is certainly one for the veterinarian to stamp out the disease amongst the cattle so long as Soparkar's work remains unchallenged.

Summary

1. Thirty-nine strains of tubercle bacillus isolated from non-pulmonary sources.
2. Thirty-seven strains have given typical human type of reaction on inoculation into rabbits.

SOME OBSERVATIONS ARISING FROM TUBERCULOSIS WORK IN THE TUBERCULOSIS CLINIC, NAGPUR

By I. E. J. DAVID, L.M. & S.

Assistant Surgeon in Charge, Tuberculosis Clinic, Nagpur

THE gravity of the menace of tuberculosis in the Central Provinces is probably similar to that of the other provinces in India and we are forced to recognize its seriousness. I will first describe briefly what is being done in the province with regard to tuberculosis.

Anti-tuberculosis activities in the Central Provinces

The Government of the Central Provinces and Berar has put forth a well-planned anti-tuberculosis campaign. The scheme, which was approved by Dr. C. Frimodt-Möller, was launched in 1937 under the leadership of Major-General N. M. Wilson, the then inspector-general of civil hospitals of the province. The scheme though a modest one is so planned as to be able to develop in the right way in an ever-increasing measure in the future.

Four tuberculosis clinics, which are more or less fully equipped, were opened in four important centres in the province, namely Nagpur, Jabulpore, Amraoti and Raipur. The Pendra Road Sanatorium in Bilaspur district, about 300 miles from Nagpur, was organized on an up-to-date basis and is under the management of the united board of eleven missions. The four clinics, which belong to the provincial medical department, and the sanatorium are in the charge of experienced and well-qualified men and work in co-operation. Forty beds in the sanatorium are reserved by the Government for indigent patients and the sanatorium receives a yearly grant for the same from the Government. The

(Continued from previous page)

3. Two other strains which appear to be human from cultures are still to be differentiated.

We are highly grateful to the Amritsar municipality for granting us annually Rs. 2,000 for a period of two years as it would not have been possible to institute the enquiry without this aid. Our thanks are no less due to Lieut.-Colonels P. B. Bharucha, V. R. Mirajkar and P. A. Dargon and other medical officers who supplied the necessary morbid materials.

sanatorium is now recognized to be one of the best in India.

From 1926 to 1937 an Anti-Tuberculosis League was in existence in Nagpur under the private auspices of the late Dr. Roy. This league had collected Rs. 27,000. This fund, and a contribution of Rs. 40,000 by the provincial Red Cross from the Silver Jubilee Fund, equipped the four clinics.

The Anti-Tuberculosis League was merged in 1937 with the Anti-Tuberculosis Association of the Central Provinces and Berar, which is affiliated to the Tuberculosis Association of India. This Anti-Tuberculosis Association, on Her Excellency the Marchioness of Linlithgow's all-India appeal, has so far collected about Rs. 98,000.

The Tuberculosis Association of the Central Provinces and Berar is providing post-graduate training for selected doctors at the Pendra Road Sanatorium. Arrangements are also being made to train tuberculosis health visitors in the province. When funds permit it is proposed to open more clinics in other important centres. Among various other measures of improvement of the existing clinics, is the plan to construct detention wards and to establish tuberculosis settlements and camps. The war has called a halt to many of our nation-building works and is affecting in no small measure our anti-tuberculosis schemes.

Tuberculosis problem in Nagpur city

Nagpur city covers an area of about 6,000 acres and has a population of over three lakhs; there are about 50,000 houses with an average of over six persons in each. The total deaths per year are about 9,000, that is about 30 per 1,000 of the population. It is estimated that about one in every ten deaths in India is due to tuberculosis, and that for every one who dies from tuberculosis, there are ten who are suffering from the disease. This would mean that there are about 900 deaths from tuberculosis in Nagpur city every year, and about 9,000 cases of active tuberculosis, most of them undetected and at large, spreading the infection.

Tuberculosis Clinic, Nagpur

The Nagpur Tuberculosis Clinic was established as a self-contained unit in May 1938, though the actual work of the clinic was started in July 1937 in the local general hospital. The cost of the building and its equipment amounted to Rs. 30,000. The clinic is equipped with a dispensary, laboratory, x-ray plant for radiography and screening, ultra-violet outfit, dark room, operation theatre, waiting rooms, consultation room, examination room, two detention wards, each with two beds; it is situated in the heart of the city and is easily accessible. It is in the charge of an assistant surgeon of the provincial medical service, specially qualified for the post. The rest of the staff consists of two qualified compounders (one of whom is also a qualified tuberculosis health visitor and the other

has received training in x-ray and laboratory work), two health visitors, one chowkidar and one sweeper.

The work of the clinic for the years 1937 to 1941 is shown in the following table:—

cases were in the group 'predominately exudative'. Seventy-two per cent of the tuberculosis cases were in the age group 15 to 35, 13 per cent in the group 35 and above, and 15 per cent below 15 years.

TABLE

	1937	1938	1939	1940	1941
Total attendance	2,469	17,471	19,087	18,472	21,654
New cases—total	711	3,736	3,925	4,079	4,292
New cases—tuberculous	223	711	672	800	862
New cases—pulmonary tuberculosis ..	170	546	461	579	568
New cases—abdominal tuberculosis ..	42	69	128	119	213
Contacts examined	Not recorded	685	1,233	1,250	1,554
Contacts diagnosed as having active tuberculosis.	Do.	82	113	133	126
Home visits } by health visitors .. {	Do.	1,112	872	723	1,495
Homes visited }	Do.	243	465	453	583
Patients sent to sanatorium	26	37	Not recorded	9	13
Laboratory examinations	Not recorded	3,649	3,375	2,467	2,439
X-ray examinations	Do.	3,899	4,704	4,941	5,474
AP inductions, pleural aspirations, pneumo-peritoneum injections.	149	1,354	1,308	701	1,234
AP cases	24	97	137	105	142
Other injections	Not recorded	1,411	2,133	2,103	2,023

If the four years are added together, it will be seen that from 1937 to 1941 in our clinic about 17,000 new patients were examined of whom 3,267 were diagnosed as suffering from active tuberculosis. There was a total attendance of about 80,000 at the clinic. Nearly 5,000 contacts were examined and about 454 of them were found to have active tuberculosis. The detection of an active focus thus leads to the detection of more unknown foci. Over 2,000 separate homes were visited and about 5,000 home visits were made by the staff. It is estimated that, in one way or another, we have given personal talks to about 55,000 individuals in these four years.

During the period under review, 11,930 laboratory examinations and 19,018 x-ray examinations (mostly fluoroscopy) were done. 4,746 artificial pneumothorax inductions and 3,675 injections were given.

Out of the nearly 3,267 cases of tuberculosis detected, 2,324 were pulmonary cases and 571 abdominal; about 10 per cent were in stage I, 30 per cent in stage II, and 60 per cent in stage III. Roughly, 70 per cent of the pulmonary

Discussion

We have achieved nothing spectacular in Nagpur. The utmost that we can say is that we are striving towards the establishment of an atmosphere, environment and knowledge which will be unfavourable to tuberculosis. One can show certain number of cases 'relieved', 'arrested' or 'cured', but one can not show the number of people prevented from getting tuberculosis through the influence of the clinic. The spread of the knowledge of the prevention of tuberculosis cannot be gauged by any known measure, and it is too early to show any influence of the clinic on the mortality or morbidity rate of tuberculosis in the city. For that, a more intensive campaign and an augmented and all-embracing scheme is required. But our present work is not in vain, for it is truly laying a foundation on which is going to be built the further development of the fight against tuberculosis in Nagpur.

During the four years we have learnt by experience and we feel that this experience, if passed on to others, may be of use to them.

The still-existing practice of keeping from the patient the fact that he is suffering from tuberculosis is dangerous. Apart from the fact

that by doing so we cannot get his co-operation he continues to remain an uncontrolled focus spreading the infection. It is the patient and his contacts who are primarily concerned in the spread of the knowledge about tuberculosis. 'The efforts against tuberculosis should not be wasted in a general broadcast type of propaganda but should be concentrated and directed to reach those among whom the disease is actually found and to educate them in tuberculosis control' (Dr. P. V. Benjamin). Indeed, every personal talk and every detection of a case goes towards the establishment in society of an environment more and more hostile to tuberculosis. Doctors and health visitors of a clinic who conscientiously strive towards this end need not be discouraged by any seemingly poor immediate results or failure to show any spectacular achievements.

In the education of the patient and the contacts, the health visitors play an important part. While the doctor-in-charge of the clinic should be the brain and heart of the clinic, the tuberculosis nurses should be the sensory and motor nerve endings and the capillaries. When the health visitors fail to do their work properly the clinic is ruined. Therefore, we require health visitors with not only good education but also character and dignity. Such health visitors are not easy to secure. The character and pursuits of the subordinate staff are either inspired or ruined by the character and personality of the man in charge. Thus a great deal of effectiveness of the campaign depends upon the selection and training of its health visitors and doctors.

It is most important that the health visitor and the doctor should din into the patients, day in and day out, information about the following subjects :—

Isolation of the case in the house, disposal of sputum, disinfection of clothes and utensils, necessity of prolonged and continued rest, eating the diet he can afford in sufficient quantity, the prolonged nature of the treatment, and avoidance of pregnancy during and for some years after the treatment. I have found the necessity of speaking specially on these subjects to the patient and contacts unceasingly and untiringly. The patient is apt to think that, as long as he takes his medicines and injections, he has done his job. Effective isolation and organized home treatment are not easy in the average case, but with the co-operation of even the worst situated patient, the spread of the bacilli can be reduced to some degree at least. The advice most difficult for the average clinic patient to follow is to cease work. Most of these are daily wage earners and they and the family have to starve during absence from work. The Care Committee can only touch the fringe of this problem. It is ultimately the responsibility of the State. Even in the best of families, if the bread winner is stricken it proves a serious disaster, and equally so if it is the mistress of the house who is

stricken. The calamity is very serious in the household of my average patient.

We have found that no stratum of society is exempt from tuberculosis, and it is peculiar to no particular occupation, sex or community. Tuberculosis is common in those employed in works where a large number congregate under one roof, as in factories, where the spread of infection is easy. The disease is common among the poor because the housing and other ways of life among them make the people easy targets to the bacilli discharged from the infected persons who inhabit their environment and dwellings. It is common among the rich because often their way of life is no better than that of the poor. Most of the communities in the cities live, more or less, under similar conditions, and the incidence of the disease among them is not dissimilar.

No difficulty has been found by us, on the whole, in getting proper reception during home visits and in getting a sufficient number of contacts for examination. There have been unpleasant incidents but only few and far between, and not serious. Work in this direction is only limited by inadequate staff. But for this limitation, it would be possible to visit almost every house and bring for examination almost every contact.

The clinic has been able to obtain the co-operation of the private practitioners and other bodies. Co-operation depends most of all on the character, honesty and sincerity of purpose of the staff of the clinic—granted which the winning of adequate co-operation is only a question of time. Especially the doctor in charge should be endowed with sufficient knowledge of his work and should prove a constant source of real help to his fellow doctors. Above all, his status and salary should be so placed that he never needs to enter into unseemly or undignified competition with the general practitioner.

One of the most valuable parts of the clinic's work is the giving of artificial pneumothorax treatment. This treatment not only considerably reduces the period of 'rest' for the bread winner, but stops or reduces the output of bacilli in many cases. Its importance is great when we realize the careless habits of the average public. In the clinic, cases often can continue with profit the artificial pneumothorax for years without any handicap to their vocation. We are finding, as the years go by, that we are getting more and more early cases, and also that cases under treatment realize the importance of prolonged treatment and years of aftercare.

During the last four years only about hundred cases could secure admission to sanatoria and only a few others to hospitals; but the majority of our cases are acutely ill and require hospitalization for a shorter or longer period. Herein lies the necessity for more beds in the clinic and need for town—'sanatorium—hospitals'. The

beds in the clinic-ward should keep patients until they become 'apyrexial' or otherwise 'ambulatory'. It appears that climate plays only a secondary part in the 'relief' or 'cure' of tuberculosis. My opinion is that expert treatment, combined with other essential conditions like rest, diet, etc., can produce almost as good a result in the town as in sanatoria situated in ideal climates. This does not belittle the sanatoria, the advantages of which I cannot discuss here.

As I said earlier, the population of Nagpur is about three lakhs. The population administered by the tuberculosis scheme of the county of Lancashire in England is about 20 lakhs. The County Council of Lancashire runs 8 tuberculosis centres each with a team of whole-time doctors, one large sanatorium of 226 beds and 5 smaller ones, and has 33 health visitors and adequate expert clerical staff. It has a total of 981 sanatorium-hospital beds and spends £105 per 1,000 of the population for the prevention and treatment of tuberculosis. The death rate of tuberculosis in 23 years, less than a quarter of a century, has declined by 52 per cent. It is really impressive, but not achieved without adequate expense and effort. The motto of Lancashire is 'find, isolate, educate and treat'.

What has been done in Lancashire shows how far behind we are in Nagpur and how much we have to do. The common argument is that we cannot, in this country, afford to conduct the campaign on the scale on which it is conducted in other countries which have controlled tuberculosis. Unless we too can expend as much, we can make no such progress. I believe we have the resources in men, money and material to wage this war and win it.

This paper is not the result of any survey, and it is far from a complete report of the work of the clinic. I have just reviewed my reactions to the last five years' work which is on the simple basis that tuberculosis is a curable disease and a preventable disease, that the front of the fight against tuberculosis is in the home of the patient, that the study and care of the patient is the beginning, but from it the desired end is attainable or control of tuberculosis.

I am grateful to the civil surgeon Major Kelly, the inspector-general of civil hospitals Col. Hance, and the provincial Government for their permission to publish this article.

A Mirror of Hospital Practice

A CASE OF IMPERFORATE HYMEN

By NANASAHEB CHATE, L.C.P.S.

Subsidized Medical Practitioner, Belavdi,
District, Belgaum

A GIRL, aged about 22 years, was brought to the rural medical dispensary at Belavdi for the treatment of retention of urine and colicky pain in the abdomen.

Examination.—A mass, globular in shape and of woody consistency, could be felt rising out of the pelvis and extending to about six fingers above the umbilicus. On auscultation nothing but a gurgling noise here and there was heard.

A second mass of about the size of a small coconut was found between the thighs, and pressure on the mass in the abdomen made the lower one more tense. The labia were stretched out and the urethral orifice was pressed to the size of a pin-hole. The position of the vaginal orifice could not be made out.

History.—On enquiring into the history of the case I found that she had felt pain in the abdomen every month lasting for about 4 to 6 days since her fourteenth year of age. She first saw the lower mass when she was 16 years old, and it grew from below upwards up to its present size. She did not consult anybody through shyness. She could not pass urine for the last twelve hours.

Operation.—After an unsuccessful attempt to pass a long-sized female catheter I made a vertical incision starting from just below the urethral orifice. After going about quarter of an inch deep thick tarry blood came out with the gradual disappearance of the mass. The total quantity of the fluid withdrawn was six pints. The hymen was then snipped off and a vaginal douche with Condy's fluid given. The patient passed urine herself after the disappearance of the mass. She is now menstruating regularly.

SULPHANILAMIDE PACKING IN THE TREATMENT OF COMPOUND FRACTURE

By JAGADISH C. BHATTACHARJEE, L.M.P.

and

LALIT C. MAJUMDER, L.M.F., L.T.M.

D. H. Railway Hospital, Tindharia, Darjeeling

A NEPALI WOMAN, aged 46 years, was admitted on 11th January, 1942, for the treatment of a compound fracture of both ulna and radius about two inches above the left wrist joint. It was reported that she had a fall of about 30 feet from the hillside.

On examination, a large gaping wound was found, situated transversely on the site of the fracture, from which blood was dribbling. The proximal extremity was found to be loosely adherent and displaced on the dorsal aspect.

Treatment.—The wound was cleaned, two grammes of sulphanilamide powder was introduced, was packed with gauze, and the limb secured in a splint. The patient was put under morphia.

Next morning the dressing was found to be soiled by blood, and was changed. Two grammes of sulphanilamide powder was placed within the gaping wound and the limb secured in the splint.

The dressings had to be changed again next morning as the oozing continued. Another two grammes of sulphanilamide powder was put into the wound and the part immobilized. After that, as little bleeding was evident, the limb was not disturbed till the twenty-second day, when the dressings and the splint were removed. The wound was found to have healed up by first intention with a good union of both the broken bones. Besides this treatment, the patient was given 1.5 grammes of sulphanilamide by the mouth during the first two days.

We are grateful to Dr. S. K. Biswas, medical officer, D. H. Railway, for his kind permission to report this case.

Indian Medical Gazette

OCTOBER

ANTI-TUBERCULOSIS WORK IN INDIA

THE seriousness and magnitude of the tuberculosis problem attracted the attention of various workers in India in the early years of the present century. The establishment of the King George Thanksgiving (anti-Tuberculosis) Fund was a natural sequel to the work that had been carried out in the preceding quarter century. The establishment of the Tuberculosis Association of India, through the untiring efforts of Her Excellency the Marchioness of Linlithgow, consolidated the position still further. Finally, the affiliation of 14 provincial and 13 state tuberculosis associations to the central body is evidence of the keenness and sincerity of the interest which the people in all parts of India are taking in the matter.

As a result of the drive carried out by the Tuberculosis Association of India, a large number of clinics have already been started in various parts of India, beds have been added to existing institutions, and new institutions have been started to accommodate both infectious and 'closed' cases which are not suitable for treatment in the home. The work done at these clinics indicates that a large percentage of new cases, particularly among the children and adolescents, originate from contact with previous known or unknown cases of tuberculosis, and the need for early detection and treatment of the 'open' case is being increasingly felt.

An important measure that has recently been completed has been the fixing of standards for classification of pulmonary tuberculosis, and the laying down of the principles and methods for tuberculosis survey in different parts of the country; this has been achieved with the help of the Indian Research Fund Association.

Properly conducted surveys are an essential preliminary to any large scale attempt at control of tuberculosis, and those already concluded are likely to yield valuable information to the administrative authorities planning the control measures in different areas. We need information not only about the incidence and types of the disease encountered in rural, urban and industrial areas, but also about the mode of infection and spread of tuberculosis in the community. It is generally accepted that when an agricultural country becomes industrialized, the incidence of tuberculous disease and deaths increase, until it is controlled by raising the standards of living and improving the sanitation of the environment, the keystone of which is the solution of the housing problem.

While tuberculosis mortality has been steadily declining in many industrialized countries, there

is strong evidence to suggest that at present it is increasing in India. As India is on the threshold of extensive industrialization and as the large majority of the workers will have to be drawn from rural areas, this is the moment for research workers and administrators alike to concentrate their full attention on the subject of tuberculosis in relation to industry. Suitable measures introduced now may prevent history repeating itself in this country and it may be possible to save the growing industrial populations from at least some of the disasters that overtook them in other countries.

The war has brought with it new problems with regard to tuberculosis. It is essential therefore that we should not allow the present situation to be used as an excuse for neglecting the tuberculosis problem, but should insist that our efforts are redoubled to face the many new aspects that it presents.

It is a well-known fact that both morbidity and mortality from tuberculous disease rise in war-time. For this, there are many causes; these include increased physical and mental strain, privations, ill-spent leisure, over-crowding, and increased opportunities for contact with sources of infection. This increased morbidity and mortality from respiratory diseases in general and tuberculosis in particular was experienced in every country involved in the 1914-1918 war, and is in evidence again during this war. In England, deaths from respiratory diseases showed increases of 6 per cent in the first year of war and of 10 per cent in the second year, as compared with the last pre-war year (ending mid-1939). The probable rise in tuberculosis in India, as in other countries, is therefore a special war-time problem which should be tackled with the sense of urgency that is being given to other war-time problems.

X-ray examination of the chest is a very valuable method of conducting tuberculosis surveys, as it is practically the only means by which symptomless cases can be detected. Hitherto this method of examination was not only costly, but also time consuming; recently however the introduction of miniature radiography has reduced both these factors and has made it possible to examine, at a comparatively small cost, large numbers of persons, *e.g.* school and university students, the staff of commercial firms and government offices, and groups of recruits for the army, the police, and labour forces. This method is being used increasingly in most of the advanced countries in the world, and, in India, recruitment authorities for the services, commercial and industrial concerns, and big employers of labour, such as the railways, tramways, etc., would do well to consider adopting this method for weeding out active or potential tuberculosis cases from amongst their prospective or established employees.

The tuberculosis programme sponsored by the Tuberculosis Association of India will not achieve

its objectives unless the governmental agencies collaborate fully with the various social welfare agencies already operating in the country, and unless the work is co-ordinated with the public-health programme of the country. The campaign should be as broad based as possible in order to ensure success, for one should not forget that tuberculosis is a social disease and therefore needs a social drive to eradicate it.

The present issue of the *Indian Medical Gazette* constitutes the 6th special tuberculosis number. It will be seen that, like its predecessors, this issue presents papers covering a wide field, including epidemiology, pathology, diagnosis, and treatment. It is hoped that its publication will stimulate other workers to define and investigate other urgent important problems regarding the disease. Continuous research is an essential adjunct to any successfully planned tuberculosis campaign, and nowhere is the need for it greater than in India where many major problems still remain unexplored.

The papers for this number were collected and selected by an editorial committee of the Tuberculosis Association of India which consisted of Dr. A. C. Ukil, Dr. P. V. Benjamin and Dr. Sikand.

Space did not however allow the inclusion of all the papers selected and two papers* have been held over for our next issue.

Our thanks are due to the editorial committee for their co-operation, and particularly to Dr. A. C. Ukil who has ungrudgingly assisted with his expert advice in the solution of many problems that inevitably arise in the publication of technical papers.

P. A. MAPLESTONE

READERS will perhaps notice that the familiar name of Dr. Philip Alan Mapstone, D.S.O., D.Sc., M.B., Ch.B., D.T.M., does not appear this month on our cover. Earlier in this year, when the Japanese threat to Australia was developing rapidly, Dr. Mapstone decided that in the circumstances he ought to return to Australia where his wife and family were living. He took four months' leave, but since his arrival in Australia he has resigned his appointment at the School of Tropical Medicine in Calcutta and also the assistant editorship of this journal.

Dr. Mapstone was in government service in the Northern Territory of Australia from 1909 until he joined the Australian Army Medical Corps in 1915. He served in France and elsewhere with distinction, being mentioned in dispatches and receiving the D.S.O. After the war, he left the army with the rank of major.

He took his D.T.M. at the Liverpool School of Tropical Medicine in 1919, and returned to Australia to an appointment at the Australian Institute of Tropical Medicine, Townsville. From 1921 to 1924 he was assistant director of the Sir Alfred Jones' Laboratory, Sierra Leone, West Africa. Later, he was appointed lecturer in protozoology at the Liverpool School of Tropical Medicine.

By this time he had already begun his work on systematic helminthology and he described many new species of tapeworms in a series of notes on Australian cestodes, often collaborating with Dr. Southwell. He also made some important observations on the development of hookworm larvae and explained the natural control of hookworm infection in some particular areas. His paper on the revision of the classification of Amphistomes of mammals helped to clear up a long controversy as to the validity of numerous families and species of these trematodes. In collaboration with Dr. Warrington Yorke he wrote *Nematode Parasites of Vertebrates*; this book has simplified the identification of nematodes and has been accepted as a standard work of reference by helminthologists all over the world.

He was appointed a research worker at the School of Tropical Medicine, Calcutta, in 1927. Here he continued his work on systematic helminthology and contributed many important papers on the practical aspects of hookworm and ascariis control. He was largely responsible for broadening the basis of the helminthological research and virtually founded the helminthology department at the School. He always had a leaning towards clinical medicine and in order to enlarge his scope he studied skin diseases under the late Colonel Acton, and later took his place as officer-in-charge of the skin diseases department. He contributed many important papers, both theoretical and practical, on this subject. During his last year at the School, he also undertook the teaching of helminthology to the students of the L.T.M., the D.T.M., and the D.P.H. classes.

Dr. Mapstone has been assistant editor of the *Gazette* for nearly ten years. He joined the staff at the beginning of 1933; when the late Colonel Knowles resigned on account of ill health. His extensive knowledge of parasitology and tropical medicine in general, his well-developed critical faculty, and his readiness to take endless trouble to get the best out of a badly constructed paper were qualities that made for success in editorial work. As an associate, the writer found him extremely helpful, entirely reliable, and very stimulating. His complete mental honesty and direct 'Australian' way of calling a spade a spade, which sometimes offended those who did not understand him, appealed particularly to the writer and in his opinion made Dr. Mapstone an ideal associate.

Dr. Mapstone's departure is a great loss to the School and to this journal; but, as he left

*An Investigation into the Incidence and Type of Tuberculous Infection in Cattle at Amritsar with Special Reference to Human Infections. By S. M. Mallick, Major, I.M.S., R. S. Dr. Het Aggarwal, M.D., B.P.N.C. (Lond.), and Ram Lal Dua, M.B., B.S. On Pulmo-circulatory Dysfunction in Lung Tuberculosis. By K. Eisenstaedt, M.D., T.D., and A. U. Rindani, M.B., B.S.

sound in wind and limb and with his mental faculties at their highest point, India's loss will be Australia's gain. We sincerely hope that he will find suitable scope for his energies and abilities.

Dr. John Lowe, M.D., who succeeds Dr. Maplestone, has an international reputation as a leprosy worker. He has had many years' editorial experience as editor of *Leprosy in India*, and will, we are convinced, prove a worthy successor to Dr. Maplestone.

Medical News

AUXILIARY NURSING SERVICE: RECRUITMENT TO BE RESUMED FROM OCTOBER

RECRUITMENT to the General Service category of the Auxiliary Nursing Service, India, which had been suspended temporarily pending the revision of the terms and conditions of training, will be resumed from October. Under the revised terms, candidates will receive a preliminary training for 3 to 9 months in certain selected civil hospitals throughout the country, provided that their services are not required in the meantime for military duty. During training the candidates will be provided with free accommodation and board in the hospital and will receive a small personal allowance in addition.

The lady district superintendents of the St. John Ambulance Brigade Overseas will, as usual, act as the recruiting agents.

IMPROVED METHODS FOR MALARIA CONTROL FOR CANTONMENTS

WITH the drive against malaria now being organized by the Army authorities, most of the cantonments in India will be free of the disease. The campaign which is expected to cost about Rs. 16 lacs will involve the expansion and reorganization of the existing anti-malarial measures.

Under the new scheme emphasis will be laid on co-ordinating anti-malaria methods in various stations. Mobile personnel will carry out operations throughout the year. These will not only benefit the military, but also the neighbouring civil population. With the collaboration of the civil and military authorities, the scheme may eventually form the nucleus of a drive against the disease in towns and villages as well as in military stations.

A special organization is being set up under an officer of General Headquarters who will be assisted by a body of doctors and scientists specially trained for the work. Each station will be under the supervision of an anti-malaria officer and an assistant each of whom will receive special training at the Malaria Institute of India. Similarly a large number of insect collectors are being recruited who will also undergo a course of training at the Institute.

The organization will be armed with modern equipment to fight malaria. They will have electric sprayers, petrol-driven sprayers, knapsack sprayers, blowers and mixers and will be provided with lorries and bicycles. The ammunition of these malaria fighters will include thousands of gallons of pyrethrum extract, malariol and paris green.

Although a great reduction in the incidence of malaria in the Army in India has occurred during the last 15 years, the rate still remains high. In 1940 total admissions to hospital per thousand of strength were 73.4 for British troops and 173.2 for Indian troops.

Any further reduction in the ratio is considered impossible with the existing arrangements, but it is confidently expected to occur once the problem is tackled on improved lines.

GENERAL LIM

A CELEBRATED London physician once said, 'The medicine of ten years hence is to be found in the pages of the *Journal of Physiology* of to-day'. Anyone turning over the pages of that high technical magazine for the year 1894 will see an historic paper on the killing of germs in the blood, by Hardy and Lim Boon Keng. Lim Boon Keng was the father of Professor Lim—now Lieut.-General Lim, Commander of the Chinese Army Medical Service, whose headquarters are at Kweiyang, in Kweichow province.

Lim, following the family tradition, took up physiology and medicine as a life's work. He was educated at Watson's College, Edinburgh, and later at Edinburgh University, where he took a prominent part in the life of the Students' Union, and in many other University activities. By reason of his modest and genial personality, coupled with his obvious ability, he was a universal favourite.

His work in the physiological department at Edinburgh, then the realm of Sir Edward Sharpey Schafer, commenced in 1919, and in 1921 he received the definite appointment of Lecturer in Histology, a subject in which Lim's artistic ability showed itself in his beautiful drawings of microscopic structures. In 1924 Lim left for China to become Director of Research and Professor of Physiology in the new Medical School to be started in Amoy. Actually, that project never materialized, but he was appointed Professor of Physiology at the Peiping Medical School.

In Edinburgh, Lim's research dealt principally with the structure and functions of the digestive glands in the stomach—a field which led him to research on the transplantation of organs, and the artificial suture of vessels, and ultimately into a study of the sympathetic system, a career which recalls that of the late Professor Langley.

Lim's influence on science in China, and indeed far beyond China, is not to be measured simply by the catalogue of his own papers. Naturally a leader, he was one of the original editors of the Chinese *Journal of Physiology*, and one of the Founders of the Chinese Physiological Society. His department must be accounted one of the important physiological laboratories of the world.

[General Lim recently visited India.]

INDIA-MADE SURGICAL INSTRUMENTS FOR RUSSIA

NEARLY 80,000 surgical instruments manufactured in India have been supplied to the Indian Red Cross Commissioner for despatch to Russia. This was revealed at the 7th meeting of the Medical Stores Supply Committee which met in New Delhi on 10th July, with Lieut.-General Sir Gordon Jolly, Director-General, I.M.S., in the chair. A representative of the drug manufacturers in India has now been included in the Committee.

Reviewing the progress of medical stores manufacture in India, the Committee noted that during the last six months 133 items have been transferred to the list of medical store articles now made in India. Marked progress has been made in the production in India of acriflavine, atropine sulphate, catgut ligatures, tannic acid, creosote and ephedrine.

There have been important developments in the manufacture in India of surgical instruments and appliances, both as to variety and quantity, and the gross output of the industry has increased tenfold within the past twelve months. For example, one million 'Suture' needles were manufactured during six months ending with May 1942, and the production of six million more over the next 12 months has been planned.

Waste of quinine

The position of anti-malarial drugs in India, particularly quinine, was reviewed by the Committee. The desirability of enlisting the aid of the medical profession in India in preventing waste of quinine in the treatment of malaria was strongly urged. The Committee noted the recommendation of the Malaria Commission of the League of Nations that the standard course of treatment for malaria should consist of 15 to 20 grains of quinine daily for five to seven days. It was agreed that if medical practitioners in general followed this rule, much waste would be avoided.

VEGETABLE INSECTICIDES IN INDIA

THE discovery of several useful vegetable insecticides and the possibilities of their cultivation in India are revealed in a leaflet (No. 20) just published by the Forest Research Institute, Dehra Dun.

For controlling agricultural as well as household pests vegetable insecticides are preferred to others, such as lead and copper salts, arsenic and nicotine, because they are non-poisonous to man and animals.

The growing demand for vegetable insecticides was hitherto met mainly by a plant called 'derris' from Malaya, Dutch East Indies and Philippines. Investigations conducted by the Forest Research Institute have now shown that other plants bearing the same toxic content as 'derris' are available in this country; and the existing materials are rich enough for the preparation of effective insecticidal emulsions and powders. Their toxic content is capable of still further improvement by proper cultivation and treatment.

Certain parts of India, it has been found, possess suitable climatic and soil conditions for the introduction and cultivation of richer varieties of Malayan 'derris'. Experiments in this direction have already proved successful in Mysore, Cochin and Assam.

INDIAN MEDICAL SERVICE RECRUITMENT

As a war-time measure, the Government of India have decided that medical practitioners who hold the following qualifications will be eligible for appointment to the Emergency Cadre of the Indian Medical Service :—

1. Bachelor of Medicine and Bachelor of Surgery of the Mysore University (M.B., B.S. Mysore).
2. Bachelor of Medicine and Bachelor of Surgery of the Osmania University (M.B., B.S. Osmania).

ADVANCE OF PAY FOR I.M.S. OFFICERS

THE Government of India have decided that candidates selected for Emergency Commission in the Indian Medical Service for duty within Indian limits may be granted an advance of pay not exceeding Rs. 300 at the time of appointment.

The advance will be recovered by monthly instalments of one-third of his pay.

GROUNDNUT AS HUMAN FOOD

(Note issued by the Nutrition Research Laboratories, I. R. F. A., Coonoor)

GROUNDNUT (*Arachis hypogaea* Linn) is really a leguminous plant, although in their chemical composition groundnuts resemble nuts such as cashew, almond and walnut more closely than they resemble pulses. The plant is a native of Brazil, from whence it spread to Africa and Asia. It has been cultivated in the tropics and sub-tropics for several centuries, and in India groundnut is an important crop. It is grown chiefly in Madras, but Bombay and the Central Provinces are also important centres of production. In normal times groundnut oil and cake are exported in large quantities to the United Kingdom and the continent of Europe. As a result of the war, exports

from the Madras Province dropped from 760,000 tons in 1938-39 to 282,000 tons in 1940-41.

The reduction of the export trade has produced a disposal problem. One method of disposal would be its wider use as human food and this raises the question of its nutritive value. Per 100 grammes, it contains about 25 to 33 grammes of protein, 40 to 50 grammes of fat and 10 to 20 grammes of carbohydrate. It is rich in phosphorus, but not in calcium. As regards its vitamin content, it contains some of the B vitamins, notably B₁ and an important member of the B₂ group, nicotinic acid, in fair amounts, but no vitamin A. Groundnut oil, like most vegetable oils, is devoid of this valuable constituent. Vanaspati or vegetable ghee, which is usually made from groundnut oil, does not contain fat-soluble vitamins A and D.

Experiments with groundnut

In the Coonoor Laboratories a long series of experiments has been carried out on the value of various foods in 'supplementing' poor rice diets. Rats are given a diet which resembles in composition poor rice diets eaten by human beings. Different foods are added to this basal diet and their effect on the development of the rats observed. This method of testing provides a good idea of their nutritive value under Indian conditions. In fact it is in some ways a better index than detailed chemical analysis. If milk is added to the rice diet, the result is a striking increase in the growth rate and an improvement in the general condition of the animals. Groundnut, however, when given in amounts equivalent to 1 to 2 ounces daily in a human diet, does not produce any striking supplementary effect. The conclusion is that groundnut, although it is rich in certain food factors, does not contain enough of the constituents which are most needed by the poor rice-eater to make good the defects of his diet. Milk, on the other hand, contains these in the correct proportions. It is possible that the relatively low calcium content of groundnut is to some extent responsible for its failure as a supplement and its deficiency in certain vitamins in the B₂ group may also be concerned. Experiments on this subject are proceeding.

Suppose half to one ounce of groundnut were distributed daily to poor children in schools. It is not to be expected that such a supplement would be as effective in improving their state of nutrition as a glass of milk. On the other hand, groundnut, taken in small quantities, is perfectly good food. Its high fat content makes it a concentrated food, with a high caloric yield per unit of weight. Since many poor school children are under- as well as mal-nourished, any supplement which increased their total food intake would be of value. In normal times peanuts sold very cheaply in small paper bags are very popular among poor children in London.

Groundnuts as such have never been used as a staple human food anywhere in the world. Consumed in large quantities they tend to be nauseating, probably because of their high fat content. Their main use has always been as a source of oil, the 'cake' which remains after the extraction of oil being employed as cattle food and manure. It is said that groundnut cake is used as human food in Spain. In the U.S.A. so-called 'peanut butter' has been fairly widely consumed, and in that country roasted peanuts are very popular. The inclusion of groundnut flour in small quantities in wheat biscuits has been suggested.

The idea that groundnuts could be used in India as an important article of diet, replacing equivalent quantities of cereals such as rice, may be dismissed. They could, however, be consumed in somewhat greater quantities as an addition to ordinary diets, either in the form of roasted nuts or as a sweetmeat with jaggery. Even a slight increase in consumption would help to dispose of surplus stocks. In the present circumstances it is unfortunate that they cannot be strongly recommended by the nutrition worker as an exceptionally valuable food, but there is no reason why their use as human food should not be extended.

Public Health Section

A NOTE ON A TUBERCULIN SURVEY IN SIALKOT TOWN

By C. L. SAHNI, M.B., B.S. (Punjab), D.P.H. (Lond.),
D.T.M. & H. (Eng.), L.M. (Dub.)

Municipal Medical Officer of Health, Sialkot

At present our knowledge of the incidence of tuberculosis in India is meagre; one of the ways of getting knowledge as to the extent and distribution of tuberculous infection is by means of carrying out tuberculosis surveys, of thousands of persons. This fact was emphasized by all the tuberculosis workers who attended the tuberculosis workers'-conferences, held in Delhi in 1939 and 1940. It was also decided at the conferences that a uniformity should be maintained in the method of planning and conducting the surveys in the whole of the country. In India, the survey work done has been small and inadequate considering the vastness of the problem of tuberculosis in the country, where millions of open cases exist.

It was decided by the writer in the middle of 1940 to start a tuberculosis survey in Sialkot town under the auspices of the District Red Cross Society. To begin with, it was decided to conduct a type I survey (i.e., a tuberculin survey) on the lines suggested in the report of the tuberculosis survey sub-committee of the Indian Research Fund Association. It was not, however, till the beginning of 1941 that the actual work could be undertaken.

Sialkot town is situated in the north of the Punjab, and has a population of 119,723 according to the census of 1941. It is an industrial town and some portions are very congested. It is specially known for its sports goods industry.

Object of the survey

The survey was conducted to ascertain by means of the tuberculin test the extent and distribution of tuberculous infection amongst boys and girls, belonging to different nationalities, in different age groups, and residing in different areas of the city.

Number of persons tuberculin tested.—Six thousand four hundred and thirty-six children, 3,455 boys and 2,981 girls, studying in thirty-two schools in the town were tested. The children to be tested were not selected in any way; all the children of both the sexes and of ages between 5 and 18 years were tested. All communities, Muslims (4,143), Hindus (2,028) and Christians (265) were included. About 95 per cent of the children belonged to the urban areas, and only 5 per cent came as day-scholars from the neighbouring villages.

Technique

The method used for the tuberculin test was that of Mantoux, as the results with Mantoux's intradermal test are more accurate than with the other tests. Burroughs Wellcome & Co.'s old tuberculin human (T) was employed in this

investigation, normal saline was used as diluent, and 0.1 c.cm. of the dilutions used contained the desired dose. Tuberculin solution was always kept in a refrigerator, and was never employed when more than ten days old. The field-workers carried the tuberculin solution in cool thermos bottles, and were supplied with special tuberculin syringes.

Dilutions.—Dilutions employed were 1 in 1,000 and 1 in 100. 1 c.cm. syringes graduated 1/20 c.cm. were used. The needles after each injection were merely wiped with cotton-wool soaked in absolute alcohol.

Site of injections.—The site of injection selected was the front of fore-arm after it was cleaned with spirit and was dry.

Dosage.—All the children were first tested with 0.1 c.cm. of a 1/1,000 dilution, a second test was done with 0.1 c.cm. of a 1/100 dilution in those who gave a negative result with the first dose. The results were read at the end of 48 hours, and again at the end of 72 hours, when the final opinion was recorded by the investigator.

The degrees of intensity were recorded according to the following standards:—

- | | |
|------------------|--|
| One plus (+) | = Slight but defined œdema raised 1 mm. above skin surface and not more than 10 mm. in diameter in the largest axis. |
| Two plus (++) | = Well-defined œdema, raised somewhat more than 1 mm. above skin surface; diameter between 10 to 15 mm. |
| Three plus (+++) | = More extensive œdema with diameter exceeding 15 mm. and thickness exceeding 1.5 mm. above skin surface; wide area of redness beyond but no vesiculation or necrosis of the skin. |
| Four plus (++++) | = Extensive œdema, redness, vesiculation and necrosis; may be associated with temperature and malaise. |

Mantoux tests were not started till propaganda had been carried out amongst the public, teachers and the children, and it was felt that there would be no opposition from the public. The managing committees of the various schools had to be addressed and the members were individually as well as collectively informed about the object of the survey and its advantages to the community. The tests, however, could not be done in two institutions, as it was not possible to secure the co-operation of the managing committees of the schools. The reason was that one or two members on the managing committees

were homœopath doctors who in spite of repeated discussions with the writer were not convinced of the utility of the survey.

Staff and equipment

The staff conducting the survey worked in conjunction with the doctor-in-charge of the tuberculosis clinic, where a properly equipped bacteriological laboratory was also provided. The tuberculin solutions were prepared in the laboratory under the supervision of the tuberculosis medical officer, and supplied to the investigator. The following staff was employed to carry on the survey: one whole-time woman doctor holding L.S.M.F. qualifications for the girls' schools, one male doctor with L.S.M.F. qualifications for the boys' schools, one typist clerk and one female peon.

Special schedule cards as recommended by the survey sub-committee of the Indian Research Fund Association were used for recording the findings, so as to permit of sorting, tabulation and analysis by modern statistical methods in order to assess the significance of the data obtained.

Finances.—The expenditure for the survey was met out of the grant-in-aid of Rs. 2,400 given by the Punjab Branch of the Tuberculosis Association, and the grants from the Sialkot Municipality, and the District Red Cross Society.

Analysis of the findings

The results of the tuberculin survey, as given in table I, show that the percentage of

Table III gives the results of the tests in the different communities, and according to the intensity of the reaction.

Amongst the Muslims and Indian Christians the incidence of positive results is 36.7 per cent and 35.0 per cent; amongst the Hindus the incidence is much lower, only 27.0 per cent.

The purdah system and other social habits among the Muslims probably increase the chances of tuberculous infection, and cause higher percentage of positives in this community.

It is of some importance to note the intensity of reaction. It will be seen from table III that 25.8 per cent of the positives are (+), 5.7 per cent are (++) and 1.7 per cent (+++), and 0.3 per cent are (++++). As regards community if we group the three stronger reactions together, Muslims have as many as 56.3 per cent of the strong reaction, while Hindus have 33.9 per cent and Christians 9.8 per cent. The higher percentage of strongly positive reactions among Muslims coincides with a higher percentage of infection rate among them as shown by tuberculin tests.

A correlation of the incidence of positive results in a locality with the sanitary conditions in that locality shows that on the whole the percentage of positives is much less in the children living in relatively less congested and open areas, than in those living in the congested part of the town. However a high incidence of positive tuberculin tests (35.1 per cent) has been

TABLE I
The results of tuberculin survey

Age periods	Boys			Girls			TOTAL		
	Number	Positives	Per cent	Number	Positives	Per cent	Number	Positives	Per cent
Below 10 years	1,529	364	23.8	1,164	376	32.3	2,693	740	27.4
Between 10 and 18 years.	1,926	632	32.2	1,817	793	43.6	3,743	1,425	38.0
TOTAL ..	3,455	996	28.8	2,981	1,169	39.2	6,436	2,165	33.6

positives for the whole group of children from 0 to 18 years of age was 33.6, that for children under 10 years of age it was 27.4 and for those between 10 and 18 years it was 38.0.

Table II shows the result of tuberculin tests in boys and girls according to the ages.

The scrutiny of table II shows that the percentage of positives is lowest (17.7 per cent) in the lowest age group (5 to 6), and increases in higher age groups to about 40.8 per cent. It is also seen that girls have a higher percentage of positives in all age groups than boys. This may be due to the fact that girls are in contact with cases of tuberculosis in the homes for longer periods than the boys, as they lead indoor lives for longer periods.

found in a school in spite of the good sanitary conditions.

It is a residential school, and all the girls reside in the boarding house attached to the school. The school building is very sanitary and several acres of land are attached to the school, which is surrounded on all sides by agricultural lands. Most of the girls come from the villages, and it is worth investigating further why such a high percentage of positive reactions is seen in these girls.

Having completed type I survey, it would be interesting to watch the results of type II survey, which it is proposed to conduct in the town with a view to finding out the incidence of morbidity and mortality from the disease. The

SAFE and INSTANT RELIEF in ASTHMA

*** SAFETY AND IMMEDIACY OF
RELIEF IN ASTHMA ARE
ENSURED BY FELSOL POWDERS**

FELSOL contains no narcotic and no morphia. It is safe for use in cardiac cases. FELSOL is absolutely non-cumulative in action.

FELSOL is compounded in powder form to obviate any crushing of tablets before use. The dictum of Hale-White (Materia Medica, 18th edition) that "Tablets . . . are very popular, but are sometimes useless, for they may be so hard and insoluble that they are found in faeces quite unaltered" is too frequently overlooked.

**The powder form and special method of manufacture are the essentials of immediacy of relief with FELSOL in ASTHMA.*

Baby's First Solid Food

Allenburys Malted Rusks are a valuable food from the age of ten months onwards, and may be used even earlier as a stimulus to salivary secretion and a help to teething. Their use encourages the development of a strong, wide jaw in which there is ample room for the teeth.

Vitamin D (calciferol), in the form of irradiated ergosterol, is added to the Rusks in the process of manufacture, in order to ensure normal calcification of bones and teeth.

The Rusks retain their crispness and flavour under the most varied climatic conditions.

In tins containing $\frac{1}{2}$ lb., 1 lb., 2 $\frac{1}{2}$ lbs.

should be admitted and cared for. These patients should stay in the hospital until the sputum becomes bacillus free or until they succumb to the disease. Another advantage of a hospital is that it provides accommodation for those sputum-positive cases who have no families. We shall thus have a complete and permanent control over 1,000 sputum-positive cases, which if treated and cared for under our present existing unsatisfactory and half-hearted measures, would spread infection in the city, and remain a source of great danger and peril to the public. If our permanent control over 1,000 sputum-positive cases proves successful, there should be no difficulty in increasing the number of health chawls to accommodate all our sputum-positive cases, under the direct supervision of our clinics.

We are spending lakhs of rupees on propaganda, education, clinics, sanatoria and hospitals, but with our present methods, are we seriously controlling the spread of infection? It would be more honest to confess that our present methods give these poor sufferers nothing but false hope and a false sense of security. A sputum-positive case stays in a sanatorium or hospital for a few months, considers himself cured on discharge, goes back to his family, breaks down in a short time, and infects his family as well as other members of the public. This vicious circle is repeated again and again. What good have we done to the patient, the family, the public and even the state by keeping such patients for brief periods in our institutions? Immediate, energetic and radical reforms are needed in our anti-tuberculosis campaign, if this deadly infection has to be exterminated. Organized health chawls, by providing permanent isolation of sputum-positive cases under constant medical supervision, and by combating poverty, overcrowding and undernourishment, offer the only hope of stamping out this scourge from our congested cities.

Current Topics

The Influence of Dietary Calcium and Phosphorus upon Tooth Formation

By W. E. GAUNT

and

J. T. IRVING

(Abstracted from the *Journal of Physiology*, Vol. XCIX, 20th December, 1940, p. 18)

THE persistently growing incisors of the rat have long been used for research on the metabolic changes in teeth induced by diet. In the present report the investigation was concerned with the effect produced by a variation in the Ca and P elements in the diet upon the structure of these teeth. It has been found that the rat incisor replaces itself every forty days and this fact is valuable for judging the effect of any change in diet over a certain experimental period. To

a basal diet, calcium lactate and disodium hydrogen phosphate were added in certain proportions; the basal diet contained calcium 0.028 per cent and phosphorus 0.066 per cent. Calcium lactate and Na_2HPO_4 were added in different proportions to form the twelve diets in the three experiments. The diets containing the largest amounts of Ca and P, either in proportion of 1.0 or 0.5, developed normally calcified bones and teeth. The rats were divided into four groups, all litter mates; all lived to 70 days except one group with the lowest Ca + P intake in which one rat died of pneumonia, whereupon the other three were killed for examination at 49 days of age. Of the other groups the rats with lowest Ca + P intake were stunted in growth, had a staring condition of the fur and hair and curvature of the thoracic and lumbar regions. There was hyperaesthesia on handling accounted for by the discovery post mortem of small beads of callus on the ribs indicative of fracture. The hair was coarse, patches of baldness appeared on the thorax and round the mouth and eyes, more pronounced when the intakes of Ca + P were lowest. No explanation of this is offered. Only two rats showed naked-eye abnormalities of the incisors, such as alternate bands of pigmented and unpigmented enamel; these were on diets low in Ca : P ratios. Chemical analysis showed a low ash content of bone in the diets, poor in Ca and P, but as these elements were increased the percentage of ash rose to almost normal. When the Ca : P ratio was 4, rickets was pronounced. The findings in the teeth were in contrast to those in bone, the weights of ash of the teeth being less affected; this was a more constant fraction of the body-weight than was that of the bone ash. The ash content of the dentine was less affected also. Histological examination showed, however, that the dentine in lower intakes of Ca and P displayed all the changes of deficiency of Ca and P, the predentine not only being much wider than normal but in the inadequate diets contained vascular elements.

Although reduction in the ash of the tooth in poor diets was less than that of bone, calcification of the tooth was more upset than that of bone. From this it is deduced that mineral metabolism of tooth is not comparable with that of bone. The authors refer to chronic fluorine toxicosis in which the ash of the tooth is always lowered while that of the bone is raised or lowered according to the Ca content of the diet, and to Schour, who maintains that calcification of the tooth is an irreversible process. This is contrary to the assumption of some authors that calcium is removed from the tooth during bodily stresses such as that obtaining in pregnancy.

Current Investigations of the Influenza Problem

By C. H. STUART-HARRIS, M.D., M.R.C.P.

(Abstracted from the *Journal of the Royal Army Medical Corps*, Vol. LXXVII, September 1941, p. 123)

DURING the winter of 1940-41 there was no epidemic of influenza either among the general population or among the service personnel in the neighbourhood of a military hospital. A small increase in the numbers of patients with acute respiratory infection admitted to this hospital occurred in January and February. The majority of the patients had symptoms suggesting clinical influenza and the presence of influenza virus A infection was proved in two ways. Of 8 garglings tested by inoculation of filtrates into the amniotic cavity of 12-day old developing chick embryos, 2 produced either directly or on passage the lesions typical of influenza virus infection. Both strains were readily adapted to mice and then proved to be serologically related to the influenza virus A group. Secondly, pairs of human sera were collected from individual patients during the fever and in convalescence and tested for neutralizing antibodies to influenza virus A. Twenty-seven of 34 pairs of sera

collected in January and February showed rises of antibody to virus A of X 5 or more. The 7 pairs of negative sera showed no rise of antibody to influenza virus B. The correlation between the picture of clinical influenza and the serological change to influenza virus A was good. An analysis of the symptomatology of 60 cases of proven influenza virus A cases from various years showed a uniform clinical picture.

Reviews

LECTURES ON AIR RAID INJURIES.—By The Madura Medical Association. 1942. Published by Mr. N. Krishnamurthy, Honorary Secretary, The Madura Medical Association, Madura. Pp. 108

THIS small handbook contains a series of lectures on air raid injuries delivered by the members of the Madura Medical Association with the object of making knowledge on the subject freely available to the whole medical profession in Madura town. The book consists of two parts, the first of which is meant for wardens and briefly deals with the elements of first aid, while the second part consists of nine lectures on various types of common war injuries, such as injuries of limbs, abdomen, chest, head, ear and eye, and burns. There are also two chapters on shock, and blood and plasma transfusion. Though printing mistakes are common, the book is quite readable and contains sufficient recent information on the subject. It can be recommended to those engaged in ARP work.

R. C.

THE NATURAL DEVELOPMENT OF THE CHILD: A GUIDE FOR PARENTS, TEACHERS, STUDENTS AND OTHERS.—By Agatha H. Bowley, Ph.D. 1942. E. and S. Livingston, Edinburgh. Pp. xvii plus 172; with 84 photographs. Price, 8s. 6d. Postage, 6d.

IN an age when the study of the psychology of the child has received in Europe and America an impetus to which few subjects have ever been submitted, it was inevitable that something of high pressure salesmanship should have crept into many of the preparations offered.

The child by some is represented as a battery of high voltage continuously emitting charges often of dangerous strength, and best handled only by the initiated. By others, he is pictured as an amoeba-like mass of sensitive protoplasm, assuming shape and form only from stimuli applied by his environment and contacts.

Miss Bowley's book represents the *via media* and offers a sane and healthy picture of the mental and psychological growth of the child put in language understandable by us all. The author has studied children from birth to thirteen years of age and the book is well illustrated by fine, pointed, photographic studies of the children.

There is an interesting chapter on 'Children and the War'. The effect of evacuation upon the child, and the part to be played by parent and teacher in the maintenance of mental equilibrium by those young citizens, are briefly outlined.

A useful book for students, teachers and parents.

L. G.

AFTER-TREATMENT: A GUIDE TO GENERAL PRACTITIONERS, HOUSE OFFICERS, WARD-SISTERS AND DRESSERS IN THE CARE OF PATIENTS AFTER OPERATION.—By H. J. B. Atkins, D.M., M.Ch. (Oxon.), F.R.C.S. (Eng.). Blackwell Scientific Publications, Limited, Oxford. Pp. xiv plus 252. Illustrated. Price, 15s.

THIS book provides a valuable and comprehensive guide to recognized methods of 'After-Treatment'.

Care is taken to stress two important aspects of successful surgery often lost sight of; of primary importance is the need to gain the confidence of the patient by giving him due consideration as a 'person' rather than a 'case'. Also emphasized is the importance of gaining the understanding and co-operation of the ward staff. The book is written in a pleasant easy style that stimulates and holds the interest, and thus should make a special appeal to the busy ward sister or house officer.

D. E. C.

MATERIA MEDICA FOR NURSES.—By A. Muir Crawford, M.D., F.R.F.P.S.G. Fifth Edition. 1942. H. K. Lewis and Company, Limited, London. Pp. viii plus 138. Price, 4s. 6d.

THIS little book supplies a very up-to-date summary of the drugs in common use, and would be a most useful possession in all hospital wards, as a reference to enable the nurses to take an intelligent interest in the medicinal therapy of their patients. The new chapter on the control and regulation of poisons provides an essential addition, completing the information required by nurses on this subject.

D. E. C.

THE PRINCIPLES AND PRACTICE OF OPHTHALMIC SURGERY.—By E. B. Spaeth, M.D. Second Edition. 1941. Henry Kimpton, London. Pp. 886. Illustrated with 451 engravings, containing 1,149 figures and 6 coloured plates. Price, 48s.

THIS is the second edition of this book and various additions have been made to the text to bring the contents up to date. The author describes the various operations in ophthalmology with which the surgeon has to deal in his everyday practice. Chapters are devoted to anaesthesia; the surgery of the orbit; the lacrimal apparatus; enucleation and allied operations; surgery of the contracted socket; the ocular muscles; reconstructive plastic surgery including epidermal and dermal grafts, mucous membrane, fascia grafts and pedicle grafts; the surgical conditions of the lids; surgical conditions of the conjunctiva, cornea, sclera, iris and anterior chamber. Three chapters are devoted to cataract, in which the author describes the aetiology, differential diagnosis, technique of the various procedures for the extraction of cataract, and the complications of the operation. Three chapters are also devoted to the surgery of glaucoma and two chapters to the aetiology, diagnosis and treatment of retinal detachment. Finally there is a description of injuries to the eyeball, and of x-ray and radium therapy.

To ophthalmologists working in India, the chapters on glaucoma and cataract are of great interest, as these diseases are so common, and large numbers of operations for the relief of these conditions are done. We cannot agree with the author's summing up of the general treatment of glaucoma. For epidemic dropsy glaucoma, it is now agreed that sclero-iridectomy is the operation of choice, and sclero-corneal trephining has been largely abandoned owing to the frequency of late infection coming on from months to years after the operation; after a unique and big experience of glaucoma operations, the reviewer has no hesitation in saying that late infection and complications are much commoner in sclero-corneal trephining than in sclerectomies; as a routine operation the former is preferred by many experienced ophthalmologists in India. In this we agree with Fuchs who gave up the operation on account of late complications. Every case of chronic simple glaucoma should be judged on its merits. Iridencleisis is not a suitable operation for the average patient in India, and the choice lies between a sclero-iridectomy and a sclero-corneal trephining, and if possible the former should be done. The filtering cicatrix should not encroach on the cornea as it is through the corneal bleb that infection is most liable to occur. The author's description of the various types of cataract operation is good, but we cannot advocate the routine use of conjunctival

sutures; they prolong the operation and complicate the technique. A generous conjunctival flap is preferred, and experienced operators often prefer to make the flap incomplete in the form of a bridge which has many great advantages in cataract work in India. The chapters on reconstructive ophthalmological plastic surgery are excellent.

The book as a whole is first class and contains a mass of practical and valuable information. It is written in a simple clear style and is admirably illustrated with 451 engravings containing 1,149 figures and 6 coloured plates.

We strongly recommend it as being most useful for medical men in India interested in ophthalmology.

E. O'G. K.

THE PRINCIPLES OF ANATOMY AS SEEN IN THE HAND.—By Frederic Wood Jones, D.Sc. (Lond., Adelaide and Melbourne), F.R.S., F.R.C.S. Second Edition. 1941. Baillière, Tindall and Cox, London. Pp. x plus 418, with 144 illustrations. Price, 25s.

THE second edition of this book is not only a welcome addition to works on the hand, but is also essential to all anatomists because in it the principles of anatomy are very lucidly expounded.

So well are the principles described that the reviewer feels that here surely is a pattern on which anatomical textbooks should be written—in fact he would suggest that a textbook of general anatomy written by the present author in the same style would form the beginning of a new era in the teaching of anatomy, an era long overdue.

Besides explaining the general principles so well, especially in the first half of the book, topographical anatomy is not neglected and certain important structures seldom stressed in the textbooks are very well described, e.g., the intrinsic muscles and the nervous pathways and mechanisms: as also are the flexor lines, the cleavage lines and the fascias. The chapter on 'The action of muscles' is particularly worth study.

The bibliography is good and the reader is thereby given much scope for further study.

It may be said with confidence that this is a book which all medical students, and of course all anatomists, should read and it should also be studied by all those surgeons who operate on the hand.

G. C. T.

Abstracts from Reports

ANNUAL REPORT OF THE KING EDWARD VII SANATORIUM, BHOWALI, U. P., FOR THE YEAR 1941

THE sanatorium remained open throughout the year and the accommodation available for the general public was fully occupied except during the winter months and, as usual, there was a waiting list during the season, especially for the cheaper classes. Enquiries and applications for admission were received not only from the various districts of the United Provinces but from other provinces also.

Forty-eight patients remained in the sanatorium on 1st January, 1941, from the previous year and 258 patients were admitted and 250 patients discharged during the year under report. The daily average number of patients treated was 112.94, the largest number being 167 during the month of May, and the lowest 43 in the month of January.

The results of treatment in 209 cases were as follows:—arrested—27.27 per cent; much improved—7.66 per cent; improved—19.14 per cent; stationary—24.40 per cent; worse—15.31 per cent; died—6.22 per cent.

The financial condition of the sanatorium remained satisfactory.

Water supply to the sanatorium being an urgent need, the public health engineer studied the problem

and submitted estimates costing about Rs. 13,500 for this purpose. The committee has accepted the estimates and has written to the public health engineer in order to find out if the work can be completed at the estimated cost on account of the abnormal conditions due to war.

The question of electric installation in the sanatorium has been kept in abeyance for the present as it would not be possible to get the necessary plant and material as long as the war lasts.

THIRD ANNUAL REPORT OF THE TUBERCULOSIS ASSOCIATION OF INDIA FOR THE YEAR 1941

THE continuation of the war and the grave international situation could not but have their repercussions on the progress of our work, but in spite of this, the association has been able not only to consolidate the work already started, but also to make considerable progress in new directions.

The most outstanding event of the year was the opening of the Lady Linlithgow Tuberculosis Sanatorium at Kasauli, which, while providing up-to-date treatment for tuberculous patients from all parts of India, will also act as a teaching centre for specialized training in tuberculosis.

There has been a further increase in the number of institutions in India for the diagnosis and treatment of tuberculous patients. Several post-graduate courses have been held for training doctors in tuberculosis work, and there have been courses for training tuberculosis health visitors, in several centres. Additional tuberculosis associations have been initiated or are in the process of formation.

The second annual general meeting of the association took place at the Viceroy's House, New Delhi, on the 25th March, 1941, and was presided over by Her Excellency the President of the association. In her presidential address, Her Excellency expressed gratification at the satisfactory record of progress of the association during the past year. She referred to the good work done by the New Delhi Tuberculosis Clinic, and to the Government of India's acceptance of the Kasauli scheme put before them by the association.

Dr. C. Frimodt-Møller continued as Medical Commissioner until 10th August, on which date he was unfortunately taken ill and placed on sick leave. Dr. P. V. Benjamin, Medical Superintendent of the Union Mission Tuberculosis Sanatorium, Arogyavaram, was appointed officiating Medical Commissioner.

Under the auspices of the Central Association, two short post-graduate courses in tuberculosis were organized in Bombay and Calcutta during the year 1941. No tuition or admission fee was charged. Certificates of attendance were granted at the termination of the courses.

At the request of the Tuberculosis Association of India, the publishers of the *Indian Medical Gazette* brought out their 1941 October issue as a special tuberculosis number, this being the fifth year in succession in which such a number has been published. These special tuberculosis numbers have not only been popular in this country but also have attracted considerable attention outside India. The committee wish to record their sense of indebtedness to the editor, Dr. L. E. Napier, as well as to the management of the *Gazette* for so willingly publishing the special tuberculosis number.

Two new tuberculosis associations were formed during the year and affiliated to the Tuberculosis Association of India. The total number of affiliated tuberculosis associations has now risen to 26.

The New Delhi Tuberculosis Clinic, which was opened by Her Excellency the Marchioness of Linlithgow on 20th November, 1940, has made steady and satisfactory progress. The clinic functions as a centre for the diagnosis of tuberculosis in doubtful cases where assistance is sought by private practitioners and other institutions. The number of new

patients who attended the clinic for this purpose was 1,694. Of these nearly 50 per cent were referred to the clinic by other institutions and doctors. Patients so referred to the clinic are returned to the respective doctors with proper diagnosis and advice, and they are treated at the clinic only at the express wishes of the doctors concerned. The total number of patients (including new and old) who attended the clinic since November 1940 was 20,375. Seventy-six patients were admitted to clinical beds for observation, their average stay being 24.4 days.

The health visitors employed at the clinic visit patients in their homes to give advice to them and their relatives, and to arrange for the attendance and examination of contacts at the clinic. Contacts examined at the clinic number 869, of whom about 10 per cent were found suffering from tuberculosis and placed under treatment.

A care and after-care committee for carrying out an experimental scheme of organized home treatment from the New Delhi Tuberculosis Clinic has been constituted under the chairmanship of Sir Shri Ram. A municipal area with a population of about 20,000 people has been chosen for this work, and four doctors practising in that area have been appointed to visit patients in their homes. Relief is provided for poor patients in the form of (a) milk to patients or under-nourished members of the family, (b) payment for transport and (c) provision of medicines and medical necessities. The expenses of this scheme are met from a grant of Rs. 4,000 from the Chief Commissioner, Delhi, and from collections by the committee members.

Reports of the work done during the year 1941 have been received from all affiliated bodies, and they are very encouraging.

Service Notes

APPOINTMENTS AND TRANSFERS

COLONEL H. E. SHORTT, C.I.E., V.H.S., is appointed Honorary Physician to the King, dated 23rd August, 1941, *vice* Major-General P. S. Mills, C.I.E., retired.

Colonel J. S. S. Martin, V.H.S., is appointed Honorary Surgeon to the King, dated 13th October, 1941, *vice* Colonel E. G. Kennedy, deceased.

The services of Colonel J. B. Hance, C.I.E., O.B.E., V.H.S., Inspector-General of Civil Hospitals, C. P. and Berar, and Director of Public Health, C. P. and Berar, in addition have been placed at the disposal of the Government of India for special duty and he made over charge in this province on the afternoon of 24th July, 1942.

Lieutenant-Colonel N. S. Jatar, C.I.E., D.S.O., I.M.S. (Retd.), Inspector-General of Prisons, C. P. and Berar, has been appointed as Inspector-General of Civil Hospitals, C. P. and Berar, in addition to his own duties with effect from the afternoon of 24th July, 1942.

Major W. Scott, on return from 1 month's leave, has been posted as Civil Surgeon and Superintendent, Robertson Medical School, where he assumed charge on the forenoon of 18th July, 1942.

Major S. P. Bhatia, Deputy Assistant Director-General (Medical Stores), Medical Store Depot, Calcutta, is appointed Additional Assistant Director-General, Indian Medical Service (Stores), *vice* Major H. B. Wright, with effect from the afternoon of the 10th August, 1942.

The services of Captain H. W. G. Staunton, an officiating Agency Surgeon, were placed at the disposal of His Excellency the Commander-in-Chief, with effect from the afternoon of the 9th January, 1942.

Notes

EYELEX

MESSRS. UNION DRUG COMPANY, LIMITED, Calcutta, announce the introduction of their sulphonamide ointment, Eyelex, in an improved packing. The current collapsible tube will be replaced by wide-mouthed glass container with a cork top. To facilitate application, a blunt-headed glass insertion rod will also be added with each packing. In spite of the increased cost, the rate and quantity of the ointment will remain as before.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Rs. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

NOTE ON ECONOMY IN THE USE OF ANTI-MALARIAL DRUGS

By G. COVELL, M.D., D.P.H., D.T.M. & H.
COLONEL, I.M.S.

Director, Malaria Institute of India

Now that the source from which the bulk of the cinchona alkaloids consumed in India in pre-war years was derived is no longer available, every possible avenue which may help to overcome the emergency thus created must be explored.

One obvious step is the extension of cinchona cultivation in India so that the country may ultimately become self-supporting in this respect, but several years must elapse before the new plantations can produce a sufficient quantity of the bark to meet all requirements. Another is to manufacture synthetic anti-malarial drugs on a scale large enough to bridge the gap which must exist until the output of cinchona alkaloids has been fully developed; but here again there must be a considerable time-lag before adequate supplies of such drugs can be made available in India.

It is therefore necessary to scrutinize anew our methods of combating malaria, both by therapeutic and preventive measures, and to explore the possibilities of effecting an immediate reduction in the consumption of anti-malarial drugs, either by modifying our schemes of treatment, or by intensifying our efforts to reduce the incidence of the disease and the scope and severity of regional epidemics. The object of this note is to draw attention to certain aspects of each of these lines of approach to the problem.

I. Dosage and duration of treatment

Perhaps the most remarkable feature of malaria as a disease is its tendency to relapse. Whatever treatment may be adopted, a certain proportion of patients continue to suffer from periodical attacks of fever, sometimes for several years. It was this consideration which led in the past to the administration of quinine and other preparations of cinchona in large doses and to the adoption of prolonged courses of treatment, frequently extending over several months.

In recent years it has come to be recognized that there is no advantage either in prescribing massive doses of anti-malarial drugs or in administering such drugs over prolonged periods. The tendency of malaria cases to relapse is to a large extent independent of the dosage given and of the duration of treatment. Short courses of treatment, frequently of only a week or even less in length, have therefore become the rule,

and the daily dosage has also been reduced. The introduction of malaria therapy for the treatment of general paralytics has provided an unrivalled opportunity for research on this subject, and it is largely on the experience thus gained that modern ideas regarding the treatment of malaria are based.

A lengthy series of carefully controlled experiments, conducted in a number of different countries under the auspices of the League of Nations, has confirmed the view that the administration of anti-malarial drugs over long periods when the infection is latent is not merely useless, but may retard the development of the defensive mechanism of the patient, without which the parasite cannot be eradicated from the body. The results of these experiments were published in the *Fourth General Report of the Malaria Commission of the League of Nations* (1937), on which most of the schemes of treatment now in practice throughout the world are based. A chart embodying the findings of the Commission in respect of the action of quinine and the various synthetic anti-malarial drugs, together with its suggestions as to treatment, was published by the Malaria Institute of India in the same year (see table).

There are certain difficulties in framing a standard scheme of treatment appropriate for all circumstances. Not only do the different species of malaria parasite vary in their reaction to treatment and tendency to relapse, but the different local strains of each parasite show wide variations in this respect. An extreme instance is that of an Italian strain of *Plasmodium falciparum*, which was found to require eight times as much quinine to control primary infections as a strain of the same species of parasite originating from India. A further complication is the great variation of individual patients in their reaction to malarial infection and thus to the effect of a particular course of treatment. It follows from these considerations that a line of treatment which would be effective for one strain of a malaria parasite may be insufficient for another. Similarly, a course which would cure an infection in one patient may be ineffective for another, even though the species and strain of parasite are identical.

For these reasons, the scheme of treatment for individual patients put forward by the League of Nations Malaria Commission was framed with considerable elasticity. The routine treatment suggested prescribed quinine 15 to 20 grains, or atebirin 0.3 gramme, for 5 to 7 days, i.e. a minimum total dosage of 75 grains quinine, or 1.5 grammes atebirin, and a maximum of 140 grains quinine or 2.1 grammes atebirin; followed in each case by 0.02 gramme plasmoquine daily for 5 days.

Much of the misapprehension and divergence of view regarding the treatment of malaria has been due to lack of precise knowledge as to the action of the various drugs employed. No drug

TABLE
Action of quinine and the synthetic drugs on malaria
(Based on 4th General Report of League of Nations Malaria Commission)

	ACTION ON TROPHOZOITES		ACTION ON GAMETOCYTES		ACTION ON ACUTE SYMPTOMS		Action on frequency of relapse	Action on splenomegaly	Effect on general condition of patient
	B. T. + Q.	M. T.	B. T. + Q.	M. T.	B. T. + Q.	M. T.			
Quinine	Daily dose of 1 gm. (15 grs.) causes disappearance, 5-7 days.	Daily dose of 1.3 gm. (20 grs.) causes disappearance, 5-7 days.	Affects pre-gametocytes and gametocytes.	Affects pre-gametocytes but gametocytes only very slightly.	Marked action from 3rd day (2nd paroxysm).	Variable action from 3rd or 4th paroxysm.	Acts on all species but in B. T. and Q. relapse rate may reach 50 per cent.	Acts on all species but effect is transient where re-infection or relapses are frequent.	No effect if treatment is limited to number of days essential.
Atebrin	Daily dose of 0.3 gm. causes disappearance after 3 days. Effects last longer than quinine.	Daily dose of 0.3 gm. causes disappearance after 4 days in 90 per cent of cases.	Similar to quinine but slightly more marked.	Similar to quinine.	Very marked action. Fever falls by 2nd paroxysm.	Marked action. Fever usually falls by 3rd paroxysm (but with some strains effect is less than with quinine).	Action slightly more than quinine especially in B. T. and certain strains of M. T.	Effect somewhat slower than quinine but seems to last longer.	Sometimes yellow coloration of skin.
Plasmochin	Slight action only.	Practically no action.	Definite action in both species.	Marked action in minimum doses of 0.02 gm.	No indications for using plasmochin alone for treatment of acute attack.		Definite effect in B. T. and Q. In association with quinine and atebrin it has a marked effect in reducing relapses in all three species.	Insufficient data.	In the doses now used (e.g., 0.2 gm.) it seems to have no depressing effect.

NOTES

A.—ACTION OF COMBINATIONS OF DRUGS

1. There is no advantage in combining quinine and atebrin in treatment.
2. Quinine + plasmochin simultaneously produce less frequent and less intense toxic symptoms than atebrin + plasmochin, but are best given consecutively where possible. Quinine (15-20 grains daily, 7 days) + plasmochin (0.02 gm. daily, 5 days) are probably the best treatment for B. T. and Q. malaria.
3. Simultaneous administration of atebrin and plasmochin aggravates the toxicity of each and is not recommended. Consecutive treatment with atebrin (0.30 gm. daily, 5-7 days) and plasmochin (0.02 gm. daily, 5 days) has no advantage in the primary attack, but acts on gametocytes and relapses in the same manner as quinine and plasmochin treatment.

B.—PRACTICAL SUGGESTIONS FOR TREATMENT

1. *Individual treatment.*—Quinine (15-20 grains) or atebrin (0.3 gm.) 5-7 days, followed by plasmochin (0.02 gm.) 5 days, or quinine + plasmochin simultaneously.
2. *Treatment in field.*—Quinine (15-20 grains) or atebrin (0.3 gm.) 5-7 days, followed by plasmochin (0.02 gm.) 5 days if funds and medical supervision are available. But if, as is usual, this is not so, short treatments with the cinchona alkaloids are more suitable.
3. *Mass drug prophylaxis.*—Daily doses of quinine (0.40 gm. or 6 grains), or twice weekly doses of atebrin (0.20 gm.).

at present known destroys the sporozoites injected by the mosquito, and therefore no drug prevents malarial infection. The chief functions of both the cinchona alkaloids and atabrin are to cut short the clinical attack and to destroy the malaria parasite in the trophozoite stage. They are useless during the incubation period or when the disease is latent, and no intensification of dosage or prolongation of treatment will effect the radical cure of more than a certain percentage of infections. Plasmochin has no effect on the clinical attack, its great value in treatment being to reduce the percentage of relapses.

The realization of these principles has led to a certain modification of the aims of treatment. The physician no longer strives to eradicate the disease in all cases by the administration of large doses of drugs over a prolonged period. His object is rather to tide the patient over his attack by giving him just that amount of medication which will enable the defensive mechanism of his body to exert its maximum effect. This is brought about by the administration of a short course of quinine or atabrin (5 to 7 days) followed by a similarly short course of plasmochin to reduce the risk of relapse. Some workers have recommended even briefer courses than this, the shortest of all being of Collins (1934), who introduced in Bulgaria a 4-day treatment consisting of 15 grains quinine daily for 3 to 4 days only. This proved effective for the treatment of the southern European strains of benign tertian malaria, but was not quite sufficient for patients infected with malignant tertian strains occurring in that region.

Under the present circumstances, when stocks of anti-malarial drugs are strictly limited, greater care than ever should be taken not to prescribe larger quantities than are absolutely essential. The basic objects of treatment should be the prevention of mortality and the maintenance of malarious populations in a condition which will enable them to carry out their daily work. As a general guide, it is suggested that routine treatment should be limited to 15 grains quinine or cinchona febrifuge, or 0.3 gramme atabrin, daily for not more than 5 days, provided that clinical symptoms have by that time subsided. This may be followed by 0.02 gramme plasmochin daily for 5 days if available. Needless to say, in putting forward these suggestions there is no intention of imposing any restriction on the treatment of cases of special urgency, such as cerebral malaria with delirium and coma, hyperpyrexia, or pernicious malaria with persistent vomiting. Such cases should receive quinine bihydrobromide or bihydrochloride by the intravenous route without a moment's delay, but with the usual precautions regarding speed of administration, to be followed by the routine oral treatment as soon as the urgent symptoms have abated.

II. Preventive measures

Hitherto we have considered only methods of restricting the consumption of anti-malarial

drugs by modifications in dosage and duration of treatment. A far greater economy in this respect would be possible if we could by any means prevent the occurrence of widespread epidemics of malaria, or at least materially reduce their scope and severity.

The public-health aspect of malaria control has been treated in a separate paper (Covell, 1942). In this the conviction was expressed that the spray-killing of adult mosquitoes with pyrethrum insecticides would ultimately prove an effective weapon for combating rural malaria in India. The principle on which this method is based is that a mosquito can only transmit malaria if it has succeeded in living for not less than 10 days after having fed on a person with malaria parasites in his blood, and that if it can be destroyed within this period, it cannot convey the disease. There is no doubt that the general adoption of the spray-killing of adult mosquitoes in rural areas would effect a substantial reduction in India's annual requirements for anti-malarial drugs.

At present, the production of pyrethrum in India like that of cinchona is insufficient for the country's needs. But, unlike the case of cinchona, the development of pyrethrum cultivation in India is comparatively easy, and the required quantity can be produced far more rapidly. It has been demonstrated that pyrethrum of high quality can be grown without difficulty in many parts of India, but hitherto the area cultivated has been inconsiderable, except in Kashmir State.

It is the considered opinion of the writer that the extension of pyrethrum cultivation in India is of even more importance for the future of malaria prevention than that of cinchona. The chief obstacles to its production on a large scale are uncertainty as to the market price of present and future crops, and difficulty in obtaining land in areas suitable for its cultivation. The extension of pyrethrum cultivation in India should be encouraged by local governments in every possible way, and it is particularly important that no difficulties should be placed in the way of either private individuals or industrial concerns in obtaining suitable land from government sources.

Summary

1. Since supplies of anti-malarial drugs are at the present time strictly limited, rigid economy in the consumption of such drugs is essential.
2. Suggestions are put forward for the modification of existing schemes of treatment with this object in view.
3. A further economy in the consumption of anti-malarial drugs could be effected by the

(Concluded on next page)

CIRCULATION IN FIBRO-SARCOMAS

By M. G. KINI, M.C., M.B., M.Ch. (Orth.), F.R.C.S. (Edin.)
Surgeon, King George Hospital and Professor of Operative Surgery, Andhra Medical College, Vizagapatam (S. India)

WHEN a growth of large size occurs without commensurate blood supply, it is well known that degeneration takes place in it. In order to study the circulation in tumours, amputated limbs were used. Two cases of fibro-sarcoma in the forearm afforded the opportunity. The following procedure was adopted:—

After amputation of the limb, the brachial vein was ligatured and into the brachial artery which was held by forceps, an intravenous cannula was introduced and fixed by a ligature. A 20 c.cm. syringe containing lipiodol diluted with equal parts of liquid paraffin was fixed into the cannula and the fluid was injected slowly. The pictures show the circulation in two cases of fibro-sarcoma, and indicate the distribution of small capillaries in the growth. In the areas where the tumour is very thick, the capillaries are absent and this fact probably accounts for early degeneration clinically indicated by softening.

A study of circulation in the living is now made possible by injecting salts of thorium which causes no discomfort or untoward effects. It has not been done so far because of the difficulty of obtaining this salt in India. It should be made available to all clinical institutions wishing to study vascular disease.

These cases are reported to show the circulation in fibro-sarcomas. In one case of bone sarcoma in which this was attempted, the result was unsatisfactory, probably because of the lack of sufficient pressure to drive the fluid into the capillaries of the bone tumour. Further attempts will be made to study in future cases.

My thanks are due to Mr. R. Mahadevan, F.R.C.S., who helped me to carry out this experiment and to the radiologist Dr. P. Kesavaswamy for the roentgenograms.

general adoption of the method of spray-killing adult mosquitoes in rural areas throughout India as a preventive measure. To render this possible the extension of pyrethrum cultivation in India is essential, and should receive active encouragement from provincial governments.

PARTIAL DEGENERATION OF THE OPTIC NERVE ASSOCIATED WITH VITAMIN DEFICIENCY

By O. P. VERMA, M.B., B.S.
Field Worker attached to the Nutrition Research Laboratories
 (Nutrition Research Laboratories, I. R. F. A., Coonoor, S. India)

THE main features of the clinical condition which will be considered in this communication are as follows:—

The patient, usually a young adult, complains of slow and progressive loss of vision. No abnormalities which can satisfactorily account for the failure of vision are found in the media of the eye, but ophthalmoscopic examination reveals pallor of the temporal half of the optic discs. The condition is a common one; some 300 to 400 cases are seen annually in the Government Ophthalmic Hospital, Madras. Up to the present the aetiology of the disease has not been investigated in India and no effective method of treatment has been evolved. It has, however, been suspected that vitamin deficiency plays some part in causation.

Investigation

A preliminary study of a series of cases of 'temporal pallor' was undertaken in the Government Ophthalmic Hospital, Madras. Forty-eight cases were examined. The age and sex distribution was as follows:—

Age	..	0-10	10-20	20-30	30-45
Male	..	1	16	10	1
Female	..	1	13	5	1

The majority were young men and women ranging in age from 15 to 30. All belonged to the poorest classes, with incomes per family ranging from Rs. 10 to Rs. 30 per month.

Ophthalmic examination.—The patients complained of dimness of vision, which had progressively increased over a period of months or years. According to histories given, the duration ranged from 10 months to 7 years. Many patients had visited several hospitals in search of relief. Near vision was fairly satisfactory, except in two patients older than the rest. No history of a sudden onset, associated with acute ophthalmic disease, could be elicited in any of the patients.

Vision in the various cases ranged from 6/12 to 3/60—i.e. from relatively slight impairment to gross defect. In most cases both eyes were equally affected.

The conjunctivæ were usually 'dirty' and pigmented. Xerosis and Bitot's spots were present in some cases. No gross changes could be seen in the cornea, but careful examination under the corneal microscope revealed very small white spots on the surface; these were seen to be distributed in greater numbers at the centre than at the periphery. The appearance given was as

RIBOFLAVIN AND ITS RÔLE IN NUTRITION : M. SWAMINATHAN

Fissured tongue in case of riboflavin deficiency.

Superficial keratitis due to riboflavin deficiency showing corneal opacities and circum-corneal injection.

[These two figures were sent for Dr. O. P. Verma's paper on 'Further Experience of the Treatment of Superficial Keratitis with Riboflavin' in our August number: they were however too late for inclusion and with his permission they are now being used to illustrate Dr. M. Swaminathan's paper 'Riboflavin and Its Rôle in Nutrition'.—EDITOR, I. M. G.]

if something had been sprinkled on the cornea. The stippling was apparently due to superficial epithelial degeneration and desquamation. The sclera, iris, and lens were normal.

The fundus was normal except for the optic disc. The latter in all cases showed pallor of the temporal half, the intensity of which varied from case to case, being extremely marked in some instances. The degree of pallor did not regularly correspond to the degree of dimness of vision. The nasal half of the disc remained pink and the disc margins were regular. The vessels were not markedly diminished in size.

The retinoscopic error was small in almost all cases (e.g. +0.5, +1.0, -0.5 spherical, or a small cylinder). Except in a few cases the rectification of the refractive error failed to bring about any improvement in sight. The field of vision was not affected. The diminution of the field on the nasal side was negligible and no central scotomata could be found.

Kahn and Wassermann tests were carried out on all patients and gave negative results. General examination revealed no evidence of disseminated sclerosis or other lesions of the nervous system. The teeth were fairly good and the throat in general normal. There was no history of acute infection, or of excessive indulgence in alcohol or tobacco. The possibility of the latter can be excluded on account of the poverty of the patients. It is to be observed that tobacco and alcohol amblyopia, in which pallor of the temporal side of the disc is often present, usually occurs in middle-aged or elderly men, whereas the patients included in this investigation were for the most part young men and women.

Co-existence of deficiency diseases.—The patients were in general in a poor state of nutrition and many showed evidence of food deficiency disease. In 18 xerosis conjunctivae was present and in 5 phrynodema. The calves were tender and the knee jerks sluggish in 6 patients; this may be regarded as evidence of vitamin-B₁ deficiency. Nearly half showed angular stomatitis and fissured tongue of the type associated with riboflavin deficiency (Aykroyd and Verma, 1942). It seems likely that the superficial stippling described above was also evidence of the same deficiency. Superficial keratitis due to lack of riboflavin has recently been observed in out-patients in the same hospital (Aykroyd and Verma, *loc. cit.*) and the small superficial spots, visible only under the corneal microscope, may represent a very early and mild degree of this condition.

The incidence of deficiency diseases in the group is shown below, superficial stippling of the cornea being included in the list. If the latter is accepted as evidence of riboflavin deficiency, 85.6 per cent of patients showed co-existent deficiency disease. No doubt the examination of any random group of patients attending the ophthalmic hospital would reveal instances of deficient disease, but it is unlikely

that the incidence would be as high as in the group showing 'temporal pallor'. The presence of deficiency diseases in the majority of the group strongly suggests that the eye disease in question is due to malnutrition.

Total number of cases	..	48
<i>Number showing :</i>		
Xerosis	..	18

Angular stomatitis and fissured tongue	..	23
Red raw tongue	..	1
Tender calves and sluggish knee jerks	..	6
Small superficial spots on the cornea revealed by the corneal microscope	..	38
No signs of coincident deficient disease	..	6

Treatment

No method of treatment can be expected to produce an immediate and dramatic improvement in a condition characterized by degeneration of nervous tissue. The administration of certain vitamins appeared, however, to have a beneficial effect if continued for 3 to 6 months. Trial of this method of treatment was suggested by the high incidence, among patients suffering from 'temporal pallor', of conditions due to vitamin deficiency.

Treatment consisted of the administration of dried yeast and shark-liver oil. In many cases yeast was given alone, in doses of 7 g. daily, for a period of about one month. This had a good effect on the oral signs of vitamin-B₂ deficiency and often appeared to clear the vision without increasing its range, possibly because of the action of the riboflavin which it contains on the superficial epithelium of the cornea. Shark-liver oil, given in doses supplying 60,000 to 80,000 I.U. of vitamin A daily, appeared to produce genuine improvement in vision in a number of cases. The oil used had a value of 10 to 12,000 international units per gramme. Injections of vitamin B₁, given without other forms of treatment, did not lead to improvement.

The effect of treatment by yeast and shark-liver oil on 13 cases is recorded in the table. These cases were the only ones which remained consistently under treatment for one month or more. Improvement was most satisfactory in cases in which the original degree of dimness of vision was less severe. In some of these cases vision returned to normal. In more severe cases the degree of improvement was in general less, presumably because in such cases nervous degeneration was more advanced and dead nerve fibres cannot be restored to function. The pallor of the disc diminished in most cases with improvement in vision, but changes in the appearance of the disc and in vision were by no means parallel. In some cases which showed very marked improvement in vision some temporal pallor remained after a full course of treatment with shark-liver oil.

The appearance of the disc in a typical case is shown in the accompanying coloured drawing.

TABLE

Description of patients showing impairment of vision with pallor of the temporal half of the optic disc

Number	Age and sex	Vision	Duration, years	Signs of deficiency disease	Fundus examination	Treatment	Duration of treatment in months	Results

TABLE—concl'd.

Number	Age and sex	Vision	Duration, years	Signs of deficiency disease	Fundus examination	Treatment	Duration of treatment in months	Results
11	30, M.	R. 6/18 L. 6/18	3	Nil	Temporal pallor of both discs.	SLO 5i, b.d.	1 $\frac{1}{2}$	R. 6/12. L. 6/12.
12	19, F.	R. 4/60 L. 3/60	5	Red raw tongue.	Do.	SLO 5i, b.d. Yeast 5i, b.d.	3 1 $\frac{1}{2}$	R. 6/36. L. 6/36. Tongue unchanged. Tongue healed but no further improvement in vision.
13	25, M.	R. 3/60 L. 3/60	4	Angular stomatitis.	Do.	Yeast 5i, b.d. SLO 5i, b.d.	2 2	R. 6/60. L. 6/60. R. 6/36. L. 6/36.

No cases except Nos. 7 and 9 showed improvement in vision from glasses before treatment.
No. 7 improved to R. 6/24 and L. 6/24 and No. 9 to R. 6/12 and L. 6/18.
SLO = Shark-liver oil.

Discussion

It has been shown by numerous workers that pathological changes in the nervous system occur as a result of vitamin-A deficiency. The literature of this subject was reviewed by Rao (1936), who carried out an extensive investigation on the effect of vitamin-A deficiency on peripheral nerves. The same worker (1938) observed myelin degeneration in the optic nerve of rabbits, rats and fowls, fed on diets lacking in vitamin A. Treatment with carotene (Rao, 1940) cured xerophthalmia in the deficient animals, but not the anatomic nervous lesions. No signs of impairment of nerve function were observed in the deficiently-fed animals. Rao (1938) expressed the following views: 'A considerable series of observations, including those reported here, point to the conclusion that vitamin A is related to the integrity of the nervous tissues, but at the same time it appears that myelin degeneration may be associated with various forms of dietary error'.

Retrobulbar neuritis followed by partial optic atrophy in African patients has been described by Moore in a series of articles, three of which (1937a, b; 1939) are available in Coonoor. The ophthalmic condition described by him was usually found in association with signs of riboflavin deficiency. The same association was observed in a proportion of the present series of cases. Pallor of the disc with impairment of vision in malnourished cases has been observed by St. John in Barbados (Moore, 1937b). Moore reported that treatment with yeast and marmite produced excellent results, while cod-liver oil was ineffective. Some of his cases were given both yeast and cod-liver oil.

Métivier (1941b), working in Trinidad, has recently reported 'nutritional amblyopia', characterized by pallor of the temporal portion of the optic disc. He ascribes this to vitamin B₂ deficiency. He states that keratomalacia is rare in Trinidad and considers vitamin A deficiency unimportant in the island. He has, however (1941a), reported the existence there of xerophthalmia and Bitot's spots caused by vitamin A deficiency.

Cases treated in the present investigation appeared to respond more satisfactorily to large doses of vitamin A than to yeast. A number of cases showed xerosis and phrynodema, which are usually considered signs of vitamin-A deficiency. The dosage of yeast given to the patients in Madras was smaller than that given by Moore. It was sufficient, however, to clear up oral signs of riboflavin deficiency in certain cases without concurrent improvement in vision. For practical clinical purposes, treatment with yeast and fish-liver oil simultaneously may be recommended.

The untreated condition does not appear to progress to permanent blindness—a point noted by Moore and also by St. John. The author paid a visit to the Institute for the Blind in Poonomalee near Madras, in order to discover whether any of the inmates had been admitted for total optic atrophy which could be suspected of being a more advanced stage of the condition described in this paper. No such cases were found.

It is of interest to refer to an article entitled 'A common deficiency disease met with in out-patient practice' (Verghese, 1936). Verghese described a syndrome frequently observed in Malabar in the following terms:—

The syndrome of symptoms consists of the following:—

1. A chronic keratoderma characterized by a minute warty eruption affecting specially the outer surface of the lower and upper extremities, which has a Malayalam cognomen called 'kara'.

(N.B.—This is the condition now* known as phrynodema.)

2. Sore-mouth.

3. A group of eye symptoms consisting of:—

*The condition was first described and named by L. Nicholls in this journal in 1933, *I. M. G.*, 68, 681—Editor.

- (i) Night-blindness.
- (ii) Xerosis.
- (iii) Impairment of vision of varying degree.
- (iv) Conjunctivitis with slight lacrymation and photophobia.

Verghese did not report temporal pallor in cases showing impairment of vision; he says, in fact, that ophthalmoscopic examination revealed no remarkable changes in the retina except a slight hyperæmic condition of the vessels. There is, however, considerable similarity between his syndrome and the conditions other than temporal pallor observed in the group of patients described in this paper. His description illustrates the close clinical association between signs of vitamin-A and vitamin-B₂ deficiency in malnourished patients. He observed that the syndrome was very common in malnourished children in orphanages.

There seems little doubt that partial optic atrophy can be added to the growing list of vitamin-deficiency diseases of public-health importance. Careful examination of groups of malnourished school-children would probably reveal that mild degrees of impairment of vision associated with some degeneration of the optic nerve were very common.

Summary

1. A description is given of a series of cases of partial degeneration of the optic nerve, evidenced by pallor of the temporal half of the optic disc. In many cases there is serious impairment of vision.

2. A large percentage of the patients were suffering from deficiency diseases.

3. Treatment with shark-liver oil led to improvement, particularly in milder cases.

4. It is concluded that the condition is due to diet deficiency.

Acknowledgments

The author wishes to express his grateful thanks to the superintendent of the Government Ophthalmic Hospital, Madras, Rao Bahadur K. Koman Nair, for co-operation in the investigation. Gratitude is also due for assistance from other members of the hospital staff.

RIBOFLAVIN AND ITS ROLE IN NUTRITION

By M. SWAMINATHAN, D.Sc.

(From the Nutrition Research Laboratories, I. R. F. A. Coonoor, S. India)

Section 1

RIBOFLAVIN—AN IMPORTANT MEMBER OF THE VITAMIN B₂ COMPLEX—ITS ISOLATION AND IDENTIFICATION—CHEMISTRY, PROPERTIES AND SYNTHESIS—ITS ANALOGUES—THE SPECIFICITY OF ITS STRUCTURE FOR VITAMIN ACTIVITY

RIBOFLAVIN is an yellowish-green water-soluble pigment which occurs throughout the plant and animal kingdoms. It is one of the important vitamins belonging to the vitamin B₂ group, and was the first factor to be separated from the group. This occurred in 1933. Since then three more vitamins included in the complex have been isolated in a pure state. According to present knowledge, the vitamin B₂ complex includes the following:—

1. *Riboflavin*.—Essential in the nutrition of human beings and various animals used in laboratory experiments. Prevents and cures cheilosis, angular stomatitis, a certain type of glossitis, scaly dermatitis of the scrotum and superficial keratitis in human beings. The terms 'flavin' and 'lactoflavin' have been employed, but 'riboflavin' is now coming into general use.

2. *Nicotinic acid and its amide*.—This has been identified with the pellagra-preventive vitamin. It has a curative action on certain types of stomatitis and glossitis, unaccompanied by other signs of pellagra, and also on sprue.

3. *Pyridoxin (vitamin B₆)*.—This prevents or cures so-called 'rat-pellagra' and also a form of microcytic anæmia produced by faulty diet in rats and pigs. Its rôle in human nutrition is not yet clear.

4. *Pantothenic acid*.—This prevents a 'pellagra-like' condition in chickens. It has a growth-promoting effect on rats, dogs and pigs. It prevents or cures adrenal hemorrhage in rats. Its function in the nutrition of human beings remains to be discovered.

5. *Filtrate factors*.—These factors have not yet been isolated in a pure state. They are known at present by their growth-promoting effect on experimental animals. There is good evidence for the existence of at least two different factors.

Isolation of riboflavin from natural sources.—There is much confusion in the literature from 1926–1941 with regard to the nomenclature of the different vitamins of the B₂ complex. In 1927, the heat-stable vitamin complex in yeast was named 'vitamin B₂' in England and 'vitamin G' in America. Most workers have followed this nomenclature but certain workers in Germany and America have applied the term B₂ and G to riboflavin only.

Until 1933 it was not suspected that the water-soluble yellow pigment of milk was of

unique importance in nutrition. As long ago as 1879, Blyth, an English food chemist, isolated the pigment in an impure state and named it 'lactochrome'. In 1925 Bleyer and Kahlmann obtained an impure preparation of the yellow pigment of milk. The next important investigation was that of Warburg and Christian in 1932. They isolated a new oxidation enzyme from aqueous extracts of yeast, and named it 'yellow respiratory pigment'. They showed that it consisted of a protein and a pigment component displaying greenish-yellow fluorescence.

In 1933 there appeared reports from three different laboratories suggesting that the greenish-yellow fluorescent pigments present in milk, liver, eggs and yeast were related to, or identical with, the pigment isolated by Warburg and Christian from their 'yellow respiratory enzyme', and vitamin B₂ or G (Kühn, György and Wagner-Jauregg, 1933; Ellinger and Koschura, 1933; Booher, 1933). The credit for isolating the pigment in a pure state, and its identification as one of the vitamins of the B₂ complex by its growth-promoting effect, goes to Kühn and his group, who had in the course of earlier work observed a parallelism between vitamin B₂ activity and the intensity of the yellow colour or of the greenish-yellow fluorescence of active extracts.

They found that both the vitamin and the pigment were destroyed by exposure to light. In 1933, they isolated in a pure crystalline state the water-soluble yellow pigment from egg white and milk, and reported that the crystalline product, in daily doses of 100 µg., had a growth-promoting effect on vitamin B₂ deficient rats. They suggested the chemical group name of 'flavin' for these pigments and pointed out that they were probably identical with the yellow pigment of Warburg and Christian. At about the same time, Ellinger and Koschura (*loc. cit.*) and Booher (*loc. cit.*) prepared highly potent preparations of the pigment, and suggested that the pigment was probably identical with vitamin B₂ or G. Since then riboflavin has been isolated from a wide variety of animal and plant substances including egg white (Kühn, György and Wagner-Jauregg, *loc. cit.*), milk (Kühn, Rudy and Wagner-Jauregg, 1933), liver (Karrer, Solomon and Schopp, 1934), kidney (Karrer, 1936), urine (Koschura, 1934), barley malt (Karrer and Schopp, 1934b), dandelion blossoms (Karrer and Schopp, 1934a), grass (Kühn, Wagner-Jauregg, and Kaltschmitt, 1934), egg yolk (Karrer and Schopp, 1934c), retina of fish eyes (Euler and Adler, 1934) and fresh water algae (Heilbron, Parry and Phipers, 1935).

In their early work, Kühn and his co-workers (*loc. cit.*) obtained from 200 lb. of dried egg white, corresponding roughly to about 33,000 eggs, only 100 mg. of pure riboflavin. Later, however, they improved the yield.

At first the flavins isolated from different sources were called lactoflavin, ovoflavin, etc., etc. Subsequent work has shown that they are

all identical, and the name riboflavin was suggested and is now generally used, since all the flavins contain a carbohydrate d-ribose in their molecule.

Properties.—Riboflavin crystallizes as yellow-brown needles and is bitter to taste. It is slightly soluble in water (about 50 microgrammes in 1 c.c. of water at 20°C.) and in alcohol. It is relatively heat-stable in acid medium and stable even in strong acids. It is completely destroyed by prolonged exposure to strong sunlight or ultra-violet light, and also by cold or hot alkali. It is not altered by exposure to atmospheric air. By the action of certain reducing agents, e.g. sodium hydrosulphide, it loses its colour by being converted into the reduced form. It can be reoxidized by oxygen or mild oxidizing agents to the coloured form.

Structure and synthesis.—The chemical structure of riboflavin has been established as the following by Kühn and his co-workers (Kühn and Rudy, 1934a, b).

Riboflavin [6 : 7 dimethyl-9-(d-ribityl)-isoalloxazine]

Its synthesis has been achieved by Kühn and Karrer and their respective co-workers (Kühn, Reinmund, Weygand and Strobile, 1935; Karrer, Becker, Benz, Frei, Solomon and Schopp, 1935; Karrer and Meerwin, 1936). In the method of Karrer and Meerwin (*loc. cit.*) an improved yield of 38 per cent of the theoretical was obtained. Starting with 2 g. of d-ribose they obtained approximately 2 g. of riboflavin. The chief difficulty in the synthesis of riboflavin is the poor yields obtained in the preparation of the essential d-ribose.

Analogues of riboflavin and specificity of structure for full biological activity.—Synthesis of various analogues of d-riboflavin has demonstrated that the number of structural alternatives with the biological activity of riboflavin is limited. The data given in table I illustrate

TABLE I
The relation of structure of riboflavin and its analogues to vitamin activity

Compound	Vitamin activity
6 : 7-dimethyl-9(d-ribityl)-isoalloxazine (natural d-riboflavin).	Fully active
6 : 7-dimethyl-9(dl-aribityl)-isoalloxazine (ariboflavin).	Half as active as riboflavin.
7-monomethyl-9(dl-ribityl)-isoalloxazine	Active only in large doses.
6-monomethyl-9(dl-ribityl)-isoalloxazine	
6-ethyl-7-methyl-9(dl-ribityl)-isoalloxazine	
5-methyl-9(dl-ribityl)-isoalloxazine	
8-methyl-9(dl-ribityl)-isoalloxazine	Inactive
9(dl-ribityl)-isoalloxazine.	

this point. They show that the position and kind of substituent group in the benzene ring, and the nature of the carbohydrate side chain in position 9, seem to determine vitamin activity.

Section 2

RIBOFLAVIN DEFICIENCY (ARIBOFLAVINOSIS) IN HUMAN BEINGS

Riboflavin deficiency in man was first described by Sebrell and Butler in 1938 in the United States of America. They reported the experimental production, in human subjects fed on a deficient diet (Sebrell and Butler, 1938; 1939), of a clinical syndrome in which lesions of the lips, accompanied by a greasy dermatitis around the naso-labial folds, were prominent signs. In some cases dermatitis in the neighbourhood of the eyes and ears was also observed. All these signs were cured by the administration of pure synthetic riboflavin, in daily doses of 5 to 10 mg. for a week or more. The syndrome was named 'ariboflavinosis'. Later Kruse, Sydenstricker, Sebrell and Cleckley (1940) reported that a specific type of glossitis, different from that seen in pellagra, occurred in subjects showing cheilosis and seborrhoeic dermatitis. Kruse *et al.* (*loc. cit.*) made the important observation that superficial keratitis occurs in patients showing other signs of riboflavin deficiency, and found that riboflavin had a remarkable curative action on this condition. In the same year, Hou (1940), in China, described the successful treatment of 36 cases of the same nature, by administering 5 to 15 mg. doses of pure riboflavin. Recently Aykroyd and Verma (1942) have reported the high incidence of superficial keratitis associated with stomatitis and/or scaly dermatitis of the scrotum in South India and the rapid curative action of pure riboflavin in the above conditions. All these investigators have administered daily doses of either 2 to 5 mg. by injection, or 5 to 15 mg. by the oral route, for periods of one week or more. Aykroyd and Verma further reported that the condition tended to recur after a period of a few weeks after the cessation of treatment, when the subjects returned to their usual riboflavin deficient diets.

Riboflavin deficiency in experimental animals

György (1935) and Chick, Copping and Edgar (1935) found that rats fed on a diet deficient in riboflavin develop a non-specific dermatitis. Cure was brought about by the daily administration of 20 μ g. of riboflavin.

Day and his co-workers (1938) reported the development of cataract in rats fed on diets deficient in riboflavin. They found that riboflavin prevented the occurrence of this type of cataract but could not cure a cataract once formed.

The dog.—Sebrell and Onstott (1938) have described a condition in dogs, called by them 'yellow liver', which is caused by the deficiency

of riboflavin in the diet. The signs characteristic of the acute attack of 'yellow liver' developed rapidly and death occurred in a few hours. The most striking changes occurred in the liver which was yellow in colour with fine red lobular markings. It was firm and often distinctly greasy to touch. The liver cells were filled with fat droplets.

The fact that riboflavin is essential in the nutrition of the chick and the pig has also been demonstrated by various groups of workers (Norris *et al.*, 1936; Lepkovsky and Jukes, 1936).

Section 3

METHODS FOR THE ESTIMATION OF RIBOFLAVIN IN FOODSTUFF, ANIMAL TISSUES AND URINE

For the investigation of the physiological and biochemical rôle of riboflavin in human beings and experimental animals, simple methods for the quantitative estimation of the riboflavin present in foodstuffs, animal tissues and urine are essential. Many methods have been described. They may be broadly classified as follows:—

(a) Biological methods

1. Based on the growth of young rats (Bourquin and Sherman, 1931; El Sadr, Macrae and Work, 1940).
2. Based on the growth of *Laetobacillus casei* (Snell and Strong, 1939; Fraser, Topping and Isbell, 1940; Strong, Feeney, Moore and Parsons, 1941; Sebrell, Butler, Wooley and Isbell, 1941).

(b) Physico-chemical methods

1. Colorimetric estimation of the yellowish-green colour of the extracts obtained after various methods of purification (Koschlar, 1935; Emmerie, 1938; Wilson and Roy, 1938).
2. Determination of the fluorescence of the purified extracts by a fluorimeter, colorimeter or photometer (Euler and Adler, *loc. cit.*; Murthy, 1937; Wilson and Roy, *loc. cit.*; Emmerie, 1938; Sullivan and Norris, 1939; Hodson and Norris, 1939; Swaminathan, 1942a).
3. Determination of the yellowish-green colour or of the fluorescence of lumiflavin formed by the irradiation of riboflavin in alkaline medium (Warburg and Christian, 1933; Kühn, Wagner-Jauregg and Kaltschmitt, *loc. cit.*; Wilson and Roy, *loc. cit.*; Shaw, 1939).

It is generally agreed that the results obtained by the biological methods are more reliable than those obtained by physico-chemical methods, which are limited in their value either because they are not specific for riboflavin or because all the riboflavin present in the biological materials is not estimated. Recently the writer (Swaminathan, 1942a) has made a critical study of the fluorimetric method and has introduced certain improvements. The chief advantages of the improved method over the existing methods are: (1) all the riboflavin present is

extracted and estimated, and (2) corrections to allow for the errors due to the presence of other interfering fluorescent substances and pigments are introduced. The method is simple and has been found to yield results corresponding well with existing biological data. It has been applied to the study of the distribution of riboflavin in foods and also to studies on the excretion of riboflavin in human beings and experimental animals (Swaminathan, 1942*a*, *b* and *c*). Recently Najjar (1941) has also described an improved fluorimetric method for the estimation of riboflavin in human urine.

Section 4

RIBOFLAVIN CONTENT OF FOODSTUFFS

A knowledge of the riboflavin content of food-stuffs is necessary for planning satisfactory diets. Some of the more recent data for common foods (1938-1942), obtained by different workers using improved biological or physico-chemical methods, are given in table II. For a more exhaustive list, the reader may be referred to a recent publication by Boas Fixsen and Roscoe (1940).

Cereals.—Whole cereals, as a group, are poor sources of riboflavin, containing from 0.5 to 1.2 $\mu\text{g./g.}$ It is interesting to note that whole cereals are fairly good sources of vitamins B_1 and B_6 ,

TABLE II
Riboflavin content of foodstuffs

	Riboflavin $\mu\text{g./g.}$
<i>Cereals and cereal products—</i>	
Cambu	1.2 (g)
Cholam	1.1 (g)
Maize	0.6 (a), 0.6 (b)
Oats	1.1 (b)
Ragi	0.5 (g)
Rice, raw, undermilled	0.7 (a)
Rice, raw, milled	0.3 (g)
Rice, parboiled, milled	0.8 (g)
Rice, polishings, raw	3.0 (g)
Whole wheat	0.4 (a), 0.8 (b), 1.2 (g)
White flour	0.4 (b)
<i>Pulses—</i>	
Bengal gram	3.3 (a)
Black gram	3.0 (a), 1.8 (g)
Green gram	1.1 (a)
Lentil	3.0 (a)
Red gram	3.5 (a), 2.5 (g)
Soya bean	2.8 (b), 2.4 (g)
Peanuts	2.4 (g)
<i>Vegetables—</i>	
Amaranth leaves	0.6 (a)
Brinjal	0.6 (a)
Cabbage	0.5 (g)
Carrot	0.4 (g)
Ladies fingers	trace (a)
Potato	1.0 (a)
Pumpkin	0.5 (a)
Spinach	1.6 (a)
Sweet potato	0.5 (a)
<i>Fruits—</i>	
Apple	0.3 (a), 0.04 (d)
Lime juice	0.1 (a)
Mango	0.6 (a)
Orange	0.5 (a), 0.3 (d), 0.4 (g)
Papaya	0.2 (a), 0.5 (d), 0.3 (g)
Pears	0.7 (a), 0.2 (d)
Plantain	0.5 (a)
Tomato	0.4 (d), 0.4 (g)

TABLE—concl'd.

	Riboflavin $\mu\text{g./g.}$
<i>Milk—</i>	
Milk, cow's, fresh	1.7, 1.8 (g)
Skimmed milk powder	20.0 (b), 16.5 (g)
<i>Flesh foods—</i>	
Beef, fresh	1.9 (c)
Beef, liver, fresh	32.0 (c)
Egg, whole, fresh	4.5 (c)
Fish, muscle, fresh	1 to 2 (f)
Fish, liver, fresh	3 to 12 (f)
Pork, muscle, fresh	2.7 (c)
Pork, liver, fresh	29.0 (c)
Sheep, muscle	3.2 (g)
Sheep, liver	47.1 (g)
<i>Yeast, dried—</i>	
Yeast, brewer's, dried	53.4 (b), 55.5 (g)
Yeast, dried (Torula strain, grown on molasses salts medium)	64.8 (g)
Yeast, dried, distillery	23.0 (g)
(a) Wilson and Roy (1938) (rat-growth method).	
(b) Hodson and Norris (1939) (fluorimetric).	
(c) Mickelson, Waisman and Elvehjem (1939) (bacterial).	
(d) Lanford, Finkelstein and Sherman (1941) (rat growth).	
(e) Sherman and Lanford (1939) (rat growth).	
(f) Lunde, Kringsted and Olsen (1938) (fluorimetric).	
(g) Swaminathan (1942 <i>a</i>) (fluorimetric).	

containing on the average about 4 $\mu\text{g./g.}$ of vitamin B_1 and 7 $\mu\text{g./g.}$ of vitamin B_6 (Aykroyd, Krishnan, Passmore and Sundararajan, 1940; Swaminathan, 1941; Swaminathan, 1942*a*). Raw rice polishings are not rich in riboflavin, containing about 3 $\mu\text{g./g.}$; this figure may be compared with their high content of vitamin B_1 (24 $\mu\text{g./g.}$), vitamin B_6 (19 $\mu\text{g./g.}$) and nicotinic acid (28 mg./100 g.). Sixteen oz. of cereals, whole or milled, will probably supply from 200 to 400 microgrammes of riboflavin daily.

Pulses.—Pulses are in general slightly better sources of riboflavin than cereals, but resemble cereals in that their riboflavin content (1.5 to 3 $\mu\text{g./g.}$) is lower than their content of vitamin B_1 or B_6 . Three to four oz. of pulses will supply from 150 to 300 $\mu\text{g.}$ of riboflavin.

Vegetables and fruits.—Vegetables and fruits are poor sources of riboflavin, containing amounts varying from 0.2 to 1 $\mu\text{g./g.}$ Leafy vegetables are in general better sources than non-leafy vegetables. A daily intake of 6 oz. of vegetables and 4 oz. of fruits will supply 150 to 300 $\mu\text{g.}$ of the vitamin.

Milk and eggs.—Fresh cow's milk is a good source of riboflavin, containing about 1.5 to 2 microgrammes per ml. One pint (20 oz.) of milk will supply about 1 mg. of riboflavin. Skimmed milk powder is one of the richest sources, containing 20 $\mu\text{g./g.}$ Eggs are also fairly rich, containing 4 to 5 $\mu\text{g./g.}$

Flesh foods.—Fresh liver (mammalian) is one of the richest natural sources of riboflavin, containing 30 to 50 $\mu\text{g./g.}$ Meat and fish muscle are fair sources, containing from 2 to 3 microgrammes per g. A daily intake of 1 oz. of liver will supply about 1 mg. of riboflavin.

Dried yeast.—Dried brewer's yeast is a good source, containing 50 to 60 microgrammes per g. Dried yeast (*Torula* strain) grown on a molasses salts medium in this laboratory compared well in its riboflavin content with brewer's yeast, containing 60–80 $\mu\text{g./g.}$ Dried distillery yeast was found to be a fair source (23 $\mu\text{g./g.}$).

It is evident from table II that milk is probably the most important and dependable source of riboflavin in human dietaries, though fresh liver and dried yeast, even when taken daily in small quantities (1 oz.), will supply as much as a pint of milk—almost the daily requirements. The majority of foods included in the diets consumed by the poorer classes in India are low in riboflavin.

Section 5

DAILY REQUIREMENTS OF RIBOFLAVIN FOR HUMAN BEINGS

Examination of the riboflavin content of diets consumed by those suffering from 'ariboflavinosis' (Sebrell *et al.*, *loc. cit.*; Aykroyd and Verma, *loc. cit.*) shows that the daily riboflavin intake of such individuals is probably in the range of 300 to 500 microgrammes. Reliable data with regard to the absolute amounts of riboflavin required for normal nutrition in human beings of all ages are at present lacking. A few estimates of probable daily requirements are, however, available (Stiebling, 1937; Rose, 1937; Sebrell *et al.*, 1941). They are given in table III.

It appears to be justifiable to conclude that the *minimum* requirements of riboflavin are probably of the order of 1.2 to 1.5 mg. (1,200–1,500 microgrammes), a conclusion in accordance with the estimates of Stiebling and Rose. The optimum amount, *i.e.* the desirable intake, is probably in the order of 3 mg., as suggested by Sebrell *et al.* (*loc. cit.*). The following standards of intake may be suggested:—

Daily requirements of riboflavin for adult human beings

Minimum requirement	1,500	microgrammes
Optimum intake	3,000	"

Section 6

METABOLISM OF RIBOFLAVIN IN HUMAN BEINGS AND EXPERIMENTAL ANIMALS

Metabolism in human beings.—Studies on the urinary excretion of riboflavin by human beings have been reported by different workers (Emmerie, 1936; Sebrell, Butler, Wooley, and Isbell, *loc. cit.*; Swaminathan, 1942b). A summary of the results of these investigations is given in table IV. It is evident from the results that the urinary excretion of riboflavin is related to the intake and that subjects suffering from riboflavin deficiency excrete less of a test dose than normal human beings. Much more work is necessary before an indirect method, based on urinary excretion, for the detection of partial riboflavin deficiency in human beings, can be developed.

TABLE III

Daily requirements of riboflavin for human beings

Author	Subjects	DAILY REQUIREMENTS OF RIBOFLAVIN	
		Bourquin-Sherman units	Microgrammes*
Stiebling (1937)	Boys under 6 years of age Girls under 7 years of age	450	1,350
" (1937)	Boys, 7 to 10 years of age Girls, 8 to 13 years of age	540	1,620
" (1937)	Other children and adults	600	1,800
Rose (1937)	Children up to 10 years of age Adults	400	1,200
		20 units for 100 calories, <i>i.e.</i> 500 units for 2,500 calories.	60 units per 100 calories, <i>i.e.</i> 1,500 for 2,500 calories.
Sebrell <i>et al.</i> (1941)	Adults	..	3,000

*According to Sherman and Lanford (1939), the results of 17 available independent investigations show an average of 67 ± 3 Bourquin-Sherman units of riboflavin per 100 g. of milk. Taking the average riboflavin content of cow's milk as 2 $\mu\text{g./g.}$ (values range from 1.5 to 2 $\mu\text{g./g.}$), 1 Bourquin-Sherman unit is about equivalent to 3 $\mu\text{g.}$ This figure has been used to convert Bourquin-Sherman units into microgrammes in table III.

TABLE IV

The urinary excretion of riboflavin in human beings before and after test doses of riboflavin

Investigators	Subjects (diagnosis)	Dietary intake of riboflavin, μ g.	Initial 24 hours urinary excretion, μ g.	Test dose, μ g.	Response to first test dose, μ g.
Emmerie (1936) ..	Normal 1	..	952	5,710	3,283
" (1936) ..	" 2	..	885	4,240	1,197
Sebrell <i>et al.</i> (1941) ..	Normal	2,540-3,680	793-1,265	5,000	50-80 per cent.
" " (1941) ..	'Ariboflavinosis'	500	24-119	2,000	The excretion rose from 34 μ g. to 1,484 on the 20th day.
Swaminathan (1942a) ..	One normal subject	1,250-1,500	320-400	5,000	About 80 per cent of test dose (4,295) was excreted.
Swaminathan and Verma (unpublished results).	'Ariboflavinosis'	400-500	50-200	5,000	About 10-20 per cent (416-508) was excreted.

Balance experiments in rats.—Riboflavin 'balance' experiments on experimental animals have been reported by Fraser, Topping and Isbell (*loc. cit.*) and Swaminathan (1942c). These workers have shown that the riboflavin content of liver, muscle, and heart of rats fed on a diet deficient in this factor was lower than in the controls receiving riboflavin supplements. Fraser *et al.* (*loc. cit.*) obtained similar results in dogs.

Section 7

THE BIOCHEMICAL ROLE OF RIBOFLAVIN AND OTHER B VITAMINS IN THE ANIMAL ORGANISM

Recent investigations have demonstrated the close relationship between certain vitamins of the B complex, *e.g.* vitamin B₁ (aneurin, thiamine), riboflavin and nicotinic acid, in the biological oxidation processes taking place in all the cells of the animal organism. Several of the coenzymes concerned in these processes contain one of the B vitamins as a prosthetic group in their molecules. The activity of these coenzymes is mainly due to the prosthetic group, *i.e.* the vitamin. These vitamin complexes (*i.e.* coenzymes, in conjunction with certain other enzymes which are of a protein nature) carry on the various biochemical processes. They act as it were like locks and keys. Riboflavin phosphoric acid, in combination with adenylic acid and a specific protein, is a very important member of the oxidative chain in metabolism. Similarly, nicotinic acid amide (the anti-pellagra vitamin), in combination with d-ribose, adenylic acid and phosphoric acids, constitutes what are known as coenzymes I and II. Vitamin B₁ pyrophosphate, known as co-carboxylase, is the coenzyme which, in conjunction with another enzyme, carboxylase, decarboxylates pyruvic acid and certain other ketonic acids.

Lactic acid is a common metabolite found in almost all normal tissues and cells. There are many processes by which lactic acid is metabolized in the tissues. One of these is represented by the following scheme :—

Lactic acid \rightarrow pyruvic acid \rightarrow carbon dioxide and water,

It has been demonstrated by a group of workers in Cambridge (Corran, Green and Straub, 1939) that coenzyme I (containing nicotinic acid amide) and alloxazine-adenine-dinucleotide-protein (containing riboflavin), isolated from heart muscle, are essential in the biological oxidation of lactic acid to pyruvic acid.

According to these workers the reaction takes place as follows :—

I Lactic acid + lactic dehydrogenase + coenzyme I \rightarrow Pyruvic acid + reduced coenzyme I.

II Reduced coenzyme I + flavoprotein (heart) \rightarrow coenzyme I + reduced flavoprotein.

III Reduced flavoprotein + cytochrome b \rightarrow flavoprotein + reduced cytochrome b.

Peters and his co-workers in Oxford (Banga, Ochoa and Peters, 1939) have demonstrated that, in the metabolism of the brain, vitamin B₁ pyrophosphate (*i.e.* co-carboxylase) is essential for the oxidative removal of pyruvic acid according to the following scheme :—

IV Pyruvic acid + carboxylase + co-carboxylase (vitamin B₁ pyrophosphate) \rightarrow CO₂ + H₂O.

In the course of their earlier work, Peters and his co-workers found that both lactic acid and pyruvic acid accumulate in the brains of pigeons in B₁ deficiency. An explanation of this fact was offered by Green and Brosteaux (1936) who showed that pyruvic acid is a potent inhibitor of the enzyme lactic dehydrogenase (0.04 M pyruvate causing 100 per cent inhibition) so that accumulation of pyruvic acid, as in vitamin B₁ deficiency, will inhibit the oxidation of lactic acid to pyruvic acid, resulting in the accumulation of lactic acid also.

It is clear from the foregoing that in the chain of the oxidative removal of lactic acid *via* pyruvic acid to carbon dioxide and water, all the three vitamins, *viz* riboflavin, nicotinic acid

amide and vitamin B₁, are essential, and the absence of any one of these will interfere in the part played by others. There is also evidence that flavoproteins play an important rôle in the oxidative removal of many other metabolites, viz d-amino acids, acetaldehyde, succinic acid, xanthine, pyruvic acid, fumaric acid reduction, ethyl alcohol, phosphoglyceraldehyde, hexonic acid, glucose, glutamic acid and iso-citric acid.

At present no explanation can be offered as to why deficiency of riboflavin in the diet, which must adversely affect the vital processes taking place in every cell in the body, should manifest itself clinically by lesions of the eyes, tongue and skin. This is a problem for future investigation.

ON SOLUBLE SULPHANILAMIDE
DERIVATIVES

PART I

TOXICITY AND ABSORPTION

By A. N. BOSE, M.B.

*(From the Bengal Immunity Research Laboratory,
Calcutta)*

IN any sulphanilamide therapy, it is the concentration of the drug in blood that determines its therapeutic efficacy. The amount of the drug itself in the circulating blood should always be determined by actual quantitative estimation (Hansen, 1939). Under ordinary conditions sulphanilamide taken by mouth is rapidly absorbed from the gastro-intestinal tract and is found in practically all the body fluids at the therapeutic level; but when a very rapid effect is necessary, when it is difficult for the patient to swallow the tablets, when nausea and vomiting are pronounced, or when conditions do not allow the easy establishment of a proper concentration of the drug in blood, parenteral administration becomes a necessity. The solubility of sulphanilamide in water at the body temperature, however, is low (about 1.5 mg. per cent) and therefore there is needed a soluble compound with a very low toxicity. The earliest soluble compound was the complex coloured azo salt, Prontosil soluble, which is often found to be less efficacious (Jauerneck and Gueffroy, 1937), and is now almost obsolete (Whitby, 1938). The disodium salt of γ -phenyl propyl-amino phenyl sulphonamide disulphonic acid (*cf.* Goissidet and Despois, 1937) is found to be less toxic (Halpern and Mayer, 1937). Although various soluble derivatives are being constantly used for parenteral administration their relative toxicity has not been thoroughly established, and the possibility of establishing by parenteral administration a high concentration in the blood has not been thoroughly studied. Accordingly work of the nature was considered to be of interest, and the

characteristics of certain soluble compounds are described in the body of this paper.

Experimental

The compounds that have been studied are I, γ -phenyl propyl amino phenyl sulphonamide α : γ -disodium sulphonate; II, γ -phenyl propyl amino phenyl sulphacetamide α : γ -disodium sulphonate, prepared by treating Schiff's base from cinnamic aldehyde and sulphanilacetamide with sodium bisulphite; III, sodium salt of sulphanilacetamide; IV, glucose derivative (m.p. 188°) of sulphanilacetamide.

Toxicity.—The toxicity in mice of a single dose of all the compounds was first ascertained. Groups of white mice weighing from 18 to 20 gm. were given intravenously different doses of a solution of known pH of each of the compounds. The animals were left for 96 hours. The results are recorded in table I. Subsequently the toxicity of the drugs given subcutaneously was ascertained in a different group of animals. The observations have been recorded in table II.

Concentration in blood.—For purposes of comparison sulphanilamide itself in one per cent solution was given to a group of mice both orally and subcutaneously. Next each of the compounds I, II and III was administered subcutaneously to a group of 30 mice. The dose given in each case was the molar equivalent amount of sulphanilamide injected subcutaneously. For estimating the concentration in the blood, blood from the hearts of four mice was taken at intervals and pooled and the amounts of drug present in terms of free as well as total sulphanilamide were ascertained according to the modified technique as developed by Marshall and Litchfield (1938), α -dimethyl naphthylamine being used as the coupling reagent. The drug concentrations attained in each case are recorded in table III in terms of pure sulphanilamide. The compound IV was found to be unstable in solution, and could not therefore be fully studied.

TABLE I

Intravenous injections. Toxicity in mice. Weight of animal : 18 to 20 gm.

Compound	pH of the solution used	Dose mg./gm.	Mortality	Percentage mortality	Symptoms or remarks

† Dose = 0.1 mg. sulphanilamide.

‡ Dose = 0.5 mg. sulphanilamide (approx.).

Discussion

From the experimental observations so far made (*vide* tables I and II) it is concluded that the compounds studied are fairly well tolerated. Amongst them, the compound I may be considered to be practically non-toxic—the mice tolerating 6 mg. per gm. given intravenously with slight reaction, and 10 mg. per gm. subcutaneously without any bad effect (Halpern and Mayer, *loc. cit.*). It is interesting to note, however, that the compounds II and IV are much better tolerated when injected subcutaneously than when given intravenously. The lower toxicity in the former case may be due to a slower absorption and subsequent gradual decomposition to its parent compound sulphanilacetamide* which is found to be less toxic than sulphanilamide. The higher toxicity of this soluble preparation given by intravenous injection may be due to the inherent property of the compound itself, or due to the lower pH of the solution. The compound III, though offering a solution of a higher pH identical with that of I, is more toxic than the latter.

In evaluating the different compounds again on the basis of their power to attain high concentration in the blood, it may be noticed from table III that, although the molar amounts of the different products were injected under identical conditions, the initial rise, the maintenance and the fall of the drug concentrations in the blood were not the same in each case. Another factor which is often found to lower the therapeutic efficacy of a sulphanilamide derivative is the rapidity with which it undergoes conjugation. From all these considerations it would be noticed that the compound I, though not attaining the concentration in the blood of the compound III or of sulphanilamide itself, maintains its concentration and is not acetylated to any high degree. All these characteristics of the compound I along with its lower toxicity point to the usefulness of this drug in any parenteral therapy. The compound III appears to be the next best.

The observations tend to establish the facts that the toxicity of any soluble sulphanilamide derivative may not depend only on the amount of sulphanilamide theoretically recoverable from it, and that equimolecular doses of different compounds do not produce equivalent concentrations in blood in terms of sulphanilamide. The whole problem is intimately associated with the rate of absorption and excretion of the particular compound. The question now arises whether the different compounds, given in such doses as give rise to equal concentration in the blood in terms of sulphanilamide, will be equally effective therapeutically. Work on this subject is already in progress.

INTRAVENOUS ANÆSTHESIA WITH SPECIAL REFERENCE TO THE USE OF THE BARBITURATES

By K. W. LEON
CAPTAIN, R.A.M.C.

General consideration

THE first successful intravenous anaesthesia produced in man was accomplished by Ore of Lyons in 1872 : for this purpose he used chloral hydrate.

Since that date a variety of drugs has been used for the same reason including the following :—diethyl ether, hedonal, ethyl alcohol, tribromethyl alcohol or avertin, and the rapidly-acting barbiturates.

I propose in this article to deal with the use of the last group but feel that a word or two on the subject of the barbiturates as a whole would not be out of place.

They fall into three main groups :—

1. *Long-acting*.—e.g. allonal, dial, luminal, medinal, trional, and veronal.

2. *Short-acting*.—e.g. sodium amytal, nembutal, pernocton, rectidon, and seconal.

3. *Rapidly-acting*.—e.g. evipan sodium, pentothal sodium, sodium thoethamyl, eunarcon, and narconumal.

Those in the first group are administered mainly by the oral route, and are used as sedatives or hypnotics, though luminal may be used as a basal narcotic. Those in the second group may be given by the oral or intravenous

(Continued from previous column)

Conclusion

The disodium salt of γ -phenyl propyl-amino phenyl sulphamide α : γ -disulphonic acid and the sodium salt of sulphanilacetamide seem to be two useful soluble drugs for parenteral sulphanilamide therapy.

The toxicity of any soluble sulphanilamide derivative seems to be independent of the liberation of sulphanilamide in the system.

The author wishes to express his sincere thanks to Dr. U. P. Basu for his interest in this work.

Note.—Compound I appears from its formula to be identical with 'soluseptasine' whose toxicity will certainly have been tested by the manufacturers, and it was probably the low toxicity that led them to choose it for marketing.—EDITOR, I. M. G.

routes, and are mainly used for the production of basal narcosis. Those in the third group, especially evipan sodium and pentothal sodium, are almost invariably administered by the intravenous method for the production of anaesthesia proper of varying duration.

All the barbiturates have a common chemical grouping

and to this common grouping sodium sulphur or other molecules may be attached. There is thus obtainable a very large variety of drugs. Other therapeutic uses to which these drugs may be put are as sedatives and anti-convulsants in the treatment of chorea and delirium tremens. They are also used for the control of late ether convulsions arising during anaesthesia, and finally they have in recent years been used extensively in psychiatry, a process known as 'narcosis analysis'.

In general the effect of these drugs is variable—so many factors are involved. In a thousand cases, it was found that the most resistant individual required four times the dose of the least resistant.

The barbiturates, however administered, cause some lowering of blood pressure and some respiratory depression. They are excreted by the liver as urea, though the blood-sugar and blood-urea values are little affected during anaesthesia. In gross overdosage agranulocytosis or toxic jaundice may occur. All the barbiturates offer some protection against the toxic effects of cocaine and chloroform.

Indications and contra-indications

The indications for this type of anaesthesia quoted in most textbooks are—

1. Short anaesthesia if $\text{N}_2\text{O}/\text{O}_2$ is difficult to obtain, especially for operations upon the mouth and face.
2. Anaesthesia where the diathermic canter is to be employed.
3. Anaesthesia where chronic respiratory disease is present.
4. Ophthalmic operations.

The contra-indications usually given are as follows :—

1. Gross impairment of liver or kidney function.
2. Severe cardiac or respiratory embarrassment.
3. Deep cervical sepsis (e.g. quinsy).
4. Asthma.

I would like to put forward a plea for the use of barbiturate anaesthesia in a much wider field than that indicated above, and I feel that this type of anaesthesia has a definite place in the surgical treatment of injuries to-day. In my opinion it is safe to employ this method in operations of any length and severity, provided that a total dosage of 3.5 g. is not exceeded.

This figure refers to pentothal sodium, which is the drug most extensively used in this work.

Continuous pentothal anaesthesia has been used extensively in London recently, notably by Quayle working with Carnac Rivett at the Chelsea Hospital for Women. Every gynaecological operation, including complete Wertheim clearances, has been undertaken successfully.

I myself have employed it for herniorrhaphies, appendicectomies, gun-shot wounds of abdomen and other parts and in some severely shocked patients.

In such cases, provided the technique described below is adhered to, it has given satisfactory if not striking results.

Technique of administration and effects of barbiturate anaesthesia

Before discussing the actual dosage and methods employed in this form of anaesthesia, I would like to point out that in my opinion some premedication should invariably be given, and that each patient should be treated individually.

I think it is true that there is no standard amount of any given drug that will suit every case. There are all kinds of factors involved, e.g. weight, general condition, presence or absence of shock, etc., and the reaction of the patient to any given dose of barbiturate (or any other anaesthetic). For these reasons every case should be assessed on its merits. As a general rule I give omnopon gr. 1/3; scopolamine gr. 1/150 but this can be increased or replaced by a morphine-atropine combination. (In this country I replace the atropine by hyoscine hydrobromide gr. 1/100.) In the selection of a vein, any vein can be used with the exception of the varicose variety: in these stagnation and thrombosis may occur, which are obviously to be avoided.

The common difficulties occurring in intravenous work are transfixation of the vein and excessive mobility of the vein, and the best methods of overcoming these are to use a short bevelled needle and to use the angle of two veins if possible for injections, viz,

There are three methods of administration, the single dose method, the repeated method, and the continuous method. In the first method, sufficient evipan sodium or pentothal sodium is injected, with or without a safety pause, till consciousness is lost—a further few c.cm. are put in and a total of $\frac{1}{2}$ to 1 g. used in all. This should give an anaesthesia lasting some 5 to 6 minutes and ample time for small surgical procedures to be performed.

In the second method, at least 20 c.cm. of solution are employed, 1 to 1.5 g. of barbiturate being injected in small quantities, the needle being kept in the vein throughout. By

this means a longer anaesthesia of some 10 to 15 minutes is obtained.

In both of these methods, a 5 per cent or 10 per cent solution is employed. In the third method a preliminary $\frac{1}{2}$ gr. of barbiturate is injected till consciousness is lost. 1 to 2 g. further are now dissolved on 560 c.cm. of either glucosaline plasma or whole blood. This mixture, which results either in a 1/6 per cent or 1/12 per cent solution, is now given by any simple drip apparatus.

I myself use a drip designed by Professor Macintosh of Oxford which was fully described in a recent issue of the *Lancet*, and have succeeded in producing adequate anaesthesia for most surgical operations which will last if necessary up to a period of two hours.

As mentioned above, no more than a total of 3.5 g. of barbiturate should on any account be given.

Induction with these drugs is rapid and pleasant, the patient gradually feeling sleepy, yawning a little and gently passing into unconsciousness. There is occasional twitching with evipan sodium, but with pentothal sodium a very smooth 'fade out' is assured. The blood pressure falls and respiration is depressed. The tongue falls back and an airway is essential. The depth of anaesthesia should be judged by the depth of respiration and by the relaxation of the masseter muscles. The eye signs are unreliable and in my opinion can be ignored.

Recovery is prolonged, and various sequelae have been described, such as excitement, drowsiness, photophobia, headache, nystagmus and bradycardia.

In the many cases in which I have administered pentothal sodium, I have never seen any of these except drowsiness, and only on the rarest of occasions has there been any post-operative vomiting. Overdosage is indicated by intense respiratory and circulatory depression. If this occurs it may be treated by CO_2/O_2 mixtures, or the intravenous injection of coramine (5 to 10 c.cm.) or picrotoxin (3 mgm.). Repeated lumbar puncture is also said to assist.

There are one or two further points I would like to make as arguments in favour of this type of anaesthesia.

Firstly, I think it can be said that by using the barbiturates, psychic trauma is reduced to a minimum. It seems to me that whatever the subsequent anaesthetic, induction by this method gives rise to the best results.

All patients with whom I have discussed the question, both in civil and military work, agree that it is a pleasant method. Those who have experienced it have not had any fear of its repetition on subsequent occasions.

A second, and to my mind important, factor is that of portability. Large quantities of barbiturate, and a few syringes and a simple drip apparatus can be conveniently carried in a small space, although for the continuous method,

ON PULMO-CIRCULATORY DYSFUNCTION IN LUNG TUBERCULOSIS

By K. EISENSTAEDT, M.D., T.D.D.

and

A. U. RINDANI, M.B., B.S.

State Hospitals, Jamnagar

RECENT advances in clinical, radiological and biological investigations have improved the accuracy of diagnosis of pulmonary tuberculosis. The routine examinations by auscultation and percussion and its completion by x-ray examination bring forth numerous findings with respect to the extent of the diseases and the anatomo-pathological conditions of tuberculous patients. Repeated blood examinations (sedimentation test, differential count of white blood cells) yield valuable information. Relatively few reports, however, are available about the influence of tuberculosis on the vital function of the lung, i.e. its respiratory efficiency. As functional examinations are of paramount importance in digestive disturbances, in urinary, nervous and many other diseases, the following discussion will show that the respiratory function also plays no minor rôle in pulmonary tuberculosis.

Before entering the subject of functional examinations of the lung, we have to remember some facts concerning the physiological purpose

(Continued from previous column)

bottles of glucosaline or plasma are necessary. This is an advantage over the carriage of heavy cylinders of $\text{N}_2\text{O}/\text{O}_2$, etc., and the accompanying machines: more particularly is it so in this country, where for the moment there appears to be a shortage of the latter articles.

Thirdly, I would like to say that I have been much impressed with the results of continuous barbiturate anaesthesia in patients who were suffering from some degree of shock.

Obviously no patient should be operated upon until resuscitation has taken place. There are, however, occasions in which operations are urgently required at the earliest moment consistent with the patient's safety.

In cases of this type, in which I have used this method, the results have been good. Blood pressure readings have at the most showed a drop of 10 mm. Hg. during the operation. There have been practically no post-operative complications, and very rarely any vomiting or headache; the long 'carry over' produced has also benefited such case, in that it produces a long period of freedom from pain, and lessens to a large degree the need for post-operative morphine.

I should like to thank Colonel Robertson of the 47th British General Hospital for permission to publish this article, and to acknowledge the help I have received in writing it from Dr. Langton Hewers' *Recent Advances in Anaesthesia*.

of this organ, viz, the arterialization of the venous blood. Furthermore, we have to deal with the purpose of these examinations, viz, to obtain the necessary information about the limits of the functional capacity.

The oxygenation of the blood is achieved not only through respiration but also through the circulatory system (heart, pulmonary circulation, peripheral circulation, the blood as such) and the regulatory factors of the nervous system controlling these organs. We have to consider, therefore, that 'respiration' means a combined function of the cardiovascular and the respiratory systems which are co-operating for the purpose of effecting satisfactory gaseous interchange between the outside air and the tissues. It is not necessary to examine all the details of this complicated mechanism in each and every case. For practical purposes, the knowledge of the following basic items is quite sufficient.

Respiratory capacity of the lung

After maximal inspiration the volume of air contained in the lung is called total capacity. After maximal expiration there remains the residual air. The amount of air between maximal inspiration and maximal expiration is called vital capacity. Tidal air is the respiratory volume of ordinary inspiration and expiration; its average amount is about 15 per cent of the

TABLE I

TOTAL CAPACITY				
Residual air		Vital capacity		
Normal capacity		Tidal air	Complemental air	
Residual air	Supplemental air			
Total collapses of the lung	Maximal expiration	Normal expiration	Normal inspiration	Maximal inspiration
— 0 c.c.	— 500 c.c.	— 1,000 c.c.	— 1,500 c.c.	— 2,000 c.c.
				— 2,500 c.c.
				— 3,000 c.c.
				— 3,500 c.c.
				— 4,000 c.c.

vital capacity. But there are many individual varieties, some people breathing rather slowly and deeply, others more rapidly and superficially.

Tidal air per minute is the product of the normal respiratory volume and the rate of breathing per minute, with an average of 8 to 10 litres. The volume of air which can forcibly be driven out after an ordinary tidal expiration gives the supplemental air. The amount of air which can forcibly be taken in over and above an ordinary tidal inspiration gives the complemental air.

The above table (figure 1) illustrates the correlation of these terms in normal condition.

Fig. 1.

In addition to this, the school of Brauer and Knipping introduced the notions of maximum breathing capacity and of breathing reserve. The maximum breathing capacity is the amount of air per minute ventilated by maximally forced breathing (average 100 litres). The breathing reserve is the difference between the maximum breathing capacity and the tidal air per minute (about 90 litres).

Gaseous exchange

Alveolar air is understood to be the air of the alveoli proper not including the 'dead space' of the bronchi, bronchioli, etc. The gaseous pressure of the alveolar air and that of the venous blood are always in equilibrium. The gaseous exchange is due to the constant composition of the alveolar air, with exactly determined proportions of oxygen and carbon dioxide. It remains under the control of the nervous centres and of the carotid sinus. The lung, therefore, becomes an organ of defence against any impairment of the ionic equilibrium of the blood. Thus the pulmonary ventilation commands the gaseous exchange, viz, the combustion of oxygen and the elimination of carbon dioxide.

In order to compare the respiratory exchange of different individuals, Brauer proposed as standard the ratio between ventilation and the basal metabolic rate. Knipping, for the same end, emphasized the importance of the respiratory equivalent, that is the amount of air that the lung ventilates in order to absorb 100 c.c. of oxygen, according to the formula.

$$\frac{\text{Tidal air p.m.} \times 100}{\text{O}_2 \text{ p.m.}} = \text{resp. equivalent.}$$

The respiratory equivalent is very variable and its rate moves between 1.8 and 3.7 in healthy

people. Within certain limits depending on more or less deep ventilation, one may also compare the respiratory exchange on the base of the respiratory quotient $\frac{\text{CO}_2}{\text{O}_2}$, the ratio between the volume of CO_2 output and O_2 intake. Still more reliable results may be obtained in basing all items upon their ratio with the body surface compared with previously fixed standard values.

The gaseous exchange, in order to be normal, requires a determinate correlation between the circulation and the ventilation. The absorption of oxygen in the blood and the elimination of CO_2 take place according to the physical laws of gaseous pressure and diffusion. The alveolar air of a healthy person at rest contains a constant percentage of CO_2 averaging 5.6 per cent. But, as the gases do not act by virtue of their percentage but proportionately to their partial pressure, we state that the alveolar CO_2 has a pressure from 35 to 45 mm. Hg, average being 40 mm. Hg. In advanced tuberculosis, however, we find insufficiently aerated areas, a stagnation with lowered percentage of alveolar oxygen and accumulated CO_2 up to 6 per cent corresponding to a pressure of 42 to 43 mm. Hg; in other words, the blood of a tuberculous patient tends to a slight acidosis, compensated by the alkali reserve of the organism. The gaseous pressure in the aveoli is almost equal to that of the blood, which is an important fact, because it permits investigation of the former which is actually easier to do, as an indication of the latter.

The quantity of oxygen in the blood depends on the quantity of hæmoglobin, on the alveolar pressure of oxygen, and on the reaction of oxygen fixation according to the partial pressure of this gas. In fact, oxygen is not completely dissolved in the blood; it is principally combined with the hæmoglobin, changing into oxyhæmoglobin. The saturation of hæmoglobin with oxygen varies mathematically according to the gaseous pressure of the blood, as demonstrated by the dissociation curve of oxygen (figure 1).

What matters is not the quantity of oxygen but the saturation of oxyhæmoglobin irrespective of the quantity of hæmoglobin. The oxygen of alveolar air in a healthy person has a pressure of about 80 to 110 mm. Hg. At this pressure, the saturation of oxyhæmoglobin is about 96 to 98 per cent, the absorption of oxygen being quite small (one may make an individual respire pure oxygen at the same pressure, without the blood becoming more saturated with oxygen than in normal respiration). Below 80 mm. Hg, however, any further decrease of O_2 pressure causes a considerable decrease of oxyhæmoglobin, so much so that the gas frees itself easily from its combination with hæmoglobin in order to pass into the tissues. On the other hand, any increase above 150 mm. Hg has no influence on the oxygenation of the blood.

Thus, the saturation of oxyhæmoglobin is largely independent of pulmonary ventilation. Increase of O_2 pressure has but little importance. Decrease causes a marked effect as soon as the pressure drops below 80 mm. Hg.

The pressure of alveolar CO_2 , however, and consequently that of arterial CO_2 , depends much on pulmonary ventilation. The carbon dioxide of the blood is partly in solution but predominantly in combination with the salt of the plasma and of the red blood corpuscles in the form of bicarbonate. Thus, the blood may be charged with a much greater quantity of CO_2 than in an ordinary solution as shown in the following dissociation curve of CO_2 (figure 2).

Fig. 2.

The abscissæ show the partial pressures of CO_2 in the blood and the ordinates the total amount CO_2 , dissolved and combined ($\text{H}_2\text{CO}_3 + \text{NaHCO}_3$). At the usual alveolar pressure of 40 mm. Hg of CO_2 the blood contains 51 volume per cent of CO_2 .

Knowing the quantity of CO_2 we are able to compute the H -ion concentration of the blood and its equivalent, the pH. At an alveolar pressure of 40 mm. Hg of CO_2 , the pH of normal arterial blood is generally computed to be 7.36, which corresponds to a low alkalinity, the neutral being 7.0.

In tuberculous patients with small and little active lesions (e.g. apical tuberculosis) the blood is saturated with about 97 per cent oxygen and contains about 51.3 volume per cent CO_2 , being therefore normal.

In extensive tuberculous cases, however, we find higher rates of CO_2 in the alveolar air and lowered oxygen values than normal. The arterial blood may show a saturation of 93 per cent or 94 per cent of oxyhæmoglobin and about 56 to 57 volumes per cent of CO_2 . Thus, the alveolar air has a higher partial pressure of CO_2 than normal, and the arterial blood tends to a slight acidosis, causing the organism to free alkali in order to maintain its pH. In these cases, the dissociation curve of CO_2 rises higher than normal (as given by the dotted line in figure 2).

These facts show that in little advanced cases the gaseous exchange is practically normal, while in extensive (far advanced) tuberculosis a state of more or less marked acidosis prevails which may be compensated for by increased bicarbonates.

Respiratory insufficiency

There is respiratory insufficiency if (a) the respiration is unable to saturate the blood with the necessary oxygen (anoxia after Van Slyke, or anoxæmia after Baneroff) and to liberate any excess of carbon dioxide; (b) if the acid-base equilibrium is disturbed; (c) if the arterial blood, i.e. the oxygen, is not distributed in accordance to the respective requirements of the tissues. Respiratory insufficiency must not be confused with what we generally call dyspnoea which manifests itself by difficult breathing, the effort of respiration becoming conscious to the subject.

According to Brauer, respiratory insufficiency may be due to—

(1) Central causes (e.g., in poisoning by veronal or morphine).

(2) Acrogenous causes (if the quantity of oxygen in the inspired air or the atmospheric pressure decreases below a certain limit).

(3) Pulmonary causes which are of particular interest to our discussion.

(a) Disturbance of the mechanical act of respiration.

(b) Impairment of the distribution of air or blood.

These conditions (a) and (b) may happen in rigid thorax, emphysema, bronchiectasis, kyphoscoliotic deformity, pulmonary stasis, tubercular cirrhosis, mediastinal displacement, collapse therapy, etc.

(c) Sometimes more or less normally vascularized parts of the lung do not get into contact with air and cannot arterialize the blood. That is what the German school calls 'short-circuit' and may be better defined as *arterio-venous deviation* (or shunt) which we encounter in pneumonia, in other kinds of pulmonary congestion and in atelectasis. Instead of being arterialized, venous blood returns from the affected area; mixed with normally arterialized blood it reduces the percentage of oxygen.

(d) *Pneumonosis* (Brauer) happens in cases of difficult gaseous diffusion of the alveolar air due to pathological alteration of the alveolar epithelium (e.g. in gas poisoning, severe emphysema, general anaesthesia, etc.).

Signs of respiratory insufficiency

It is very important to differentiate between respiratory insufficiency in exercise (dynamic insufficiency) and such in rest (static insufficiency). In both ways, there is respiratory insufficiency if the breathing reserve tends to disappear and becomes insufficient for the arterialization of the blood. Its most evident

manifestation appears if the maximum respiratory capacity is inadequate to deal with increased respiratory needs. It can be recorded through the *ratio between the maximum breathing capacity and the tidal air per minute*, which is in normal conditions about 10:1; a ratio below 2:1, at rest, proves respiratory insufficiency. Thus, a reduced respiratory reserve may bring about an oxygen deficit in the blood and an increased CO₂ content. This anoxæmia combined with increased acidosis becomes the cause of tissue asphyxia.

Another manifestation of respiratory insufficiency is the *peripheral oxygen deficit* which is computed through the difference between O₂ consumption in ordinary respiration of air and that in respiration of pure oxygen. There is respiratory insufficiency if the latter is increased. It appears in some cases with reduced oxygen content in certain peripheral parts of the circulation as if to save oxygen for the supply of more vital parts of the organism, e.g. decrease in the limbs for the benefit of the intestinal circulation in digestion. In very marked peripheral oxygen deficit we may almost always presume some want of oxygen of the cardiac muscle.

Again, a very reliable respiratory test is the *apnoic interval* breath holding which gives a good indication of the combined respiratory and circulatory efficiency. Normally, a person can hold the breath for about 50 to 70 seconds, but in cases of pulmo-circulatory deficiency hardly 15 to 20 seconds.

The circulatory function, which is in close correlation with respiration, can be tested by the cardiac output per minute at rest as well at exercise. It is the quantity of blood which the heart is able to put into circulation per minute. The normal average at rest amounts to 4 or 5 litres, increasing with exercise up to 30 litres. The maximum amount of oxygen thus transported in exercise may be 2 to 3 litres in healthy people, beginning with about 200 c.cm. in rest. In cardiac or pulmonary affections the maximum transport of oxygen may possibly remain below 1,000 c.cm. Knowing the amount of oxygen which the blood receives per minute through the alveolar exchange, the ratio between this value and the amount of oxygen distributed in the organism at the same time gives the amount of blood passing through the lungs per minute. After withdrawal of a specimen of arterial blood, the saturation of arterial oxygen is found by gas analysis.

The test of cardiac efficiency is completed by taking an *electrocardiogram*, again at rest and exercise. The causes of alterations in the three usual leads are usually classified in three groups:—

(1) Acute toxic effects with functional disturbances.

(2) Chronic toxic alterations which correspond generally to manifestations as seen in myocardial affections.

(3) Mechanical effects of the pulmonary tissues upon the heart and mediastinum. The knowledge especially of the last group is very important in tuberculosis as they should not prevent collapse therapy in otherwise suitable cases.

Often lung tuberculosis brings about some degree of deficiency of the right heart generally not to be seen in the electrocardiogram. Gradually, however, the deficiency spreads into the left ventricle causing, in the long run, a lowered voltage in all three leads. There is cardiac insufficiency if the voltage drops below 0.2 millivolt.

Recent experience has shown that many cases of post-operative collapse are due to sudden failure of the peripheral circulation which cannot be predicted from an ordinary electrocardiogram. Examinations in this respect by direct leads from the heart in exercise (Schlomka) revealed however some particular aspect of the T-wave. There are two types of T-wave reaction to exercise. The first group shows a small decrease with following increase and short recovery period. The second group shows delayed reaction and recovery and especially a primary increase which lasts rather long before returning to the normal. If this second type of reaction occurs in lung tuberculosis, its particular feature is much more accentuated, viz, a very high T-wave sometimes persisting up to half an hour before returning to the normal. It seems that this phenomenon is less due to the heart muscle itself than to individual causes in cases of vegetative-neurotic lability (vagotonic and sympathicotonic reactions). We find similar phenomena in vasoneurotic, hypertonic and thyreotoxic conditions.

Thus, the differentiation between cardiac and vasoneurotic disturbances of the circulation may become very useful with respect to timely interventions in precarious pre- or post-operative conditions.

Functional examination

From the above-mentioned discussion it will be seen that the functional examination should on principle be carried out twice, at rest and after exercise. Careful precautions are very important. Maximal breathing and cardiac capacity should never be overstepped lest the patient may incur some strain with aggravation of symptoms.

Generally, any apparatus for measuring the metabolic rate will do. The apparatus introduced by Knipping (figure 3) has shown many advantages: The patient is breathing through a closed system of circulating gas (air or O_2). From the mouthpiece or breathing mask the gas is passing into the spirometer proper, a bell floating in a water-filled tank, the weight of the bell being counterbalanced by a counterpoise. The spirometer, of course, is filled beforehand with gas through a special pipe of supply. From the spirometer the gas continues its way through

an electric air pump driving the gas continually through the whole system in order to overcome any resistance or dead space disturbance. From there, the gas has to pass through a solution of soda-lime which absorbs all CO_2 . The carbon dioxide may be liberated again by adding HCl which is kept ready for use on the top of the soda-lime bottle. In breathing, the bell of the spirometer will move up and down, the movements being recorded upon a kymograph driven by clock-work. The record of the kymographic chart shows the volume of ventilated gas in c.c. by its ordinates and the time in minutes by its abscissæ.

The spirometer records all necessary respiratory values mentioned above, except the residual air which is measured by the 'closed rebreathing circuit' method. The results should be collected for practical purposes on a special chart (table II) and compared with the calculated values in each individual case based on square metres of the body surface.

Fig. 3.

Dysfunction in tuberculosis

A. In parenchymatous changes.

In dealing with pulmonary tuberculosis we are used to think first and foremost of its anatomical aspect with its clinical, radiological and serological manifestations. We think less of toxic influences on the organism and bother but little about its 'blocking' action upon the respiratory and circulatory system, and the physiological repercussion of the mere presence of the lesions.

TABLE II

	Computed value	Recorded value	DIFFERENCE IN %	
			Decrease	Increase
Basal metabolic rate ..				
Complemental air ..	2,000			
Supplemental air ..	700			
Tidal air ..	350			
Vital capacity ..	3,000			
Residual air ..	800-1,000			
Total capacity ..	4,000			
Residual air Total capacity $\times 100$..	$\frac{1,000}{4,000} \times 100 = 25\%$			
Respiratory rate ..	15-18			
Tidal air per minute ..	8-10,000			
Oxygen consumption per minute.	200-300			
Respiratory equivalent	1.8-3.7			
Max. breathing capacity	100,000			
Breathing reserve ..	90,000			
Max. breathing capacity	$\frac{100,000}{10,000} = 10$			
Tidal air per minute	$\frac{10,000}{1} = 1$			
Peripheral oxygen deficit				
Apnoic interval ..	50"-70"			
Recovery after exercise	5'			

The influence of tuberculosis on pulmonary function may be toxic (indirect) or local (direct). If, up to the present time, little has been known about the toxic influences on the organism, it is because their nature is difficult to grasp and to define. Considering, however, that the toxic reaction may easily influence the regulatory centres of respiration and circulation, we may expect to get some useful information by studying the respiratory and circulatory efficiency. (It is known, *e.g.*, that an ordinary 'cold' may decrease the maximum breathing capacity in exercise up to one-tenth of its due.) The influence of the tuberculo-toxin on the heart has long been observed, so much so that one expects that every case of tuberculosis of long duration always shows some toxic alteration of the myocardium. The rest of the circulatory system seems to be less involved or at least less manifestly so, though the peripheral circulation and its central regulation play no minor

part in the transportation of oxygen. Again, the oxygenation of the blood is the result of the respiratory and circulatory concert; frequently we encounter a toxic tachycardia causing some degree of oxygen deficit with subsequent alteration of the pulmonary and general circulation while, on the other hand, the venous congestion may slow down the pulse rate for a certain time. Sometimes there is a circulatory stasis in the peripheral regions; sometimes, as in caseous pneumonia, there is a circulatory stasis in the lungs. Thus, it may happen that we try to stimulate the circulation by bleeding, mustard plasters, cardiac analeptics, etc., without knowing for certain whether the stimulative effect may not cause another and perhaps more serious congestion. A short functional examination and an electrocardiogram enable us to elucidate many doubtful conditions and to guide our therapeutic indications.

Direct or local influences of pulmonary tuberculosis depend on various causes. Impairment of circulation varies with the extent of the lesions and the consequent resistance to the circulation which are caused by infiltration, cicatrization, local or general emphysema, atelectasis, miliary sclerosis, etc. In the long run, hypertrophy of the right heart appears, and finally symptoms of cardiac insufficiency, *viz.*, venous congestion, increased venous pressure, cyanosis, dyspnoea, etc. In these conditions, there will always be a more marked impairment of the maximal cardiac output than of the cardiac output at rest.

Numerous examinations have shown that a deficit in arterialization does not happen as frequently in lobar pneumonias or other dense infiltrations as was formerly believed. The deficit by arterio-venous deviation (blood shunt) again is less important than was previously thought. The most marked want of saturation happens rather in stasis and pulmonary oedema, in broncho-pneumonias and in cardiac decompensations with hypoventilation. These are the cases where oxygen application has its most striking effect, because the deficit of oxygen saturation cannot be compensated by artificial stimulation of the heart output and no nervous impulse can help to induce any hyperventilation.

In emphysema the dead space and consequently also the residual air are very great, but the impairment of arterial saturation is not as evident as might be expected in these large but badly aerated areas, provided that the maximum breathing capacity is not too much decreased. The reason for this observation may be seen in the reduced pulmonary circulation and in the fact that the reduced O_2 tension still allows a quite sufficient arterialization. These rules, however, do not apply to cases with already rigid emphysema.

Thus, cases of emphysema with or without rigidity may show more or less satisfactory

results in functional examinations while in rest. The problem of dysfunction in exercise, however, is of utmost importance. The least effort may cause a sudden manifestation of failing respiratory reserves and incomplete arterialization. A case of combined emphysema and scattered fibrosis has been recently recorded by Cournand and Richards, which shows a narrow margin of safety with precipitation of acute respiratory insufficiency when the small part of remaining normal lung tissue was encroached upon by induction of an artificial pneumothorax. The resulting intensity of dyspnoea and anoxaemia could be strikingly controlled by oxygen application. The functional examination revealed a marked degree of ventilatory insufficiency due to advanced emphysema, the residual air being 64 per cent of the total lung volume, the maximum breathing capacity only 32 litres per minute.

If, simultaneously, there is a more or less marked decompensation of the cardiovascular system, these cases rapidly manifest complete insufficiency of oxygenation. On the other hand, if there is circulatory insufficiency with more or less normal respiratory values, we have to expect a miliary form of sclerosis rather than emphysema.

B. In collapse therapy.

At present, functional examinations are mostly carried out preliminary to collapse therapy in order to define its indications and to check partial or definite results. It is most important to know the limit of suitable collapse and the decrease of respiratory function still compatible with a minimum capacity of work.

Dyspnoea, being subjective and variable, does not give sufficient information, nor does cyanosis appearing only when stasis is already present. The best criterion is the oxygen saturation of the blood. An arterial deficit at rest prohibits any operation whatever, whereas intervention may be possible so long as the oxygenation of the blood is sufficient.

The ideal is to secure a collapse which allows still complete arterialization in daily average exercise. In overstepping this limit we neglect the main purpose of collapse therapy, *viz*, to obtain rest for the affected lung; ventilation would be increased by oxygen deficit; the acid-base equilibrium being disturbed, the whole organism would become deficient.

Effusion.—A large effusion always favours a respiratory deficit.

Pneumothorax.—We have dealt already with the fact that in extensive tuberculous lesions the affected part of the lung is insufficiently aerated; showing a stagnation of alveolar air with decrease of oxygen and increase of carbon dioxide. Suppose the other lung to be normal, yet it is unable to interfere with the defective respiration of the affected side. The mixed arterial blood coming from both lungs has therefore a subnormal saturation. This saturation of oxyhaemoglobin decreases consequently

to 92 per cent or 93 per cent (the normal being 97 per cent). After induction of a pneumothorax, the deficient blood flow from the affected area will be mostly suppressed. The blood now arising predominantly from the healthy lung is perfectly saturated. Already after a few insufflations, the oxyhaemoglobin value may rise again to 96 per cent and simultaneously the volume percentage of CO₂ may return to its normal rate.

Sometimes we are struck by an apparently paradoxical phenomenon in unilateral cases, *viz*, disappearance of dyspnoea after induction of pneumothorax. As we know that anoxaemia affects the respiratory centre causing hyperventilation, our above-mentioned exposition demonstrates that by suppressing this anoxaemia we may be able to obviate hyperventilation and dyspnoea.

The effect of a *bilateral pneumothorax* on the respiratory equilibrium is less disturbing than the same total amount of air given into one side. Thus, 500 c.cm. filled into each side may be devoid of any effect on the alveolar pressure, whereas 1,000 c.cm. filled into one side may cause a very marked disturbance. The more an AP filling is increased, the more arterial oxygen pressure and blood circulation will decrease, additionally driving to rapid decompensation. The resulting anoxaemia causes hyperventilation (with or without dyspnoea) and counteracts the therapeutic purpose. The functional examination will serve as a reliable test for the margin of sufficient arterialization.

Thoracoplasty.—What has been said about pneumothorax treatment applies still more to thoracic operations. While the method of Forlanini allows a certain elasticity of physiological factors, capable of being controlled and directed by the physician, plastic operations will always result in a rigid and irrevocable collapse of the whole lung or part of it. Thoracoplasty, whether complete or partial, leads principally to a decrease of functional capacity. It has been observed, however, that even with improved method of selection of cases most of the suitable cases always show some respiratory or circulatory impairment before the operation and also that with improved operative technique, the increase in impairment was less than the extent of the operation led one to expect. As we saw in pneumothorax treatment, the suppression of the breathing of the affected lung allows a renewed equilibrium of the physiological condition.

A markedly beneficial effect on the cardio-pulmonary function may be obtained by thoracoplasty in cases which need this operation in order to replace an ineffective pneumothorax or still more a phrenic interruption. According to Cournand and Richards, a marked degree of ventilatory, respiratory and circulatory dysfunction existed in such cases before thoracoplasty, most of which are significantly improved, the patient's physical capacity being greater after

completion of thoracoplasty. Similar observations of benefit from thoracoplasty were made in cases with long-standing empyema or with fibrothorax or thickening pleurisy.

Phrenic interruption.—Although the diaphragmatic paralysis frequently produces striking anatomical improvement and is easy to do and causes little or no operative shock, it gives the worst functional results of all collapse procedures. Cournand and Richards found impairment of function evidenced by low ratio of breathing reserve to maximum breathing capacity at rest, and also oxygen unsaturation of arterial blood at rest or after exercise. There is a distinct tendency to pulmonary congestion. Phrenicoparalysed cases are seen, indeed, to become more rapidly dyspnoic at the least exertion than others with bilateral pneumothorax or extensive thoracoplasty.

Extrapleural pneumothorax (Graf, Schmidt).—If for any reason ordinary AP treatment is not practicable, extrapleural pneumothorax is the least mutilating and most elastic operation in collapse therapy. The idea behind the introduction and development of this operation has been to produce the best collapse with the least functional impairment. Functional examinations show that this object has largely been attained. According to Gaubatz, the functional impairment seen after extrapleural pneumolysis is remarkably less than, sometimes only half, that seen after apical or other partial thoracoplasties of corresponding extent.

In estimating immediate surgical risk and ultimate physical capacity, any dysfunction on exercise is much more important than at rest. As the present discussion shows, such dysfunctions happen if the breathing reserve is reduced by extensive tuberculous lesions or by excessive emphysema in long-standing fibrotic-cavernous diseases. The patient's physiological output in exercise consequently fails much more rapidly than in health, although all signs of insufficiency may be absent at rest. Serious deficiency is present if the maximum breathing capacity on exercise is reduced more than 60 per cent. Again, the time needed for recovering after exercise is much more significant than the immediate effect. In tubercular patients the recovery may last more than 30 minutes compared with 3 to 5 minutes in healthy persons. The duration of recovery depends on the amount of oxygen deficit after exercise and on the time needed to compensate it.

Generally, it may be stated that unsatisfactory results in surgery may be predicted—

- (1) in reduced breathing reserve of less than 85 per cent of the maximum breathing capacity;
- (2) in arterial oxygen unsaturation at rest or after exercise;
- (3) in high peripheral oxygen deficit;
- (4) in increased ventilatory equivalent above 3.6; and

(Concluded at foot of next column).

AN INVESTIGATION INTO THE INCIDENCE AND TYPE OF TUBERCULOUS INFECTION IN CATTLE AT AMRITSAR WITH SPECIAL REFERENCE TO HUMAN INFECTIONS

By S. M. MALLICK

MAJOR, I.M.S.

RAI SAHEB HET AGGARWAL, M.D., Dip., Bact. (Lond.)

and

RAM LAL DUA, M.B., B.S.

Medical School, Amritsar

THE idea of bovine infections being transmitted to human beings was first advanced by Theobald Smith (1896) on his finding this type of bacillus in the cervical glands of a child. Searching investigations of this matter have since then been carried out by numerous workers including Robert Koch and the necessary precautions to safeguard the milk were taken in many countries. In India enquiries on similar lines were carried out by Nield (1902), Wilkinson, Joshi and Gloster (1914) and Taylor (1918). The details have been examined by Glen Leston and Soparkar (1917), who concluded that the cattle infection with tubercle bacillus in India was lower than in the west.

Shethler (1921) carried out investigations at Muktesar and typed the strains of bacilli isolated from the specimens collected by Taylor at Ferozepur slaughter house, and advanced his view of the low toxicity and virulence of the various strains of tubercle bacilli affecting the

(Continued from previous column)

- (5) in myocardial damage as revealed by the electrocardiogram.

Conclusion

Diagnosis, prognosis and indications for collapse therapy can be precisely determined by adding functional examinations to our current clinical, biological and radiological investigations. By these examinations, our useful anatomical and biological knowledge will be much increased. The time is near when our diagnosis, hitherto expressed in anatomical and biological terms, will be completed in those of functional capacity.

cattle in India, the infection being restricted to a few glands, usually calcified. Taylor himself made a systematic examination of over 6,000 selected cattle slaughtered at Ferozepur and recorded about 3.5 per cent being affected with tuberculosis, of which over 2 per cent showed tubercle bacilli in the lesions. Later in 1927 Soparkar, Edward and Krishnamurti studied the problem again, and on experimental results agreed that the low incidence of clinical tuberculosis in Indian cattle is due to their usual mode of open air living, rather than any question of immunity or resistance in them, or the low virulence of the causative bacillus. Recently in 1931, Soparkar stated in an abstract of paper presented by him at the Indian Science Congress held at Nagpur, that out of 1,116 animals examined by him at the Lahore slaughter house, 225 or 22.85 per cent were found to be infected with tuberculosis and tubercle bacilli were detected in the sinews of some, exclusive of others found to be infected on animal tests. The cows showed a lower incidence (21.3 per cent) than buffaloes (23.6 per cent to 31 per cent). No information was however given by him with regard to the type of bacilli found.

We made the study of this problem, by trying to find out the type of bacillus responsible for the infection of extra-pulmonary lesions of the local populace. Strains of bacilli were isolated and typed from the variety of pathological materials received from various hospitals in the Punjab. We observed that out of a series of 62 successfully isolated strains of tubercle bacilli, not a single one was found to belong to the bovine type. An investigation on similar lines had been carried out by Ukil (1933), wherein he did not find a single bovine type of bacillus, out of a series of 60 cases of glandular and osteo-articular lesions. Soparkar (1929) mentioned a similar investigation conducted by him, in a paper read by him at the Indian Science Congress held at Madras. He dealt with 65 cases out of which 40 were of cervical adenitis, 8 of axillary gland tuberculosis, and 17 of pulmonary tuberculosis. None of the above cultures obtained was found to be of the bovine type. It was only at the close of his investigation that he discovered a bovine type of bacillus in a child suffering from cervical adenitis, which was the first case described in India.

The failure to find the bovine type of bacillus in lesions expected to yield it, stimulated further interest in the subject and efforts were made to find out what part, if any, was played by bovines in the transmission of infection to human beings by contact with cattle or by the consumption of milk.

It was thus planned to find out first, the amount of infection in bovines, by carrying out a tuberculin survey with tuberculin obtained from the Imperial Veterinary Research Institute at Muktesar. We started with the eastern side of Amritsar city, our chief areas of operation

being division 7 and division 9 of the city. All the herd and the individual cattle of these divisions were subjected to the double intradermal test.

Once the positive reactors were detected, it was our aim to investigate them further for the presence of tubercle bacilli in their milk. The individual animals belonging to the herd under test were seen a day prior to the inoculations, and a clinical examination was made of their general health. Notes were always kept for any special signs such as emaciation, cough, diarrhoea, rise in temperature, enlarged glands, swollen udder or any other lesion suggestive of tuberculous disease. It is of interest to note here that mastitis, recognized to be the stage of the disease when tubercle bacilli are passed freely in milk, has been met with in only two cows which, surprisingly however, did not reveal any bacilli in their milk on repeated examinations. In one of these animals, a sero-sanguinous discharge was made to ooze out on squeezing the udder. Cattle have however been seen showing extreme emaciation and enlarged glands and having a chronic cough or a chronic diarrhoea.

The injections were given intradermally in two divided doses of 0.1 c.cm. each, of the concentrated tuberculin, the first or the sensitizing dose being followed by the second or the testing dose of the same quantity after 48 hours.

Technique of injections

A four-inch-square area of the skin, on the side and in about the middle of the neck, was washed with soap and water and shaved preferably a day prior to the inoculations. Recently British workers have preferred to give injections under the skin of the caudal fold to avoid shaving (*Tubercule*, 1938, vol. 8, 347), but we preferred to stick to the side of the neck, on account of greater convenience. The fold of the shaven skin was firmly held in the jaws of a callipers with a sliding scale, to find out the normal thickness of the animal's skin.

On the following day the part was rubbed with an alcoholic disinfectant and pinched up firmly with the left hand. The injection was then given in the tightly drawn layers of the skin. A broad handled dental syringe of 2 c.cm. capacity, with the barrel marked into divisions of 0.5 c.cm., was employed for the purpose. A fine sharp but short needle fixed to the syringe was pushed in the skin parallel to the surface and just when the eye of the needle had gone under the skin 0.1 c.cm. of tuberculin was pushed in, sometimes requiring a good deal of pressure. A bleb-like elevation of the epidermis about the size of a pea was raised, if the injection was properly done. The depth to which the needle should go under the skin depends upon the normal thickness of the latter. Injections accidentally given deeper into the subcutaneous tissue, elicited a very severe local response, which is not significant. The second or the testing dose was given at the same site and in

exactly the same manner as the sensitizing dose, after an interval of 48 hours.

It has been advocated by some writers that the second dose need not be given to the animals showing a marked reaction to the first dose, but in the present series we gave the second dose in every case for the sake of uniformity of the results.

Reading of the results

The measurements of the fold were taken 40 hours after the first and 24 hours after the second dose, the ultimate results being based on the latter reading. Other factors indicating a positive reaction were local heat, tenderness and oedema. These were always found to accompany a reaction producing an increase of more than 10 mm. to the original measurement of the fold. Without these factors being present, the result was not regarded as positive, except when the measurement showed an increase of at least 30 mm. No marked general reactions have been noted, except that the milch cattle showed a definite decrease in the quantity of their output of milk on the day following the injection, a phenomenon with no explanation.

In cases showing a positive reaction, a classification was made based upon the degree of response elicited, in the following manner :—

The difference between the original and the final reading of the fold	Class of reactor
(a) Less than 10 mm. ..	Negative
(b) Between 10 mm. to 30 mm. ..	One plus
(c) Between 30 mm. to 50 mm. ..	Two plus
(d) Between 50 mm. to 70 mm. or above. ..	Three plus

In all 1,234 animals were subjected to the test, 282 of which exhibited positive reactions of one degree or another, as follows :—

Plus one reactors	141
Plus two reactors	87
Plus three reactors	54
	282
Negative reactors	935
	1,217
Sold during the test	17
TOTAL ..	1,234

It has been further observed that buffaloes showed a higher incidence and a greater intensity of reaction than cows.

So intense has been the response in some of the buffaloes that an increase of more than 120 mm. was obtained to the original measurement of the fold in about three cases.

All the animals that were tested, were further divided into certain age groups, to find out the

frequency of infection in different spans of life, which is represented in the following table :—

Age groups in years	Total number tested	Positives	Percentage
One to three years ..	165	24	14.5
Three to six years ..	263	40	15.2
Six to nine years ..	368	98	26.6
Nine to twelve years ..	234	65	27.8
Twelve to fifteen years ..	49	17	34.7
Fifteen to eighteen years ..	12	5	41.6
Eighteen to above ..	6	3	50.0
Unknown age ..	120	30	25.0
	1,217	282	

It will be noticed that the amount of infection increases with age in cattle as in man, in India, in contrast to that in human beings in which a steady decline is reported after early adult life.*

Problem of milk

After having found a positive reactor, our further aim had been to proceed with the study of its milk. Samples of milk were collected aseptically, and subjected to microscopical, cultural and biological tests, to find out the presence of tubercle bacilli in them.

Method of collection of milk

Four wide-mouthed sterile test-tubes, which had been plugged with sterile cotton, were taken and about 10 to 15 c.cm. of milk from each quarter of the udder milked into each tube. The upper portion of the tube heated on a spirit lamp flame, and the plug of cotton inserted again after having been flamed. The udder and the hands of the milker were thoroughly washed with soap and water before milking. It has been always preferred to have the specimen of the residual milk, known as strippings. After the tubes had been plugged they were placed in a brass holder and carried to the laboratory.

Treatment in the laboratory

Here the tubes of milk were placed in an electric centrifuge and rotated at 2,500 r.p.m. for 5 to 10 minutes, which would separate the milk in three layers.

(a) The top layer of the cream, with a few bacteria.

(b) The middle layer of clear bluish white fluid.

(c) The bottom layer of suspended particles and the majority of bacteria.

Microscopic examination

A little of the top cream was spread on the slide by means of a platinum loop, after which

* Available data in India and elsewhere are not in agreement with the author's statement. As a rule, the incidence of infection increases with age in man, as has also been noticed in cattle.—EDITOR, I. M. G.

the cream was separated by a small metal spoon, which had been passed through the flame. The remaining portion of the milk was decanted to about half an inch of the bottom by means of a wide-bored pipette. A drop of the deposit that had been left was transferred to a clean slide by means of a capillary pipette. A new glass slide was then placed at an angle to the drop and a film made by drawing the slide from one end to the other. The slides thus made were allowed to dry in the air for at least half an hour and then fixed, defatted with ether and alcohol, and stained by the Zeihl Neelsen method.

In our series of experiments on 101 specimens of milk, we examined about 500 slides in the above manner, but were unable to find out the particular octahedral cell groups. Under the 1/12 objective the usual finding met with have been the cellular debris, believed to be leucocytic or alveolar in origin. Bacteria that have sometimes been seen, belong to the cocci group in chains or clumps, or the aerogenous bacilli. *Mycobacterium tuberculosis* was not found in any of the slides.

Biological testing

Two guinea-pigs were inoculated for each specimen of milk. The deposit from the bottom of the tube was drawn into a sterile syringe and inoculated in the muscles of the right thigh of the pig in quantities of 5 to 7 c.cm. The inguinal glands on the side of inoculation were rubbed a little before and after the inoculation to cause them a little injury, to facilitate the development of infection in them. The animals were then caged and examined at weekly intervals for any signs of developing tuberculosis. The glands on the inoculated side were carefully palpated on each examination, to find out enlargement of tenderness in them. After 3 weeks one of the animals was sacrificed, to study its viscera, for the progress of the disease, the second one being kept for further observation till 6 to 8 weeks and ultimately sacrificed.

About 48 hours before killing an animal, an injection of 10 c.cm. of old tuberculin was made subcutaneously, to find out if there was a reaction, in case the infection had successfully occurred or, in case the death of the animal took place, if the disease was in active progress (Joseph Race).

It has been observed that animals reacting negatively to the inoculation never revealed any lesions when subsequently post-mortemed. Hence in the latter part of this series of experiments, we did not destroy the animals that had reacted negatively to the tuberculin inoculation and had survived it.

In all about 70 animals were subjected to the tests, out of which 8 died of inter-current infections. Forty-six were inoculated and later on autopsied.* Sixteen were inoculated without any reaction being elicited.

*The results of autopsy have not been given.—
ERROR, J. M. G.

Cultural tests

To the deposit in the tubes an equal quantity of sterile solution of 15 per cent hydrochloric acid was added, and the tubes shaken vigorously. A few drops of the sterile litmus solution were also added as an indicator. A flamed cotton plug was then applied to the mouth of the tube, which was then kept at 37°C. in an incubator for a period of not less than half an hour to dissolve the suspended particles and the cellular debris. The tube was then taken out and the product titrated with a sterile solution of 15 per cent NaOH till the neutral point was reached, as indicated by the litmus indicator. About 3 to 5 c.cm. of this product were now pipetted on the slopes of the artificial culture media (Lowenstein's or Petroff's), the tubes of media plugged with flamed cotton and placed in the incubator in a slanting position for a day or two to allow an intimate contact with the inseminated product. After the material had dried the tubes were put in the vertical position and a hole bored through the cotton plug, to allow oxygen to the growing bacillus. An examination of the tubes was made every 5 to 6 days. None of the tubes in this series of experiments showed a growth of tubercle bacillus.

Discussion

From the above it has been observed that, whereas the infection in cattle is quite common, the milk has shown markedly negative results, with regard to the presence of tubercle bacillus in it. The question arises as to why it should be so? If cases of surgical tuberculosis are quite commonly met with here as in the European countries, as was suggested by Major-General Hutchinson, at the second all-India veterinary conference held at Calcutta, the question arises what can be the actual source of such infection, if the agency of milk so far held to be a chief factor in the causation of the disease is altogether ruled out? Bradfield (1925) in a paper in the *Indian Medical Gazette* draws attention to this form of disease as met with in Madras, where the surgical form of tuberculosis comprised 2.1 per cent total admissions in 1924. We have been in communication with the veterinary research workers, and wrote to J. R. Haddow and J. F. Shirlaw, of the Imperial Veterinary Research Institute, Muktesar, on the negative findings of our results, and they were kind to let us know in return, that attempts had been made by them to find out tubercle bacilli from the milk of 22 cases of suspected tubercular mastitis during the last four years with unsuccessful results. It therefore seems that the disease in the cattle so far as this country is concerned takes a very mild course, confining itself to a few glands as stated by workers like Soparker (1925), and the infection of the udder, which is likely to contaminate milk, is rarely reached. The experiments of the Royal Commission on Tuberculosis show that a dose of 50 mg. of culture of bovine origin given subcutaneously is

almost invariably fatal to the English cattle and, with rare exceptions, produces a generalized tuberculosis of a very severe type, which proves rapidly fatal. A certain proportion of Indian calves equally small in size remain well after similar infection, and when autopsied show slight or minimal lesions, indicating that they are possessed of very high power of resistance to tuberculosis as compared to the English calves' (*Indian Journal of Medical Research*, 1923-26, page 765).

This power of resistance in the Indian cattle, accompanied with the open-air mode of living of these animals, serves to restrict the course of the disease. Hence very few cattle reach a stage when they can infect human beings by contact, or when their milk is teeming with tubercle bacilli. It therefore seems that if a case does happen, in whose lesions the presence of bovine type of bacillus is demonstrated, the bacilli behave in a manner entirely 'zoogenic' and not 'anthropogenic' (Kolle and Hetsch, 1934) and hence the infection persists with that particular case, ultimately perishing with the death of the host. Apart from the above, it has been observed that the actual transmission of the disease took place, only if heavily contaminated milk is consumed for a long period of time.

According to Kossel, investigations made from 1905 to 1909 by the Imperial Sanitary Office in Germany show that 151 children and 200 adults had regularly consumed for a longer or shorter period raw milk from cows seen to have tuberculous lesion of the udder. Only two individuals (and they were very young and belonging to different families) were found to have tuberculous glands of a benign form. In both the cases the cow had a very severe form of mastitis involving the whole gland. The other individuals remained quite healthy. It was thus concluded by Weber, who published this account, that infection could only be produced, with repeated ingestion of considerable quantities of bovine bacilli. In New York City Alfred F. Hess followed for three years 18 cases of children who drank milk in which tubercle bacilli were demonstrated, and found that all but one remained free from tuberculous disease (Fishberg).

It therefore appears that the dangers of milk infection have been overestimated by many writers, when considered in the light of the above facts.

It is further reasoned that if animal tuberculosis were causally connected with the origin and spread of human disease, primary tuberculosis of the intestine would, as Koch pointed out, be a much more frequent disease, especially in large towns where tuberculous milk and butter are used in enormous amounts. Referring to the countries where bovine tuberculosis is practically non-existent or where cow's milk is not used in feeding children, e.g. Greenland, we find that the morbidity rate especially of the abdominal type of tuberculosis is not less.

Apart from the above, the usual practice of boiling the milk before consumption is an additional safeguard against the disease in this country.

It therefore appears that the cases of surgical tuberculosis are evolved through human infection of man to man by the human type of bacillus.

If further research in the problem be taken up, and strains of tubercle bacilli be isolated and typed from the bovine lesions, there is a likelihood, that the causative type may be found to be the human type of bacillus, that has been unsuccessful in causing a generalized infection.

Summary and conclusions

1. That about 25 per cent of the 1,234 cattle tested were tuberculous as demonstrated by the double intradermal tuberculin test.
2. That the buffaloes reacted rather strongly to the same amount of tuberculin as compared with cows and showed a higher percentage of infection.
3. That the incidence of infection increases with the age of the cattle.
4. That 101 specimens of milk taken from positive reactors were found to be negative for tubercle bacilli, when investigated microscopically, culturally and by animal inoculation tests.
5. That it is not necessary to boil the milk before use to guard against tuberculous infection, though that would be a good preventive against brucella infections and lapses in sanitary precautions.

Acknowledgments

We are indebted to Professor G. S. Wilson of the London School of Hygiene for his kind suggestions in the initial arrangements of this enquiry. To H. R. Haddow and J. F. Shirlaw, of the Imperial Veterinary Research Institute, Muktesar, and to Professor A. C. Aggarwal, of the Punjab Veterinary College, for their kind help in giving us the information of the details of animal tuberculosis in India, and suggesting many works on the same. Our thanks are also due to Dr. Nazir Sadique, of the veterinary dispensary, Chatiwind Gate, for his assistance in the conduct of the survey in the beginning, and to Dr. Baldev Raj, in-charge Veterinary Hospital, Hathi Gate, for supplying us with the specimens of milk from suspected cases of mammary tuberculosis. We should also express our gratitude to G. Durrant, superintendent of police, and Dr. S. Rozden, medical officer of health, Amritsar, for the departmental aid that they rendered facilitating this work.

A NOTE ON PARANITRANILINE POISONING

By R. LOBO-MENDONCA, B.Sc., M.B., B.S.

Assistant Chemical Analyser to Government, Bombay

PARANITRANILINE is frequently used in the preparation of red dyes. It is therefore fair to presume that a certain number of cases of poisoning from this chemical would occur, but the only references made to it are found in the reports of the chemical examiners of Calcutta and Bombay which rarely, if ever, are available to the medical profession in general.

Within the space of a few months, six or seven cases of paranitraniline poisoning were admitted into the various hospitals in Bombay.

Chemistry.—Paranitraniline ($C_6H_4NO_2NH_2$) is a nitro- and amido-derivative of benzene. It is a yellow powder prepared from parachloronitrobenzene or acetanilide, and is used in the manufacture of the red dye paranitraniline red. It is a chemical generally imported by textile mills and other dyeing factories. It is easily soluble in alcohol, ether, and sparingly soluble in hot water. Beautiful long crystals are obtained if it is made to separate out from dilute alcohol. The melting point of the pure product is $147^\circ C$. On reduction with tin and strong hydrochloric acid, it yields paraphenylenediamine which can be readily identified by its melting point.

Toxicology.—Like all amido- and nitro-derivatives of benzene, e.g. dinitrobenzene and aniline, this dye is poisonous; and of the nitro-compounds of aniline ($C_6H_5NH_2$), paranitraniline is the most poisonous. It is very interesting to note that the symptoms and effects produced by both the nitro- and amido-compounds are allied to one another.

Poisoning by paranitraniline through ingestion of the powder rarely takes place, as it is not easily absorbed by a full stomach. Inhaled as dust it sets up poisonous symptoms, but the chief manner in which it is commonly absorbed is through the skin. It has been found that most of the cases of poisoning occurred during the hotter part of the day or during the summer months. This is because the sweat helps to dissolve the dust on the skin, and dilatation of the surface vessels aids in the absorption of the dye. Moreover, paranitraniline being a powder adheres to the wet body. In industry the process of packing, loading, and unloading supplies the greatest number of casualties, as in such cases the powder is apt to settle over the whole surface of the body unless an efficient system of exhaust ventilation exists.

An empty stomach helps in the absorption of the dye, and indulgence in alcohol precipitates an attack just as in plumbism.

The elements most affected are the central nervous system and the blood. The hæmoglobin of the red blood cells is changed to methæmoglobin, the blood taking on a chocolate colour. This causes a state of internal asphyxia and

air-hunger. The central nervous system is paralysed. Death is usually due to cardiac paralysis.

Amido-compounds of benzene after excretion into the bladder have an irritating effect on this organ, producing not only cystitis, but even malignant growths.

Another closely related compound, metanitrilaniline, which is used in the preparation of alizarine yellow and other dyes, is also poisonous, and the symptoms produced are akin to those caused by the para-compound.

Symptoms.—Before the onset of severe symptoms, which generally come on after cessation of work, there is a feeling of weakness and nausea, and sometimes giddiness. In one reported case, only cyanosis of the lips and ears was noticed which however disappeared by next morning. The man resumed work, though he looked pale and weak. Suddenly he collapsed and died from cardiac paralysis.

In the milder cases that occurred in Bombay, the men after working the whole day in packing the powder in boxes, felt weak and tottering in the evening. Soon after, they became unconscious, and were therefore removed to hospital. Some exhibited twitchings and clonic movements of the upper extremities.

In the more serious cases in which absorption was on a large scale, the patients vomited and soon became unconscious, cold and clammy; reflexes were lost, the pupil being dilated and fixed. There was marked cyanosis, lips, tongue, and nails all appearing dark blue or black. When the finger was punctured for obtaining a blood smear, it was noticed that the blood was chocolate-coloured, and that it clotted rather easily. The lack of oxygenated blood caused air-hunger, a rapid feeble pulse due to its action on the heart, and finally coma brought on by irritation of the medulla. The temperature usually rose to over 100° , even up to 105° .

The milder cases improved gradually the next day, but those patients who had absorbed a large amount of the poison died without regaining consciousness. The blood pressure was not affected in any of the patients. It is stated that in some fatal cases convulsions appear just before death.

Paranitraniline causes eczema, specially when, in the form of a solution, it is used during the process of imparting a red colour to fabrics. The solution comes in contact with the hands and chest of the dyers and this produces a serious form of chronic eczema known as 'purpurism'. It was found that the use of gloves or machinery eliminated this disease altogether.

Those exposed to paranitraniline over a long period are apt to suffer from vertigo, headaches, weakness of the limbs, inflammation of the liver and increased perspiration, as well as the bladder tumours referred to above.

Diagnosis.—The characteristic of these cases is marked cyanosis. The chocolate-coloured

blood should be examined spectroscopically for the bands of methæmoglobin. Very often a compound appears in the urine which reduces Fehling's solution. If the patient lingers for some time, hæmoglobin liberated through the destruction of red blood cells is excreted as hydrobilirubin and hæmatoporphyrin, and the latter may therefore be looked for in the urine.

An oxidation product, para-amino-phenol, which is excreted in the urine, can be extracted by means of ether after rendering the urine neutral. The residue after removal of ether may be tested for the above compound by the following reactions:—

(1) Boiling with Millon's reagent produces a violet colour which quickly fades to brown.

(2) A violet coloration is also obtained with ferric chloride solution.

(3) Bromine water produces a violet colour which disappears with excess of reagent.

In some cases paranitraniline itself can be demonstrated in the urine.

Prevention.—As the skin is the chief portal of entry, scrupulous cleanliness is the main precaution for preventing cases of this form of poisoning. As far as possible, work should be suspended during the hotter months of the year. If this is not possible for any reason, work should only be permitted in the early hours of the morning before the heat begins. Exhaust ventilation to prevent the dissemination of dust is a necessary adjunct. Facilities for bathing with hot water as well as for frequent washing of hands and face during work should be provided. In well-equipped plants, tub baths are erected and some solvent is added to aid the removal of the poison from off the body. As women and children under eighteen are more prone to poisoning, they ought to be excluded from such work. Needless to say, strict medical supervision is absolutely necessary. Any workman who complains of ill-health should be immediately directed to take a full bath and change all clothing including underwear. He must then be thoroughly examined by the factory physician.

Lastly, strict factory laws must be enacted so that every single case of poisoning is immediately reported, compensation paid, and precautions taken against recurrence.

Treatment.—As soon as symptoms are noticed, the patient is taken out into the fresh air and if necessary treated by artificial respiration. Paranitraniline being easily soluble in alcohol, it is advisable to wash the body with this solvent. Removal of blood and its immediate replacement by blood transfusion may prove a very useful measure. Continuous administration of oxygen is resorted to. As the dye paralyses various brain centres, stimulants such as strychnine, adrenalin, cardiazol or lobeline should be administered. The cyanosis present in this form of poisoning is due to the presence of methamoglobin as in the case of sulphanilamide

intoxication. Therefore administration of methylene blue orally or by injection is indicated.

Post-mortem appearances.—The general picture that presents itself at the *post mortem* is one of congestion. The lungs, liver, spleen, and kidneys all appear enlarged and dark or blue. The stomach and intestines are inflamed, and one of the cases showed submucous hæmorrhages. The bladder contained yellow-coloured urine.

Sections of the liver and kidneys were made, but they failed to demonstrate any lesion.

Chemical analysis.—The viscera of two fatal cases were extracted with alcohol which resulted in a yellow fluorescent solution. The residue from this gave tests for paranitraniline. The yellow powder handled by the patients was also sent for test and this on analysis was confirmed as the dye in question.

Case I.—On 15th December, 1941, five workers in a dyeing factory, four men and one woman, were packing paranitraniline powder. In the evening they felt giddy and later on three of them became unconscious and were therefore removed to the J. J. Hospital. The other two became unconscious gradually the next day, and were admitted into the K. E. M. Hospital.

(a) R. A., female, *æt.* 25, widow, admitted unconscious on 15th December, 1941. Restless, pupils dilated and fixed. All muscles were flaccid and reflexes could not be elicited. Urine—nothing abnormal. Red cells 3 million, leucocytes 4,000, polymorphonuclears 78 per cent, lymphocytes 15 per cent, monocytes 5 per cent, eosinophils 2 per cent. Pulse 90, respiration 38, temperature 96.5. Blood pressure 100/80.

16th December. Patient improving, temperature 101.5.

17th December. Patient conscious and normal. Left 18th December.

Treatment. Cardiamid and glucose.

(b) R. R., male, *æt.* 30, admitted on 15th December, 1941, unconscious and sweating. Limbs spastic, pupils dilated and fixed. Reflexes all brisk. Blood—polymorphonuclears 67 per cent, lymphocytes 30 per cent, monocytes 2 per cent, eosinophils 1 per cent. Blood pressure 120/70. Temperature normal.

16th December. Temperature 99.5, patient conscious and normal.

Discharged on 18th December.

(c) N. R., male, *æt.* 25, admitted at 10-10 p.m. on 15th December, 1941. Patient unconscious, lies quietly in bed but exhibits occasional twitchings of muscles of the shoulder girdle. Pupils normal. Tongue blue, respiration 30, pulse 116, temperature 98. Urine—nothing abnormal. Blood—chocolate coloured and clots easily.

16th December. Patient conscious and normal. Temperature 99.

Discharged on 18th December.

Case II.—Two coolies were employed in loading packets of paranitraniline on to a lorry at 9 a.m. on 17th April, 1942. One of the packets was damaged and the powder leaked out. It is stated 'the coolies threw handfuls of the powder at each other and also at the driver of the lorry, and rubbed some of it on their bodies'. They took meals at noon and resumed work of loading another lorry with bags of white clay. At 1-30 p.m. both the coolies vomited, felt faint and became unconscious. They had twitchings of their limbs. They were admitted into G. T. Hospital.

(a) D. B., male, *æt.* 32, admitted into hospital on 17th April, 1942, unconscious, intensely cyanosed, cold and perspiring profusely. Pupils dilated and fixed. Reflexes absent. Pulse 120, feeble but regular. Respiration gasping. Temperature at noon 97, rose to 103 in the evening. Patient died at 1-45 a.m. next day (18th April).

THE CONTROL OF ANOPHELES MINIMUS BY 'SHADE' AND RELATED METHODS

By R. C. MUIRHEAD THOMSON, D.Sc.

Research Worker supported by the Royal Society and the London School of Hygiene and Tropical Medicine

DURING the last ten or fifteen years there have been rapid advances in the control of *A. minimus* in Assam and North Bengal, and one of the most interesting features of this campaign has been the widespread and increasing use of 'shade' as a control measure in the tea districts (Ramsay, 1930; Ramsay and Macdonald, 1936). Although the efficiency of this simple method was well established, there was some doubt as to the exact way in which it worked, and accordingly an investigation was started in 1938 the main object of which was to find out the principles underlying control by 'shade', and if possible to put this and related methods of control on a firmer scientific basis. In order to tackle this

(Continued from previous page)

(b) G. D., male, *æ*t. 35, admitted into hospital at 2-40 p.m. on 17th April, 1942, unconscious, cyanosed, cold and clammy. Pupils dilated and fixed. Jerks sluggish. Pulse 85, feeble, and regular. Respiration gasping. Temperature rose to 103. Urine examined on 18th April—albumin traces, sugar 0.5 per cent, bile present, casts granular, a few.

18th April. Patient's condition same, intensely cyanosed and frothing at the mouth. Temperature came down to 100. Pulse—volume good and regular. Patient catheterized, 28 oz. urine of deep yellow colour resulting.

20th April. Condition same. Temperature rose to 105 in the evening and patient died at 8-30 p.m.

(c) The lorry driver against whom the powder was thrown suffered from giddiness and twitching of the limbs in the evening. He was treated in a private hospital and discharged.

Conclusion.—The incidence of industrial poisoning though not high is increasing in India. It is likely that in the near future, when industrialization is speeded up, industrial diseases will occur much more frequently than heretofore.

Though such diseases are usually dealt with in the larger textbooks used by medical students, very little attention is paid to them in our colleges. Hence no importance is attached to industrial toxicology, a highly interesting branch of medicine.

The first five cases of paranitraniline poisoning occurred in December 1941. Three months later, three more workers were poisoned by the same dye, two of whom died of the effects of the poison. The latter accident would certainly have been avoided if warning had been given and precautions taken in time.

Acknowledgments

I am very grateful to the superintendents of the Jamsetji Jijibhoy Group of Hospitals and of the Goculdas Tejpal Hospital for allowing me to make use of their hospital records and also to the Chemical Analyst to the Government of Bombay, for permitting me to publish in the medical press the results of toxicological analyses.

problem it was necessary to study the reactions of *A. minimus* and its larvæ to different components of the environment in turn, such as light and shade, water movement, temperature, organic pollution, etc., and the reports on these separate aspects of the work have been published from time to time in the *Journal of the Malaria Institute of India* (Thomson, 1940, 1941). As these published results contain full details of all laboratory and field experiments on which the following conclusions are based, the reader might encounter difficulty in selecting from all that material those findings which lend themselves to direct practical application in control work. When the investigation came to an end in 1941 it was therefore felt that the time had come to review the work of the previous 3½ years and to discuss its practical possibilities. As the question of 'shade' is the one that claims first attention, it seems advisable to publish a preliminary communication to clear up some points which might previously have lent themselves to misinterpretation. One of the first points is that in the following account the system of control known as 'shade' will be printed in inverted commas in order to avoid confusion with shade as distinct from light, and it will soon become evident why this distinction is necessary.

If we select a grassy edged garden drain where *A. minimus* is breeding, and shade a section with bamboo matting or thatch, *A. minimus* continues to breed in the dense shade as long as the grassy edge remains. Dense shade by itself will not kill the larvæ, nor prevent the female mosquito from laying its eggs. When the grassy edge under the bamboo matting dies after a few weeks, in the same way as it does under 'shade' hedges of lantana, eupatorium, titapat, etc., *A. minimus* disappears.

Now if we clean weed a stretch of the same garden drain, to produce bare earth edges exposed to light, *A. minimus* is again eliminated. It appears therefore that the breeding place becomes unsuitable for *A. minimus* under 'shade' not because of low illumination but because of the ultimate disappearance of the grassy edge.

Our experiments also showed that the female *A. minimus* lays its eggs in the still water among the grass at the edge of the stream. When the grassy edge is clean weeded or removed by the action of 'shade', the increased water movement makes it unattractive to the female. Similarly, the larvæ of this mosquito are really very susceptible to water movement. Normally they are well protected by the still water among the grass at the very edge of the stream. When the grassy edge is removed, the increased flow makes it difficult for existing larvæ to maintain their position, and they are very liable to be washed away.

It appears therefore that the absence of *A. minimus* from streams under 'shade', and also its absence from streams whose edges have been clean weeded and exposed to light, is really due

to the same cause, namely, the removal of the grassy edge and the resulting increased water movement.*

We have noted above that the shade or low illumination itself is not repellent to *A. minimus*. In fact when the female mosquito is looking for a place to lay its eggs, it is attracted by a certain amount of shade, such as exists in among a thick grassy edge, or a shaded pool or pocket of water at the edge of the stream. In some parts of Assam *A. minimus* is found breeding in little dark pits or 'crab-holes' in the bank of the stream, and it is obvious that the low illumination itself has no harmful or deterrent effect. In streams, the attraction of *A. minimus* to a shaded spot is overruled by the repellent effect of moving water at the edges, but in the still water of *katcha* wells, where *A. minimus* also breeds, the reactions of the female to shade have a direct bearing on control. If we remove the vegetation from the well there is no increase in water movement such as occurs when the grassy edge of a stream is destroyed by 'shade' or by clean weeding. In the deeper wells, where the edges are shaded by the vertical or overhanging earth walls, breeding of *A. minimus* will still continue. But if the clean-weeded edges are fully exposed to light by converting vertical walls into smooth sloping ones, *A. minimus* is no longer attracted, and effective control is brought about.

If these fundamental facts about the influence of light, shade, and water movement are borne in

mind, it will be seen that there is nothing incongruous about the fact that streams can be controlled equally well by 'shade' and by clean weeding, and that the two methods of control are really due to the same causes. Clean weeding is merely a subsidiary method which has been evolved during the course of experiments directed towards an explanation of control by 'shade'. The removal of the grassy edges of a stream and exposure of the bare edges to light is a sound and simple control measure, recommended as a temporary method to be applied in places where 'shade' does not exist or where it would be impracticable to plant it. It should be a particularly useful control measure at the edges of broad streams and perennial rivers, and in rural areas where it is difficult to establish and maintain good 'shade'.

The studies on the behaviour of the mosquito have shown that there is nothing antagonistic about what appear to be two very different methods of control, 'shade' and clean weeding. In fact, we may regard 'shade' as a more permanent form of clean weeding, and both measures could be considered as forms of flushing, since the increase in flow or movement of water at the edges is the main factor which renders the breeding place unsuitable in all these cases.

A Mirror of Hospital Practice

A FEW UNUSUAL CASES OF POISONING

By M. M. SYDDIQ HUSSAIN, M.B., B.S. (Punjab),
 M.R.C.S. (Eng.), L.R.C.P. (Lond.), D.P.H. (Lond.),
 D.T.M. & H. (Lond.), D.O.M.S. (Lond.)

*Chemical Examiner, Bacteriologist, and Superintendent,
 Vaccine Depot, H. E. H. the Nizam's Government,
 Hyderabad (Deccan)*

Case 1.—A Hindu female from district Warangal, Hyderabad (July 1940), killed her husband by giving him a drink containing ground *Bhilawan* (marking nut) and snake poison. No snake poison was detected but *Bhilawan* was detected on a stone on which it was ground and in the remnant of the prepared poison which she said she gave to her husband. It could not be detected in earth soiled with vomited matter nor on a *dhoti* soiled with stools.

The man presented symptoms of severe gastro-intestinal irritation. He died within twelve hours. Quantity administered was not known.

Case 2.—A Hindu female from district Raichur (February 1942) administered with her finger 'something' to a child seven months old. The child started vomiting and diarrhoea soon after. There were blisters on his tongue. A blister also appeared on the part of the chest that was touched by the soiled finger. The child died within twenty-four hours. On the piece of stomach sent to me, there were several blisters

on the mucous membrane and small black particles were sticking to the mucous membrane all over. The particles proved to be *Bhilawan*. Later, the woman confessed to have given *Bhilawan* to the child and a box (tin) containing ground *Bhilawan* was found on her. Some unknown alkaloid was also detected in the *post-mortem* organs which failed to kill a frog even in large doses. No alkaloid was present in the acid extract.

Case 3.—A Hindu male, aged 22 years, from district Nalgonda (June 1940) committed suicide by taking a whitish salt at 12 noon. One hour later he was trembling all over, with fists clenched and shouting incoherently, partly unconscious. Vomited once and passed two liquid stools. Died at 6 p.m. Sodium nitrite (not nitrate) was found in the *post-mortem* organ and on a soiled *dhoti*, etc. A tin containing a salt was also recovered by the police. This salt was also sodium nitrite.

Case 4.—A woman from Nalgonda (September 1940), it was alleged, was bitten by a snake in the morning and died after two hours, but no sign of snake bite was found on the body. *Post-mortem* the organs contained sodium nitrite. Later it was discovered that a man had two wives, the senior wife (deceased) complained of backache, so the junior wife said that she would give her some decoction of anisi seeds. With the decoction she mixed a 'salt' and gave it to the deceased. Soon after the victim began to feel

uncertain about herself, and became unconscious. Vomited once and passed one liquid stool. She died within three hours. The amount administered was about half an ounce in this case. Some more salt was found on her hidden in a box. It was also sodium nitrite. No cases of sodium nitrite poisoning are recorded, so far as I know.

Case 5.—A Mohammedan male, aged 25 years, from Hyderabad (January 1940) thought there was some water in a cup and drank it. Soon after he felt a burning sensation in the stomach. He vomited several times and had a good many watery stools. He walked to the hospital and was quite sensible. The stomach washings contained sodium thiosulphate. The salt was kept in the house for photographic purposes, as stated by the patient.

Case 6.—A Mohammedan female, aged 20 years, from Osmanabad district (October 1941) was suffering from venereal disease. Her husband asked a local amateur physician to treat her. They took her to the fields where some medicine was administered to her. Soon after she had diarrhoea and vomiting; towards the evening she passed away. The physician said he had administered to her two crushed insects without the wings. Two such insects were also sent to me. The wings had black and yellow stripes, and there were similar stripes on the thorax and abdomen of the insects. From the *post-mortem* organ and the insects an alkaloid was obtained. When this was injected into the frog, the latter became very sluggish but did not die. No cantharidin was obtained.

In another case, one of suspected alcohol poisoning, *post-mortem* organs were sent to me in concentrated salt solution. After distillation and extraction, the residual watery solution instantaneously killed the frog. Chemically however no poison could be detected. Later a control sample of concentrated salt solution was injected into the frog, repeatedly with similar results. Therefore simple concentrated sodium chloride solution is very fatal to frogs.

Note.—These reports of a chemical examiner are of more interest from an administrative and legal point of view than from a medical.—Editor, I. M. G.

A CASE OF TETANUS SIMULATING ACUTE ABDOMEN

By N. LAHA, L.M.P.

Medical Officer, Jashpur State, Eastern States Agency

AN adult male, aged 22 years, was admitted on 4th January, 1942, at 10 a.m., into the Deosaran Hospital for the following complaints:—

- (1) Pain in the whole of the abdomen—duration 10 hours.
- (2) Faecal stasis—duration two days.
- (3) Absence of micturition—duration 10 hours.
- (4) Vomiting once the night before admission.

Present illness.—Two days back the patient attended the dispensary for some pain in the neck and was treated with sodium salicylate mixture, local anodyne and a purgative. About 10 hours back, after his supper he vomited once and felt intense pain round the umbilicus which was of colicky nature and referred to the whole of the abdomen. He did not pass any urine since then and had no motion for the last two days.

On examination.—Pulse—120 per minute. Temperature—normal. Patient restless and much distressed. The whole of the abdomen was rigid and tender, and on percussion it was tympanitic. No area of maximum tenderness elicited. He was given the following treatment:—

- (i) atropine sulphate gr. 1/100 intramuscularly,
- (ii) soap-water enema,
- (iii) catheterization,
- (iv) glucose water in sips by mouth.

About 2 ounces of urine was evacuated but no faecal matter came out with enema. Pain was not relieved,

but came on intermittently when the abdomen became rigid. In between the pains, the abdomen was relaxed. Any attempt at palpation was followed by spasmodic contraction of the abdominal muscles.

The case was diagnosed as one of acute obstruction, and it was decided to open the abdomen, but the patient's relatives were against any operation.

As the colicky pains were devitalizing the patient's general condition, morphia gr. $\frac{1}{4}$ was given intramuscularly, and glucose saline administered per rectum. In the afternoon the pulse was 100 per minute, temperature normal, and pain in the abdomen same. Hot water bags were applied.

5th January.—Pulse 100 per minute. No rise of temperature. Bowels not moved and no urine voided. The patient got the same sort of intermittent colicky pains with tender and rigid abdomen. He now complained of maximum tenderness at McBurney's point, where no rigidity was found in the intervals.

No permission was obtained for operation and so the following treatment was again given:—

- (i) soap-water enema and flatus tube per rectum,
- (ii) catheterization twice a day,
- (iii) patient was put in Fowler's position, and anti-phlogistine was applied on the right iliac region,
- (iv) morphia $\frac{1}{4}$ gr. intramuscularly,
- (v) glucose water by mouth in sips,
- (vi) paraldehyde 2 drachms in normal saline was given per rectum at night.

Bowels were not moved. Pain in the abdomen was same.

6th January.—Pulse 90 per minute. Temperature normal. The spasms of pain and contraction of the abdomen came on more frequently. Abdomen was distended, and rigid and tender during the pains. Maximum tenderness at McBurney's point. Patient passed urine twice at night by himself.

The same treatment was repeated with the omission of enema and morphia.

7th January.—Pulse 84 per minute. Temperature normal. Bowels not moved. Urine passed once in the morning.

Patient now complained of pain and rigidity of the neck and inability of opening the mouth properly. With each spasm of contraction the mouth was closed, the facial muscles contracted, the abdomen became rigid and distended, the whole spine was stretched and the patient rested on his heels and occiput. Previous to this he never complained of any lock-jaw.

History revealed some injury by fall from a bicycle, and on examination a healed scratch was found on the right hand.

A diagnosis of tetanus was made. The wound in the hand was cauterized with carbolic acid after an incision, and the following treatment given:—

- (i) anti-tetanic serum 6,000 units intramuscularly,
- (ii) morphine gr. $\frac{1}{4}$ and atropine sulphate gr. 1/100 intramuscularly.

Towards the evening the spasms were more prolonged. Another injection of serum 10,500 units was given intramuscularly.

8th January.—Pulse 90 per minute. No rise of temperature. The spasms continued with contraction of the spine, and lock-jaw, but more prolonged. Bowels not yet moved and the abdomen was rigid and tender during contraction. He was given:—

- (i) soap-water enema,
- (ii) anti-tetanic serum 9,000 units intramuscularly,
- (iii) 25 per cent solution of magnesium sulphate 10 c.cm. intravenously, and
- (iv) a chloral and bromide mixture thrice daily.

In the evening he had another injection of the 25 per cent magnesium sulphate solution, 8 c.cm. intravenously and serum 10,500 units intramuscularly.

9th January.—Bowels moved once at night. Pulse 92 per minute. Temperature normal. Spasms prolonged. He was given:—

- (i) 50 per cent magnesium sulphate solution 6 ounces per rectum,
- (ii) anti-tetanic serum 6,000 units intramuscularly,

(iii) 25 per cent magnesium sulphate solution 10 c.cm. intravenously, and
(iv) chloral and bromide mixture thrice daily.
In the evening bowels moved twice, urine passed twice. Pulse 86 per minute. Abdomen relaxed and spasm less.

He was given—

- (i) anti-tetanic serum 10,000 units intramuscularly,
- (ii) 25 per cent magnesium sulphate solution 10 c.cm. intravenously.

10th January.—He was more quiet. Pulse 80 per minute. No rise of temperature. Spasms sluggish. Bowels moved once at night. Urine passed at night and in the morning. He was given:—

- (i) anti-tetanic serum 20,000 units intramuscularly,
- (ii) 25 per cent solution of magnesium sulphate 8 c.cm. intravenously, and
- (iii) chloral and bromide mixture thrice daily.

Another dose of 10,000 units serum was given in the evening.

After this 40,000 units of serum intramuscularly and 25 per cent solution of magnesium sulphate 10 c.cm. intravenously were continued twice daily for two days more. Thereafter the former was reduced to half the dose and continued for five days more and then stopped. The patient then made an uneventful recovery and was discharged cured on 20th February. He is now leading a healthy normal life.

Summary of the case.—The patient, an adult male, attended the out-door for some pain in the neck which was thought to be rheumatic and was treated accordingly. He was then admitted after two days into the hospital ward for acute abdominal obstruction for which an operation was decided upon. But as no permission was obtained for operation the surgical intervention was deferred. Three days after, he showed signs of tetanus. He was initially given low doses of anti-tetanic serum combined with 25 per cent magnesium sulphate solution intravenously, a devise which was made as our stock of the serum was limited. Then higher doses of serum were given, and the patient made an uneventful recovery.

Points of interest

(i) Tetanus resembling acute abdominal obstruction.

(ii) Even low doses of anti-tetanic serum combined with 25 per cent solution of magnesium sulphate can be given with confidence, proving* the efficacy of the latter in the disease.

My thanks are due to my chief Dr. P. K. Roy, M.B., for kindly going through this paper and permitting me to submit it for publication.

A CASE OF GAS GANGRENE

By N. R. KONAR, M.B.
Civil Medical Officer, Kurseong

S. B. C., male, aged 14 years, was admitted into the hospital on the 19th May, 1942, at about 2 p.m., for the treatment of a lacerated wound on the back of his right leg, caused by an accidental fall from a tree at about 9 a.m. The wound involved almost the whole of the back of the right leg. The calf muscles were badly lacerated and the wound was full of dirt. The temperature on admission was 99.8°F., pulse 118 and respiration 28 per minute. His general condition was good. The wound was cleaned with antiseptic lotions and ether, and the edges which were widely

apart were stitched together. Anti-tetanic serum, 1,500 international units, was injected. He was put on an alkaline mixture and sulphonamide tablets (septanilam 0.5 gramme) 6 a day divided in 3 doses. An injection of morphia grain 1/6 with atropine grain 1/200 was also given to relieve the pain. On the next morning the temperature was 103°F. Pulse rate was 130 and respiration 30 per minute. The patient was toxic and his tongue was dry and coated. It was noticed that gas gangrene had started over the injured part. The wound was blackish in colour and crepitus was elicited over an area which extended above the knee and below the heel. Considering the toxic condition of the patient it was seriously considered whether the leg should be sacrificed to save his life. Before deciding finally to operate on him, the following line of treatment was adopted: The stitches were removed, the wound was widely opened up, the dead tissues were snipped off, the part was thoroughly washed with hydrogen peroxide solution and sulphonamide powder prepared by crushing septanilam tablets was applied liberally over the wound. The sulphonamide dressing was changed twice a day. On the same day he had an injection of anti-gas-gangrene serum of 8,000 units intramuscularly. Along with the local application of the powder, 6 tablets of septanilam 0.5 gramme each were given daily by mouth. The temperature was less on the next day and by 48 hours of the beginning of the treatment it came down to normal. Along with it the condition of the patient and the wound improved remarkably. The toxæmia was much less, the tongue was moist though still coated, the spread of the gangrene had stopped and the wound looked healthy. The sulphonamide dressing and oral administration of the tablets were continued till the 25th May. The patient still had slight rise of temperature which however settled by the 1st June. As no more anti-gas-gangrene serum was available locally and the condition of the patient improved, the injections of the serum were not continued. He stayed in the hospital till the 23rd August, as the large raw area on the back of his leg took a long time to heal. A good amount of scar tissue was formed as he refused to undergo the operation for skin grafting.

The present position of the topical application of sulphonamides has been reviewed by Hamburger (1942). Hawking (1941) carried out experiments in determining the efficacy of local application in preventing gas gangrene. He however advocated simultaneous use of anti-gas-gangrene serum with the topical application of sulphonamides. Opinion is still divided as to the efficacy of anti-gas-gangrene serum once gangrene has definitely started. Though in the present case sulphonamide was given from the beginning it could not prevent gas gangrene as the drug was probably not present in sufficient concentration in the blood before the onset of the disease. It is difficult to assess the value of the small amount of the serum used in this case. However to tackle such a grave infection it may be a good plan to attack the disease in all possible ways, e.g. oral and topical use of sulphonamides and the administration of serum.

My thanks are due to Lieut.-Colonel G. H. Mahony, I.M.S., civil surgeon, Darjeeling, for kindly allowing me to publish the report of the case. I have also to thank Dr. K. L. Bose, medical officer, Kurseong, for recording the data of the case.

NOVEMBER

THE 'AUSTERITY' COURSE OF QUININE AND THE PRESENT SHORTAGE OF ANTIMALARIAL DRUGS

THE present position in which India is placed regarding quinine is a tragedy, a tragedy that could so easily have been obviated. It is unnecessary to recount in detail the history of cinchona cultivation in India, as the subject has been discussed editorially in this journal on several occasions during the last ten years or so.

The story, told in a few words, is that in the middle of the last century India and Ceylon were far ahead of Java in cinchona cultivation. So much cinchona was grown that there was a slump. The price of quinine fell so low that the cultivation ceased to be a paying proposition, with the result that practically all the commercial concerns engaged in growing cinchona went into liquidation, and private cultivation of cinchona practically ceased. The Government of India at that time might very well have shown more foresight and fostered the cinchona industry in the way the Dutch Government did for their industry in Java. They did however see the wisdom of growing cinchona for their own requirements, and plantations were started, or maintained, in several parts of the country. For many years in this journal we have advocated the adoption of some forward cinchona policy in this country, but nothing has been done in the matter and now we are faced with this very difficult position.

For a number of years the average consumption of quinine in India has been about 200,000 pounds annually; this is of course far below her real requirements which can be placed, on a conservative estimate, at a million pounds. The amount of quinine and other cinchona alkaloids obtainable from the cinchona grown in India is about 70,000 pounds. There is thus a deficit of 130,000 pounds, which has had to be imported annually to meet our normal requirements.

It is of course too late to consider the question of meeting the present emergency by extending cinchona plantation, since it takes eight years at least for the plant to reach maturity; consequently the strictest economy in quinine consumption will have to be practised in India.

The teaching regarding the treatment of malaria has undergone a very striking change during the last twenty years. Quinine is a specific for malaria; it can be taken in relatively large doses over a long period without doing the patient any harm; it was therefore argued that

the longer the course of treatment, the better are the chances of complete cure. The treatment course prescribed covered a period of two months, and the amount of drug consumed ran to several ounces. There has however been a new principle creeping into the practice of malaria therapy. It is realized that it is not the drug but the patient's resistance that knocks out the malaria parasite, and that the drug only helps the human organism in its fight against the parasite. It is believed, on very sound grounds, that the patient's resistance, or immunity, will be greatest if it is allowed to develop naturally and the quinine is kept as a reserve that is thrown in at a critical moment in the struggle between man's resistance and the parasitic infection. Quinine given over long periods is thought to depress rather than increase immunity. Therefore the tendency for some years has been to give shorter and shorter courses of quinine treatment and to allow the patient's immunity full play.

This is not by any means based on purely theoretical grounds, for it has been shown that, in benign tertian infections, the percentage relapse rate is barely influenced by the amount of quinine given provided the dose is not allowed to fall below a certain minimum. It is mainly on what this amount should be that experts disagree. Such disagreement is very natural, in view of the fact that malaria strains differ so much in their response to treatment, some requiring many times as much drug to knock them out as do others. A compromise has been arrived at by the League of Nations Health Organization Malaria Committee who in its Fourth Report place it at a maximum of 7 days' treatment of 30 grains a day, or a total of 210 grains.

The new situation that has now arisen naturally makes it necessary for all of us to revise our opinions and even those who favoured a much larger dosage of quinine are now prepared at least to give a trial to the shorter course, advocated, not as a measure of economy but as the best course of treatment, by some of their colleagues. We shall await the results with great interest; it is an ill wind—and it is quite conceivable that when once again more quinine begins to flow to, or better still grow in, India, there will be many converts to the shorter course of quinine; on the other hand, it is possible that many doubters will have been convinced of its inadequacy by personal trial.

There have been during the last few months a number of letters and articles by medical men in the public press in India, on the subject of quinine treatment of malaria. Contrary opinions have been expressed, to the confusion of the lay reader and the embarrassment of the medical profession. We are in entire agreement with our correspondent (see p. 701) that the public press is not the place for medical men to air personal points of view, though informative articles on medical subjects may in some circumstances be

seemly and useful. We therefore welcome the authoritative paper which Colonel Covell, the director of the Malaria Institute of India, has contributed to our present number. Most of the points that we have touched on and others are dealt with in his paper.

There is another aspect of this subject. The cinchona alkaloids are not the only drugs that cure malaria. There are some very potent synthetic compounds that do this also. Why cannot these be used? They can be and are being used, but before the war these drugs were made mainly in Germany. They are relatively easy to synthesize on a small scale, but their wholesale production is a much more difficult matter.

Atcbrin or, to use the *British Pharmacopœia* word, mepacrine was synthesized in India even before the war, and it can be and is being prepared on a small scale in India to-day. But its preparation needs a number of chemical substances that are not available in India. Even if Britain and America were prepared to export these basic chemical substances, something like 16 tons are required to prepare one ton of mepacrine (we must think in tons and not pounds), and, in addition to this, much machinery would have to be imported. Therefore, to meet our immediate requirements, it would not be sound policy to do this, and it would be far better to import the finished article. Before the war, or even before the loss of Java, neither Great Britain nor America was manufacturing mepacrine on a large scale. For larger scale production, time is required and though much headway has already been made and this drug is beginning to arrive in this country in increasing quantities, it will probably be at least another year before we have sufficient for all our requirements.

Is there any other source of antimalarial remedies? The Indian indigenous system contains a very large number of drugs that are reputed to be either febrifuges or actually specifics against malaria. This source should certainly be investigated. Many of these drugs have already been tested and shown to be of little or no value in the treatment of malaria, but there are certainly others that should be similarly investigated.

Advantage has been taken of the present situation both by genuine enthusiasts for some indigenous drug, and by the opportunist exploiters who hope to make money out of some secret remedy. The latter in particular are not hesitating to make political capital out of the inevitable refusal of co-operation that they receive from scientists and particularly from those working in government institutions, and non-medical administrators are very liable to be misled by the plausible stories that these enthusiasts or that charlatans tell. This is no time for academic or purely scientific investigation; any work undertaken should have a direct immediate application to the present situation.

Before a government officer or institution undertakes to investigate a drug, certain facts should be ascertained:—

The exact composition of the drug, in order that it can be made again in exactly the same form.

Whether the different ingredients are available in sufficient quantities for the drug to be made on a large scale, or, if it is made from an indigenous plant, whether this plant is available, or can be cultivated at short notice, in sufficiently large quantities.

Whether it will be possible to organize the manufacture or preparation of the drug on a sufficiently large scale, so that it will be available for the general population within a reasonably short time.

Finally, whether the cost will be sufficiently low for its general adoption by the poorer members of the community.

Further, a sufficient amount must be provided for a proper clinical trial. It is useless for the discoverer, or rediscoverer, of some new, or old, specific to produce enough of the drug to treat a couple of cases only, as spontaneous remission is the rule in malaria, and at least twenty cases should be treated before any opinion can be given regarding the clinical efficacy of such a drug.

Every reasonable effort should be made to supplement the available antimalarial drugs, and if any indigenous drug, that is available in large quantities, is shown to be efficacious, full use should be made of it, but it will not serve the nation's interest to demonstrate that Dr. X's specific for malaria is in fact efficacious in this disease, if only Dr. X knows the formula and he can only produce the drug on a very limited scale, though it may fill Dr. X's pockets for him.

Special Article

COMMENTS ON THE HISTORY OF LEPROSY

By JOHN LOWE, M.D.

School of Tropical Medicine, Calcutta

For a number of years the writer has been collecting material on the history of leprosy. No comprehensive account of this subject has been traced, although there are numerous excellent papers on individual countries and periods. The writer has, however, been struck by the lack of sound evidence to support statements sometimes made on this subject even by well-known writers. These statements are apparently copied without verification from earlier to later editions and from older to newer books.

It was in the late eighteenth century and in the nineteenth century that the history of leprosy aroused considerable interest, and several publications on the subject appeared. The first history, and in many ways the best, appears to have been that of Hensler (1790), and later historians included Shapter, Simpson, Virchow, Kaposi, Munro, Creighton, Newman, and others. Some statements made in the earlier books have since been shown to be untrue, but they are still quoted from time to time.

Most writers have expressed the view that in some countries in ancient times and in medieval Europe, leprosy was common, but early in the nineteenth century Shapter, and late in the nineteenth century Creighton and to some extent, Newman, expressed the view that the prevalence of leprosy in Europe in the Middle Ages might have been greatly exaggerated. A more recent writer in the same vein has been McArthur (1925; 1926), who used the following words regarding the published statements regarding the history of leprosy; 'Oh, history, what crimes have been committed in thy name'.

Actually the present writer thinks that this critical attitude is sometimes carried too far, and that the evidence indicates that leprosy in the past was both common and severe in Europe as well as Asia, but there is no doubt that there has been written much bad history of leprosy. In a new (1942) edition of a standard American book on tropical medicine, the chapter on leprosy includes an historical section in which some of the old mistakes have been repeated.

In the present article no attempt is made to discuss fully the history of leprosy, for it is a vast subject. It is proposed here to discuss a few of the commonest misconceptions about the ancient history of leprosy in the world as a whole, to make some general comments on the subject, and to adopt the principle that the use in ancient literature of a word which might have been used at that time for leprosy is of no value as evidence unless supported by clinical details definitely suggesting if not clearly indicating leprosy.

Leprosy in ancient India

It has been stated by many writers that leprosy is mentioned in the Vedic writings of India. The Rig Veda and the Atharva Veda have been cited. Rogers and Muir state that leprosy is mentioned as *kushta* in the Vedas of about 1400 B.C. although in the recent edition they say that it is not sure that *kushta* meant leprosy. *Kushta* (or more correctly *kushtha*) is now usually used specifically for leprosy but in ancient Hindu medicine it meant skin diseases in general, one of which was leprosy. In the Vedic writings the word *kushtha* appears in a very few places, and it is not certain that leprosy is meant. There is, however, no doubt that leprosy was well known and described in ancient India. Many writers have cited the *Susruth Samhita* as mentioning leprosy, and Dharmendra (1940) has recently quoted and translated those passages from the *Susruth Samhita* which have a bearing on this subject. The present recension of the *Susruth Samhita* was probably written about 600 B.C. but it embodies traditional knowledge from still more ancient times. The *Susruth Samhita* describes treatment of leprosy with chaulmoogra oil.

This is actually the most reliable ancient reference which I have been able to trace, and

it is also in many ways the most accurate and complete of the old descriptions. Under different heads it describes most of the signs and symptoms of leprosy, even in its milder forms with which we are familiar to-day. This fact suggests the possibility that in ancient times, as in the present times, leprosy in its milder forms may have been more common in India than in some other countries.

It has sometimes been stated by writers in India that the Laws of Manu contain definite instructions about the prophylaxis of leprosy. The Laws of Manu (the Manava Dharma Sastra) have been attributed by various European scholars to various periods between 500 and 1300 B.C. Sir William Jones placed the writing between 1200 and 500 B.C. Max Muller was of the opinion that in its present form it is of relatively recent date, but that its origin is much more ancient. In India it is popularly regarded as being of extreme antiquity.

Possible references to leprosy are made in four places. The Sanskrit word *shitri* almost certainly meant leucoderma, and *kushtha* meant skin diseases in general, prominent among which was possibly or probably leprosy. In Book III, sloka 161, a man suffering from *shitri* is included among the list of those who should not be present at religious ceremonies. In the same book, sloka 177, it is stated that the presence of a man who suffers from *shitri* causes the giver of the feast to lose the 'merit' acquired by entertaining one hundred suitable persons (Brahmins, etc.). In Book VIII, sloka 205, it is stated that if a man giving a girl in marriage has openly declared her blemishes, that she is insane, afflicted with *kushtha* or not a virgin, that man is not liable to punishment. In Book III, sloka 7 states that a 'twice-born' in choosing a wife should carefully avoid families whose members are subject, among other things, to *shitri* or *kushtha*. These are the possible references to leprosy detected in the translation of G. Buhler. A Sanskrit scholar has verified for me the accuracy of the above statements.

These passages of the Laws of Manu are therefore not regarded as conclusive proof of the prevalence of leprosy, but when studied in relation to the Hindu medical writings of a similar period, they afford strong evidence that leprosy was common. There is, however, no evidence of the truth of the assertion recently made in a medical journal in India that in the Laws of Manu, the prophylaxis of leprosy is well described.

Leprosy in ancient China and Japan

In the literature of ancient China there is little definite evidence of the existence of leprosy. A study of the history of Chinese medicine by Wong and Wu leads to the following conclusions:—

The Chinese medical classic, the Nei Ching, attributed by Wong and Wu to the period of 220 B.C. but attributed by tradition to Huang Ti. (2700 to

2600 B.C.), contains four possible references to leprosy under the two names Ta feng and Li feng. None of the four references clearly indicates leprosy although numbness is mentioned in one of them. There is also an ancient tradition that one of Confucius' disciples about 600 B.C. died of leprosy, but here again there can be no certainty. In the third century A.D., there is a description of a disease with numbness which is suggestive of leprosy, but it is not until the seventh century A.D. that fairly definite clinical descriptions of leprosy appeared, and it is stated that the disease was common, one record mentioning six hundred cases treated, and one in ten cured. During this and the succeeding centuries, ostracism of lepers was practised, and in the fifteenth century is made the first mention of treatment of leprosy by chaulmoogra oil, at least 2,000 years after it was used in India. The treatments for leprosy mentioned in old Chinese medical writings include purgatives, diaphoretics and diuretics, arsenic, and snake and scorpion venoms.

In Japan, according to the Japanese writers Tashiro (1905), Kitasato (1910) and Mitsuda (1924) leprosy is described in the literature of the eighth and ninth centuries A.D. Japanese medicine seems to have been much influenced, if not dominated, by Chinese medicine. It appears that there is little foundation for the statement made in the textbook of tropical medicine mentioned above, that 'In Japan it (leprosy) seems to have been recorded first in 1250 B.C.'. This is probably a copyist's error. Newman gives the date 1250 A.D. for Japan.

Leprosy in Biblical writings

The whole question of leprosy in Biblical writings has been discussed by many authors, and the matter can be discussed only briefly here. Writers of the Middle Ages and later mostly assumed that the *zaraath* of the Old Testament and *lepra* of the New Testament were leprosy as it was known in the Middle Ages and as it is known to-day. Some recent writers have however challenged this view and there has been much discussion on this point. Lie (1938) discusses the matter well. Among his many interesting points one is that 'Zaraath', even if it included leprosy, could only have covered the 'maculo-anæsthetic' variety of leprosy, and that nowhere in the Bible is there any mention of the 'nodular' form of the disease which looms so large in the ancient literature of leprosy.

Lie (1938a) concludes that a study of the Bible does not prove that leprosy existed among the ancient Jews but since the Jews spent a long time in Egypt 'which certainly must have been infected with leprosy' he finds it difficult to believe that leprosy was not found among the Jews.

To this brief discussion of the subject about which there has been much controversy, I will add only a few remarks. As we see later there is no conclusive proof of the presence of leprosy in ancient Egypt, although it was possibly and even probably prevalent. According to various authors, Manetho is quoted by Josephus (*De Antiquitate Judæorum*) as recording 90,000 cases of leprosy among the Jews, an incredibly high number for true leprosy.

Finally, nowhere in the Bible is there any clinical description corresponding to leprosy as we know it to-day, no mention of numbness and loss of skin sensation, or of the manifestations of leprosy of the 'nodular' type such as are found in the ancient literature of India and of some other countries. The 1942 edition of the standard textbook on tropical diseases states 'in Leviticus 13 and 14, truly remarkable passages regarding the diagnosis and prevention of leprosy are to be found'. The passages are remarkable but they do not describe leprosy.* In Leviticus 13 the chief criterion for a diagnosis of leprosy is whiteness of patches of the skin and more particularly of the hair on the patches. Such patients are to be isolated indefinitely. Now leprosy patches are not white, and, most important, the hair is not white. This whitening of the hair in white patches of the skin is very suggestive and almost diagnostic of leucoderma. Moreover, the patches of leprosy are only partly depigmented; but verse 38 says that if a person has patches which are dull white, he is clean, that is, not suffering from leprosy, and need not be isolated.

It appears therefore that the 'leprosy' of Leviticus 13 was not our leprosy, and was much more probably leucoderma; but leprosy may have been found and may even have been common among the Jews.

Leprosy in ancient Egypt

In the literature of the last seventy years there are numerous references to leprosy as being mentioned and described in ancient Egyptian writings. Munro writing in 1876 mentions an Egyptian record of the time of Ramesis II about 1350 B.C., describing the occurrence of leprosy among the Negro slaves from the Sudan and Dafur. This record is also mentioned by Rogers and Muir although they state that its authenticity is disputed. Newman, writing in 1895, goes even further back and states without any reference that 'it existed in Egypt in the reign of Husapti at least 3000 years B.C.'. The recent textbook above mentioned gives the date as 4600 B.C. It has repeatedly been said that leprosy (like many other diseases!) is described under the term *Uchedu* in the Ebers papyrus written about 1550 B.C. Sauton writing in 1901 recorded the existence, in the Cairo Museum, of stone statues belonging to the early dynasties of the Pharaohs, which showed typical leprosy mutilations. Engel Bey reported in 1890 (published in 1893) that the Berlin papyrus contained a treatise on leprosy of a very early period, that is of about the time of the fifth Pharaoh. This is a selection of statements that have been made by different writers at different times. Others could be quoted.

* They describe skin diseases and, from the administrative point of view, divide the patients into three classes: those to be isolated indefinitely, those to be isolated for seven days at a time; and those not needing isolation. If our leprosy appears at all, it is in the last group!

A critical examination of these records, however, makes it exceedingly doubtful whether a single one is authentic. Engel Bey, who worked for many years in Egypt in close touch with Egyptologists, wrote in 1903 correcting his earlier statements that the Berlin papyrus mentions leprosy, and said that no particulars of the symptoms of the disease are given. He reported a fruitless search to discover the statues showing leprous mutilations said by Sauton to be in the Cairo Museum. He did not produce any definite record of leprosy in ancient Egyptian writings or monuments, although he stated, on what grounds it is not clear, that leprosy existed in Egypt long before the Christian era.

Ebbel (1935) has made a study of the subject including particularly the Ebers papyrus. He finds that the disease described under the name of *Uchedu* does not correspond with leprosy, and he thinks that the translation of this word as leprosy is wrong. He states however that in another part of the same papyrus, leprosy is described under the name 'Chons' swelling'. The passage he cites indicates that this is mainly an affection of limbs. The present writer finds that the identification of leprosy with either *Uchedu* or 'Chons' swelling' is unsatisfactory, the distinguishing features of leprosy not even being mentioned.

Unless more recent work has produced new evidence, it appears that we have no definite proof that leprosy was common or even known in ancient Egypt. We have to come to far later times for the first definite reference to leprosy in Egypt.

Leprosy in royal persons in Europe in the Middle Ages

It is frequently stated that Robert the Bruce suffered from and died of leprosy, but it is by no means certain that he did. Both Simpson (1841; 1842) and McArthur (1926) studied the historical documents but arrived at opposite conclusions. During their lives or shortly afterwards, reports were made that Henry III and Henry IV of England suffered from leprosy, but, as McArthur has pointed out, statements of this kind made by personal enemies are of no historical value. Simpson, however, rightly said that these reports at any rate clearly indicate that in the Middle Ages, leprosy was not considered incompatible with the highest rank and wealth, and we have authentic records of leprosy in such persons.

Possibly the best authenticated case is that of King Baldwin the Fourth of Jerusalem who was related to the Kings of England. Jeanselme gives interesting abstracts from historians of the period, who describe in detail how Baldwin when a child developed anæsthesia of the limbs, and how by the age of 23 he had become blind, and his hands and feet had become crippled, mutilated, and putrescent. He resigned his kingly powers and shortly afterwards died.

Leprosy in medieval Europe

Medieval medical writings leave no room for doubt that the true leprosy of the Middle Ages was our leprosy of to-day.

Again and again during the last hundred years the statement has been made that the number of leper-houses in Christian Europe in the Middle Ages was 19,000, and this statement once more appears in the latest book on tropical medicine mentioned above. This statement possibly originated from Hensler's writings in 1790, and it appears to be based on a quotation from Matthew Paris. (Matthew Paris was a chronicler who lived from 1200 to 1259 and was, according to Green, the last and the greatest of the monastic historians of England.) In 1903 Pernet stated that as early as 1819 it was pointed out, by an unknown writer on leprosy in Rees' Encyclopædia, that the statement was based on a mistranslation of a passage in Matthew Paris' 'History of the English up to 1244'. The original Latin sentence runs as follows:— 'Habent nisuper Templari in Christianitate novem millia maneriorum, Hospitalarii vero novem decim'. This sentence apparently means that the Knights Templars in Christendom held 9,000 manors and Knights Hospitallers 19,000 (the second 'millia' being understood). The word for manor seems to have been translated as leper-house, with no justification. It is true that the Knights Hospitallers (or the Knights of St. Lazarus) administered many of the leper-houses in Europe, and that the order existed for this purpose, but this does not justify the statement that there were 19,000 leper-houses. Ehlers (1903), however, pointed out that the number of leper-houses was probably not much smaller than the number of manors, since many if not most manors would include a leper-house; that in the thirteenth century, 3,000 of the leper-houses in Europe were under the 'commanderie magistrale' of Boigny, the headquarters of the Order of Knights Hospitallers; that at the time of St. Louis there were officially recorded 1,502 leper-houses in France and there were probably others also; and that even in 1693 when leprosy had practically disappeared, the order for the closure of the leper-houses in France affected 1,133 establishments the income of which was thereafter devoted to other charitable purposes.

Virchow (1860; 1861), as quoted by Rogers and Muir, recorded that there were 636 leper-houses in Italy, Verdun, and Maestricht. Newman gave a list of 200 leper-houses in England and Wales alone, and stated that it was incomplete, as it undoubtedly was. Pooth (1939) traced records of nineteen leper-houses within one small area of Eastern Germany which to-day has a population of only 150,000 and was then much less thickly populated.

The standard English book on leprosy is by Rogers and Muir (1940), who in their historical section are in general soundly sceptical, but who in their last edition appear to have adopted perhaps rather an excess of scepticism

regarding the number of leper-houses and the prevalence of leprosy. They state for example that the number 2,000 often quoted for leper-houses in France 'has been discredited by Jeanselme', but a study of Jeanselme's (1934) big work on leprosy does not bear this out. Jeanselme himself gives a list of over 900 leper-houses in France, and this list makes no claim to completeness and applies only to certain parts of France.

Rogers and Muir (*loc. cit.*) also quote the estimate of Creighton (1891) of the extent of leprosy in England in the Middle Ages at its worst period: 'There might have been a leper in a village here and there, one or two in a market town, a dozen or more in a city, a score or so in a whole diocese. Thus in the records of the city of Gloucester, under the date 20 October 1273, three persons are mentioned by name—a man and two women—as being leprous and as dwelling within the town to the great hurt and prejudice of the inhabitants'.

The same author Creighton (1891) in his 'History of Epidemics in Britain' adopted the attitude that while the existence of leper-houses in England in the Middle Ages cannot be denied, it was attributable not so much to the prevalence of leprosy, as to the misguided piety of the period. He seems to have thought that the high figures often given for the number of leper-houses is attributable mainly to the misguided enthusiasm of romantic historians of modern times, whom he accuses of labelling as leper-house every charitable institution of doubtful nature of which they can find any record in medieval writings.

Creighton's statements appear to be very one-sided. He mentions only the three known lepers living in the town of Gloucester but does not mention the two leper-houses outside the town which according to Bigland's 'History of Gloucester' (quoted by Newman) were founded in the twelfth century under a charter. We know that the population of Gloucester at that time was only about 4,000. We know that the city of Norwich in the fourteenth century with a population of a few thousands (the generally accepted figure is about 7,500) had no less than six leper-houses. It appears that the diocese of Exeter at the beginning of the fourteenth century had 39 leper-houses, for there is still extant (Button, 1890) the will of Thomas Button, Bishop of Exeter, who died in 1307 and left 200 legacies, including legacies to lepers lodged at 39 places in the diocese; this is confirmed by the statement of the executors of this will (Boggis, 1935).

It is interesting to note that Newman's list of the 200 leper-houses in England and Wales includes only one-third of these 39 leper-houses in the diocese of Exeter, but that it does include five or six other leper-houses which were established later in this diocese. It therefore appears that the number of leper-houses in the diocese altogether totalled even more than 39,

and that Newman's list of 200 leper-houses for England and Wales is, for this area, very incomplete and probably for other areas also. It is therefore considered that the number of leper-houses in England has not been exaggerated.

Some writers have expressed the view that not only has the number of leper-houses been exaggerated, but also their size and the extent to which they were actually used for cases of leprosy, and that therefore ideas about the prevalence of leprosy in the Middle Ages in Europe are exaggerated.

As we have seen the number 19,000, often given for the number of leper-houses in Europe in the thirteenth century, is wrong and based on a mis-translation, but it also appears that the number was probably at least several thousands. There is no doubt that most of the leper-houses were small, but we know that some of them had accommodation for over fifty patients, and, although it cannot be quoted fully here, good historical evidence exists for the belief that the leper-houses were used to a considerable extent for genuine cases of leprosy. Even when they were not so used, it was often not because there were no lepers, but because the funds were being misappropriated by kings, barons, local lords and the clergy!

It has often been suggested that inaccurate diagnosis must have led to the committal to leper-houses of persons who were not suffering from leprosy, and this undoubtedly must have occurred. Nevertheless a study of the medieval medical writings on the subject, such as those of Guy de Chauliac (fourteenth century), indicates that the need for care in this matter was realized. This writer describes the unequivocal signs of leprosy which alone justify the diagnosis of leprosy and committal to a leper-house, and it is interesting to note that he wrote as though a diagnosis of leprosy was usually, if not always, followed by such a committal. His unequivocal signs of leprosy however are such as are seen only in what we should call very advanced cases. It is obvious that if this was the criterion for a diagnosis, there must have been very many cases of leprosy outside the leper-houses.

Another matter stressed by a few writers is the frequency with which other diseases such as secondary and tertiary syphilis must have been wrongly diagnosed as leprosy. At a later date this was undoubtedly true, but at the time that leprosy was at its height in Europe and most of the leper-houses were being built, syphilis was either rare or absent from Western Europe. Most historians are in agreement that leprosy was at its height about the thirteenth century but that syphilis did not appear commonly in Western Europe until much later.

Another factor that is often overlooked is the small size of the population of European countries, particularly England, at the time that leprosy was at its height. In England, for example, in the latter part of the fourteenth

century, the total population was probably not more than three millions. Actually the figure generally accepted by historians for the year 1377 is just over 2½ millions. This figure is from calculations based on the figures of the number of persons paying the poll tax of that year. There were in England at that time only 41 towns with more than 1,000 people, only 22 with more than 3,000, only 10 with more than 5,000, and only 3 with more than 10,000, namely London, York and Bristol with 40 thousands, 13 thousands and 12 thousands respectively. This, however, was in the period following the Black Death, which killed, it is said, one-third of the whole population of England and probably a higher proportion of the population of the towns. Nevertheless it is certain that many towns were little more than large villages centred round a castle or an abbey. In spite of their small size, nearly all the towns had one, and some two or more leper-houses, Norwich having no less than six.

There is much more which might be said on the subject. A general consideration of the available literature has led the writer to the view that the prevalence of leprosy in England, and in fact in medieval Europe, was very considerable. Nevertheless there is not adequate historical evidence to justify the impression given by some historians that leprosy affected a large section of the population and became a scourge not much less serious in its way than the Black Death.

In no large area of the world, even under conditions most favourable to leprosy, does the incidence to-day rise much above 5 per cent, and a much more usual incidence is about 1 per cent even in countries which are regarded as being heavily affected. It seems unlikely that the incidence of leprosy in the Middle Ages in Europe was any higher than it is to-day in certain parts of Africa, Asia and South America, and it was possibly much lower, although of course any accurate estimation is out of the question.

Medical News

COW AND GATE MILK FOOD

COW AND GATE MILK FOOD, although a first-class infant food of paramount importance—especially in a country such as India—continues to be classified by the authorities for customs and other purposes under the generic heading of 'Farinaceous and Patent Foods', tariff item no. 19. As such it is treated on the same level as unessential articles such as old newspapers, marble and stone cigars, etc., to mention only a few of the other headings to which the import restrictions apply.

Stocks in the country are almost finished and the public who have been relying upon Cow and Gate Milk Food to safeguard the health and welfare of their infants—the future generation—are bound to be gravely concerned at the stoppage of the supply of such an important item, upon which they have come to place so much reliance. We wish to add and to

emphasize the fact that plentiful supplies of Cow and Gate are available at the Canadian Factories of the Company, waiting to be shipped as soon as import restrictions in India are removed.

THE FACULTY OF TROPICAL MEDICINE AND HYGIENE, BENGAL

THE following students are declared to have passed the L.T.M. Examination, Session 1942.

Passed

(Arranged in alphabetical order)

1. Benoy Kumar Banerjee, L.M.F., private practitioner.
2. Romesh Chandra Barua, L.M.F., private practitioner.
3. Saileschandra Bhattacharyya, L.M.F., private practitioner.

4. Kashi Nath Bondopadhyay, L.M.F., assistant medical officer, Bahipookni Tea Estate, Darrang, Assam.
5. Monoranjan Chakraborty, L.M.F., private practitioner.
6. Amarendra Narayan Choudhury, L.M.F., clinical laboratory assistant, Pabna Sadar Hospital.
7. Amarendra Nath Das Gupta, L.M.F., private practitioner.
8. Bijoy Krishna Ghosh, L.M.F., private practitioner.
9. Mahadeo Prasad Joshi, L.S.M.F., house physician, Chittaranjan Hospital, Calcutta.
10. Charu Chandra Karkoon, L.M.F., medical officer, Mahaluxmi Cotton Mills, Palta, 24-Parganas.
11. Ronjit Kumer Mazumder, L.M.F., private practitioner.
12. Jati Bhusan Ray, L.M.F., medical officer, Viswa Bharati, Sriniketan, Bolpore.
13. Bimal Kanti Roy, L.M.F., private practitioner.
14. Naresh Chandra Sett, L.M.F., private practitioner.
15. Shah Md. Lutfur Rahman, L.M.F., private practitioner.
16. Bhopindar Singh, M.B., B.S. (Punjab), private practitioner.
17. Ram Behari Lal Srivastava, L.M.F., house surgeon, Chittaranjan Hospital, Calcutta.

BRITAIN'S HEALTH

BRITAIN has been at war for more than a thousand days. What are her gains and losses on the battlefield of health? Has the enemy of mal-nutrition pierced her defences? Has epidemic disease ravaged her towns and cities? Has the strain of long days at the bench or in the field lowered the resistance of her people? Or is Britain standing the strain? The Registrar-General of Births and Deaths has just given the answer, based on figures which none can contest.

The birth rate in 1941 was lower than that for 1939. Indeed, the number of births was the lowest since 1933. But for the first quarter of 1942 the birth rate was the highest recorded in this quarter for the past ten years.

One index of the health of the country's mothers is the number of babies still-born for every one thousand total births. This is called the still-birth rate, and it has fallen steadily since 1939. 1941 shows an improvement on both 1940 and 1939.

The infant death rate

The infant death rate has risen slightly, although fifty years ago the figure was twice as high as it is to-day. The infant mortality rate in 1941, though slightly higher than in 1940, was no more than that in 1937, and lower than the figure for 1936. It is considerably lower than the average for the years 1931 to 1935.

Once again, the first quarter of this year shows a remarkable improvement. Indeed, the infant death rate in the first quarter of 1942 is the lowest ever recorded in the first quarter of any year.

The general death rate tells its own story. In 1941 it was lower than that in 1940, but somewhat higher than in 1939. But these figures include the violent deaths in England and Wales caused by the war. It was in August 1940 that the Luftwaffe began large-scale air attacks. It was in the third quarter of 1940 that the effect on Britain's death rate became evident. This accounts for the rise in 1940 and for almost all the difference between 1939 and 1941. Excluding all such deaths from violence from the figures, the death rate in 1941 was 11.7 per thousand of the population, compared with 11.5 in 1939 and 12.7 in 1940.

In the first quarter of 1942—and it is in the first quarter of the year that there is always registered a higher death rate than for the year as a whole—the total death rate, even including deaths from violence, was under 15 per thousand, lower than in the first quarters of all three preceding years. This figure does not, of course, cover the fighting Services.

Figures for infectious diseases

Then consider the Registrar-General's figures for deaths from infectious diseases. Here, there are both

increases and decreases. The most important increases in 1941 were in tuberculosis, whooping cough and the enteric infections.

Tuberculosis has given rise to some anxiety. There was an increase in the number of deaths from lung tuberculosis in 1940 over those in 1939. But there was no further rise in 1941. It was in other forms of tuberculosis, particularly tuberculosis of the coverings of the spinal cord, that a further rise took place.

One explanation of the figures for lung tuberculosis is that the additional stresses of war, both physical and psychological, proved too much for many patients already ill with lung tuberculosis. They died in 1940 or 1941, before they would otherwise have done. Whether there is any new tuberculosis infection abroad in Britain can be judged only when the full figures for 1941 are available.

The position is being watched with care, and the task will be made easier by the use of machines for mass radiography by means of which 200 chests can be photographed in an hour.

To compensate for these increases there were decreases in the deaths from other infectious diseases. Typhoid fever, scarlet fever, erysipelas, late syphilis and, among males, recent syphilis, all show a decrease in the number of deaths.

Fewer people died

To these infectious conditions may be added some other diseases from which fewer people died in 1941. They include appendicitis, gastritis, infections of child-birth, rheumatic fever and ear and mastoid diseases.

There have been fewer deaths from toxic goitre, from cirrhosis of the liver, and from the toxæmias of pregnancy.

Balancing the increases and the decreases, 1941 was a remarkably healthy year, judging by death rate from diseases. But death is not the only index.

What of general resistance?

Has there been a serious increase in infectious disease which causes illness and incapacity, but not a fatal issue? The answer is 'no'. Has there been a serious increase in non-infectious diseases of a non-fatal character? Again, no. Are there signs among the children or the grown-ups of mental strain finding expression in neurosis? On the contrary, war has brought a fall in the number of neurotics seeking treatment from doctors and clinics. People are too busy to permit themselves the luxury of a nervous breakdown.

Lastly, are there signs of malnutrition? Are there, in the streets of Britain's cities, and the lanes of her countryside, children who look pallid, listless and weary? Are there signs of vitamin shortage? For instance, has the disease of scurvy, due to shortage of vitamin C, appeared as it did in some areas in the first world war? The answer is a plain and unqualified 'no'.

It is friends overseas, the seamen of all free nations, and Britain's own farmers and other workers who have secured a food supply sufficient for all the country's basic needs. There are no signs of malnutrition. Lord Woolton has reorganized British dietary, but not to the detriment of health. Britain is as fit as she has ever been—and the figures prove it.

CHARLES HILL, M.D.

THE ANTISEPTIC

WE have received a copy of *The Antiseptic* for October 1942; it is a special number on 'war medicine and surgery'. The decision to bring out such a number is a wise one in view of the present situation. There are in this volume thirteen articles by different contributors. Most of them (on war injuries, burns, etc.) are of practical nature. The article on typhus by Professors Heilig and Naidu will be read with interest and their classification will be helpful. Medical practitioners will appreciate this volume by having this opportunity of reading these articles in a concise form.

Public Health Section

PUBLIC HEALTH ORGANIZATION

IV. PUBLIC HEALTH ENGINEERING

By K. SUBRAHMANYAN, B.E. (Madras),

M.Sc. (Harvard), A.M.I.E., A.M.I.N.S.T.C.E.

*Assistant Professor of Sanitary Engineering, All-India
Institute of Hygiene and Public Health, Calcutta*

PUBLIC health engineering is a modern idea of very recent origin. The public health engineer used to be known as the sanitary engineer, and is still described as such in many countries.

The new designation represents a gradual change of concepts regarding the scope, functions and training of the person responsible for the public works relating to environmental hygiene.

Forty years ago, the sanitary engineer was not a specialist. He was an ordinary civil engineer, engaged on the construction and maintenance of water-works, drainage works, and sewerage projects. He was well versed in hydraulics. He could build a dam or reservoir, and lay pipes and sewers. He knew a little bit of plumbing, but was not so sure of his ground in the installation of pumps and engines. He felt equally competent to construct irrigation works, water-works, or land drainage works, because the applications of hydraulics were involved in all these. As regards water purification or sewage treatment, he knew a few thumb rules, and had some inflexible notions; but he was ignorant of the complex physico-chemical, biological and bacteriological processes involved in modern water purification and sewage treatment. Regarding health and disease, the origin and progress of epidemics, biology, physiology and ecology, he knew nothing. His service to society was through constructive work on dead or inert material, such as concrete and steel, not living material.

Those concepts have been modified during the last twenty years. Public health has been recognized as one of the important functions of governments all over the world during the last two decades, and health programmes have been initiated or intensified everywhere. The assistance of the sanitary engineer has been sought for carrying out these programmes. He has been required to draw up schemes for water-supplies and sewerage for innumerable villages, towns and institutions; and to treat water and sewage of urban communities as in refined industrial processes. He has had to devise methods of collection and disposal of refuse and garbage. He has been called upon to clear slums, plan townships, improve ventilation and lighting under a variety of conditions ranging from the rural hut to the mammoth factory,

abate nuisances from smoke, dust, noise, etc., and make living conditions comfortable. His services have been requisitioned for extermination and control of pests, bugs, rats, flies, fleas, lice, anopheline and other mosquitoes, etc., in public health measures for the control of plague, typhus, malaria, yellow fever, etc. He has been required to watch the pollution of natural streams and harbours and estuaries by community wastes and industrial wastes, and safeguard the purity of natural waters. He has been required to take care of environmental conditions so as to ensure the purity and wholesomeness of milk and dairy products, food, vegetables, fruits, fish, shell-fish, and meat, all the way from production through handling, transport and marketing down to consumption. Increasing attention is being paid to rural public health, and the old sanitary engineer has been asked to put forth practical ideas suitable for the limited resources of villages, for water-supplies, for refuse disposal, for the prevention of soil pollution, for schools, dairies, markets and many other things. The public health engineer's duties have become manifold. He has to advise the villager on the construction of cheap latrines, the factory manager on the disposal of his trade waste, the theatre owner on measures of safety and ventilation and air-conditioning. He has to look after the fumigation of grains at a port, or carry out subsoil drainage in a malarial region. The demands upon his services call for great skill, broad education, erudition, tact and social aims. He is required to render social service in a less spectacular but much more intimate way than his colleague who builds bridges and roads and factories. He has to co-operate with the health officer in practical measures to carry out health ideals.

The modern public health engineer has to be fundamentally an engineer, i.e. one with a practical outlook, imbued with a sense of realities and economy, clear-cut ideas and methods, and capacity for organization and execution. He must be well educated in all the basic sciences pertaining to his profession, such as strength of materials and theory of structures, mechanics, physics and chemistry and bio-chemistry, hydraulics and surveying, geology, physiology and biology, construction, estimating and specifications, and in public health subjects. Unless he is well trained in public health subjects, he will not be in a position to appreciate and assist the medical officer of health who will be his colleague and critic. Instead of thinking out for himself he will be reduced to the position of constantly taking orders from his colleague who will not know practical details. It will be an irksome position for both.

The public health engineer has been suddenly called upon to meet these multifarious demands, and has been evolving under some handicaps,

The orthodox civil engineer did not usually get any training in public health and allied sciences, such as bacteriology, biology, physiology, epidemiology, etc. When an engineer ignorant of these things took up public health engineering, he did not command even scanty respect from his colleague, the medical officer of health. An antagonism developed between the two, instead of mutual confidence and respect. This antagonism was specially noticeable in the field of malaria control some years ago. Medical men used to write books on malaria, referring to the engineer as a blunderbuss scattering malaria in his wake, a public enemy digging borrow-pits along his railroads and highways, and sowing the seeds of malaria in the places where he stepped in for irrigation or power projects. When medical experts on malaria referred to man-made malaria, they had only one man in view, the engineer. That antagonism has since vanished. It is true that the engineer committed a lot of mistakes owing to his ignorance of the causation of malaria and the life and habits of the malarial mosquito. But when he was educated in these matters, the engineer became a valuable ally to the health officer in the control of malaria. It is now realized that malarial engineering is a highly specialized form of work that medical men cannot do by themselves. With understanding and co-operation between the medical man and the malarial engineer, intricate schemes of drainage, subsoil drainage, filling, flushing, adult spray-killing and naturalistic measures of control are now carried out more efficiently and expeditiously than before.

Another handicap under which the public health engineer has evolved is the prejudice of the old classical engineers, against one who is engaged on such humble work as designing latrines and cattlesheds. This is unreasonable and stupid, like every other prejudice, and has not yet disappeared completely. It used to keep away ambitious young men from the humble fold of 'stink experts' who have developed into public health engineers now.

The greatest handicap, however, has been the lack of facilities for special training in public health engineering for engineers. The multifariousness of their duties, and the versatility required to discharge those duties efficiently, have already been indicated above.

There are no post-graduate courses in Indian engineering colleges in public health engineering. In the undergraduate courses leading to a degree in civil engineering of the Madras, Calcutta, Bombay and Mysore universities, sanitary or public health engineering is taught as applied hydraulics. Water-supply and purification and sewerage and sewage disposal are taught, more from the point of view of structural design than from the point of view of public health. These subjects take up only a small part of the student's time, when he prepares for a general degree in civil engineering.

In England, London and Manchester universities offer courses in municipal engineering, covering the commoner phases of urban sanitation.

In the United States of America, many universities offer under-graduate courses in sanitary or public health engineering leading to a degree distinct from, or as major courses of study under, civil engineering. Such universities are well distributed all over the States. The courses are not stereotyped. Besides, there are some universities offering post-graduate courses leading to degrees in sanitary or public health engineering. Harvard has a wide and comprehensive course with excellent laboratory facilities and field inspections, with perhaps slight over-emphasis on the theoretical side. Most of the state sanitary engineers are sent to Harvard for training. Chapel Hill, the Massachusetts Institute of Technology, Columbia, the Carnegie Institute of Technology, Pittsburgh University and Michigan are also offering good courses.

The modern public health engineer has not only to be well read and cultured; he must express himself elegantly on the platform and through the press. He has to sell his ideas to the public. He has to educate them, convince them, and ask them to put up funds for his projects. He is thus coming more and more into the limelight. Health work is expensive, and funds have to come from several sources, some of which may be voluntary, some from private and philanthropic sources, and some from municipalities, governments, etc. The health engineer has to convince all these sources about the soundness and urgency of his projects. In some cases he is asked to spend the allotment himself. More often he is called in as consultant. As such, he has to draw up alternative schemes to suit the resources of his clients. The schemes that he executes personally are only a tiny fraction of those that he draws up or expresses an opinion upon.

Sometimes his schemes are given to engineers of the public works department to execute, as he may not have the time, staff, or tools and plant to carry them out. In his capacity as consultant he has to use tact and avoid harsh criticism of other engineers executing his ideas. Unrestrained criticism may produce hostile reactions.

In India the position of the public health engineer to-day is beset with difficulties. The funds for works are mostly from Government or under their control, and have to be spent according to rigid plans and procedure. If the health engineer is directly responsible for the execution of works, he has to cut down consulting work to a minimum, for want of time and staff. He is placed between the health and the public works departments, and tries to maintain harmonious relations with both and with local bodies. If his duties are mainly executive, he is attached to the public works department, to give him the benefit of tools, plant, uniformity

of procedure in accounts, etc. This appears to be the case in Madras. If his work is mainly that of consultant to the health department and local bodies, it is better to have him attached to the health department for administrative purposes. This is the position in most state health departments in the United States of America, and in Ceylon. It fits into the organization outlined by Dr. Jacocks in his introductory paper to this series on Public Health Organization.

Considering the amount of work that lies ahead, the number of public health engineers in India is too small. There must be competent and qualified health engineers in every municipality, besides regional health engineers. There is plenty of work before them, whether they are administratively under the health department or under the public works department of Government. Barely 4.5 per cent of the population of India enjoy the benefits of protected water-supply. Our villages and towns lack the most elementary sanitary amenities. Our public health engineers have to prepare planned programmes for water-supply, drainage, latrine construction and malaria control in the rural areas where so many millions of our people live. The water resources of the country have to be located and surveyed. The schemes must be within the financial resources of the rural population. They must be classified according to urgency, and carried out according to timetable.

For the requirements of India, the teaching of public health engineering as a small part of civil engineering is inadequate. The four-year curriculum is already overburdened, and it is not advisable to enlarge the syllabus in this branch alone in the under-graduate course, before the student has had time to decide which branch of civil engineering he will practice. Hence it is necessary to introduce public health engineering as a subject for post-graduate study leading to a degree such as Master or Bachelor in Public Health Engineering. The course must be of at least one year's duration and must include water-supply and purification, sewerage and sewage disposal, sanitary chemistry, ventilation, housing, industrial hygiene, malarial engineering, bacteriology, biology in relation to public health, epidemiology and statistics. These subjects must be taught with equal emphasis on the engineering and health aspects. The courses must fulfil the duty of a university; which is to prepare students for the most diverse post-graduate activities and equip them for continuing their own education in life unaided by class-room instruction. It must not aim merely to produce good craftsmen. Such courses can be planned at the existing engineering colleges of Calcutta, Madras, Bombay, and Mysore, with the collaboration of the All-India Institute of Hygiene, the public health and medical departments of Madras, Bengal and

PREVENTIVE PÆDIATRICS :

AN ACCOUNT OF HEALTH WORK IN TRENGGANU, MALAYA

(Continued from September issue, p. 552)

THE SCHEME FOR HEALTH WORK

By J. W. SCHARFF

PART I

THE object stated in the terms of my assignment to Trengganu was the duty of carrying out a 'health survey' within a period of six months.

(Continued from previous column)

Bombay, and the Indian Institute of Science, Bangalore. Besides these, specialized instruction in a particular branch, like malarial engineering, can be given by the All-India Institute of Hygiene. The students for such post-graduate courses must be men who have already decided to take up public health engineering as their career, i.e. graduates in engineering who have taken up municipal engineering or service in the local boards, or who have worked for a year as apprentices to sanitary engineers.

The public health engineering division for a state or province may consist of a chief with three or four assistants at headquarters and the necessary number of district engineers in the field. The assistants at headquarters may have functional instead of regional jurisdiction, so that each assistant may have a chance of specializing in a particular field of work. There must be a workshop and a laboratory at headquarters, besides an efficient drawing office. The district engineers must be in a position to undertake surveys, to collect data, and to carry out works. The staff at headquarters must be in a position to give expert advice, carry out research, and evolve standards.

If the present district board engineers and municipal engineers are relieved of some of their routine work in connection with the maintenance of roads, they can devote time and attention to public health engineering after receiving specialized post-graduate instruction.

If this idea finds favour, promotion to the higher grade among local board engineers and municipal engineers must depend among other things on their qualifying in public health engineering. The pay and prospects of such qualified engineers must in general be better than those of ordinary public works engineers.

Summary

The evolution of the modern public health engineer from the sanitary engineer is outlined. His functions, qualifications, handicaps and opportunities are described. His position in public health organization is discussed, and the work awaiting him in India is pointed out. A scheme is outlined for post-graduate instruction in public health engineering, in India.

It is generally assumed that a health survey implies an investigation into the causes of ill-health, followed by a report, upon which action may or may not be taken at a later date.

There have been many surveys, but few have led to an attack on the fundamental causes of disease, already so well known. Consequently my design, to avoid such a lamentable ending, was to originate a scheme in place of an inquiry, to try out certain of the most obviously necessary and acceptable health procedures and policies which might be followed up with benefit in the future.

It was my purpose to show that the state of Trengganu could cope with its own health problems within the orbit of its existing organization and that local initiative and local labour, coupled with the proper use of local materials, could and should become the mainstay of public health and progress.

Abundant information, both in Trengganu and elsewhere in Malaya, led to the conclusion that there were three important avenues to health, which offered almost unlimited and unrivalled opportunities to benefit a rural population depressed and victimized by the stranglehold of sickness. These avenues were better feeding, malaria prevention and infant welfare.

The first and foremost of these objectives was improved nutrition but without improved sanitation the mere betterment of the food supply would be of small avail to a community infested with intestinal worms and other filth diseases. Thus a scheme of improved sanitation, though discussed under a separate heading in these notes, had improved nutrition as its background and was linked with an effort to foster agriculture and animal husbandry. These twin objectives should never be torn apart in any programme of rural uplift. Next comes a brief account of what has been newly attempted in the prevention of malaria; and lastly a more detailed discussion on infant and maternal care. In this closing section, my close collaboration with Dr. Williams renders us both almost equally responsible for what is recorded on this item of our work.

Improved nutrition

The factor most generally associated in Trengganu with the problem of ill-health, and, in particular, with a high infant mortality was the habit of eating polished rice. This habit is partly accounted for by the fact that polished rice keeps longer. Therefore the shopkeepers find it more profitable, if they can sell it to an unsuspecting population. It was clear that this unfortunate preference for the white polished product should be one of our chief targets for attack. The health giving quality of under-milled rice was stressed by constant demonstration at welfare centres and in schools. It was shown how, by correct cooking, the unpolished rice could be most appetizing as well as wholesome. Thanks to the support of all concerned a rice mill, which had been set up in the town, was made to produce

under-milled rice as an experiment. The public and the shopkeepers were fully persuaded, the Malay rulers and their people gave a fine response. The experiment has been successful. There is now a vigorous and growing demand for under-milled rice, which has greatly helped to bring about a reduction in ill-health.

Home gardening

The lack of vitamin in rice was not the only nutritional defect which lent itself to prompt and successful action. The obvious need for increasing the production and consumption of home-grown vegetables and fruit was another direction in which rapid progress could be made. Interest was soon aroused in the growing of many useful leafy vegetables and fruits, such as papaya, in gardens and allotments.

Compost making

The secret of success in gardening depends upon the making and maintenance of soil fertility. If more vegetables are to be eaten, more must be planted and if a larger total area of vegetable gardens is to be cultivated successfully, more manure must be used.

Trengganu is now well ahead in the solving of this problem which is concerned in the production of kampong and village compost. Developing along these lines many of the townsfolk and villagers are now pulling their weight in this campaign of digging for health and victory.

Town and village sanitation

The necessity for clean surroundings increases in proportion to the growth and concentration of a population. Consequently the major problem of sanitation was concerned with the larger villages and towns. Schemes to improve scavenging and conservancy have been put in hand. Wherever practicable, bore-hole latrines have been introduced and scavenging gangs organized to meet local needs.

Anti-malaria measures

Whereas better nutrition and improved nurture have almost universal application, malaria control measures need only be regarded as a primary essential in places where this disease overshadows the other health problems of a community. These are the places where the people are repeatedly struck down by epidemic visitations of malaria or where the inhabitants are so saturated by continual infection that the vicious cycle of ill-health and incapacity can only be reversed by severing the chain of malaria incidence at the point where it is the most vulnerable to attack.

In Trengganu one is set the task of applying the methods of malaria prevention which will suit an unusually backward and impoverished people. A beginning has been made, for the first time, in the application on a large scale, of what has been described as 'naturalistic' measures of malaria control. This is a course of action first made known to science by Professor

Williamson, a former Professor of Biology at the College of Medicine in Singapore.

The effect of this work in a number of villages controlled, has been sufficiently encouraging to ensure a further extension of these works and to compel more investigation along these lines of progress.

PART II

By CICELY D. WILLIAMS

Scheme for health work

Welfare work { Development of maternity and child welfare.
Permeation of medical work with preventive.

(a) *General*

THIS section is an attempt to explain the relations of welfare work.

The original function of the state medical service in the dependencies was to provide medical attention for the individual, to begin with mostly members of the European staff. As time went on there was more demand for treatment by non-Europeans and by the general public. Also the 'Preventive' function of the medical department was developed, and means for combating the spread of epidemic diseases were enforced by the government medical service.

It is now being gradually realized that just to prevent the spread of epidemics is a negative function of limited usefulness; that a healthy population is essential to the state; that health depends on housing, nutrition and education, not merely on the prevention of epidemics, and that the function of the medical service is to raise the standards of living and of health.

Now, in Malaya, medical attention for the individual is provided by dispensaries and hospitals and bedside nursing, for all of which there is considerable provision, as well as for the training of personnel, doctors, nurses and dressers.

For the impersonal side of preventive work, port health, sanitation, malaria control, plague and smallpox prevention there is again considerable provision and training for personnel, i.e. a school of training for sanitary inspectors.

As a whole the outlay on buildings and equipment has been large compared with the amount spent on training.

But for the third and newer aspects of health work, welfare, health education, the personal side of preventive medicine, nutrition, social services, and all the ancillary departments which perform such an important (though sadly disintegrated) part of medical services there is as yet little in the way of planning or training for personnel and regrettably little awareness of the need for these things.

Now in a comparatively backward country this aspect of medicine has a special importance which is far beyond that in a 'civilized' state. In a civilized community there is a multitude of

organizations, like the boy scouts, women's institutes, cinemas, newspapers, extension lectures, workers' guides, etc., etc., which largely help to form public opinion and to give popular instruction and assistance. But in a backward country there is the major part of the population that never comes in contact with the medical service either in its preventive or in its curative capacity or else comes in contact with it so very slightly as not to count. This section has none of the health knowledge that is taken for granted in a civilized community, in fact it looks upon many of our basic health measures as incomprehensible extravagances. Secondly, malnutrition and preventable diseases, apart from major epidemic diseases, form the most important factors in the health landscape, and thirdly, it is through work of this sort that a backward population could most easily and most profitably be reached.

The medical service in the colonies and dependencies should therefore devote a great deal of attention to teaching, both for the members of its staff and for the general public. In fact it may be said that education is the chief function of medicine.

The rationale of welfare work is often neglected. The result is that in some countries it has proved disappointing. Welfare centres of the pattern forged in Europe, whetted in America and burnished in the Antipodes have been established without first consulting the conditions and needs of locality.

In a country such as Trengganu, setting up a welfare centre of the orthodox pattern would be no more good for the health of the people than setting up Fortnum and Mason would be for their nutrition.

Orthodox welfare centres, that claim to prevent disease but not to cure it, were introduced in Britain to fill gaps in health work in a country that already had an established and acceptable hospital system. In spite of many limitations their success has been enormous. There are only a few people who are in a position to appreciate this success. Dr. Eric Pritchard, writing in November 1940, compares the modern welfare child with the old pre-welfare child as 'Hyperion to a Satyr'. He says 'infant mortality and morbidity are mainly a matter of maternal ignorance, and infant well-being and health a matter of education'. In saying this he acknowledges that welfare work is merely the specialized channel through which improvements in education, nutrition, housing, industrial hygiene, etc., have been brought to bear on the condition of infants and children. It is a type of work that has none of the dramatic appeal of surgery, or of biochemical discoveries, but in its way it is probably even more life saving.

But nowadays even in the West it is being increasingly realized that in work with children, prevention and cure must go hand in hand or both are comparatively useless. It is futile to imagine that there is always a clear distinction between a sick and well child. In order to

prevent disease it is essential to have a sound knowledge of the diseases one means to prevent. There can be no rational excuse for putting a child with a deficiency disease into one hospital, and for the pneumonia which is secondary to that deficiency into another.

There are three separate tendencies now to be seen in England and America. One is that nurses undergoing a '*General training*' do not only study bedside nursing. A great many of them are going to be employed in non-institutional activities. It is found to be impossible to understand the significance of illness unless wellness is also studied. Welfare and environmental hygiene form an essential part of general nursing. Another tendency is to avoid the present overlapping in the various welfare services. Instead of one family being visited by school nurse, factory nurse, T.B. nurse, hospital almoner, etc., it is preferable as far as possible to replace all these visitors by one polyvalent worker, more on the lines of the '*familienfursorge*' of central Europe. The third tendency is to give a training to these workers that is both clinical and preventive, that will fit them for their polyvalent function without the necessity for going through a whole series of isolated diplomas.

In starting welfare work in a country such as Trengganu, it must be remembered that the system must be a comprehensive one. In fact, it should be built on the 1950 model rather than on the 1900.

There are serious difficulties which have stood in the way of the development of welfare work in the dependencies. In the first place, many of those who are responsible for it have only been acquainted with welfare centres of the old-fashioned British type, and they do not conceive of any other. The second difficulty is the complement of the first. No doctor who has had first-hand experience of welfare work has ever yet been appointed to a senior position in the government service.

The welfare doctor's difficulties have not only been administrative, they have been professional as well. At its best the work must be both preventive and curative. But its preventive aspect is intensely personal. In some places it has happened that a welfare doctor who has attempted to investigate or to treat efficiently disease that she has been told to prevent, has been accused of 'treachery to preventive medicine'. On the other hand, a clinician who attempts to take an interest in preventive medicine is regarded with dark suspicion, and in fact is looked upon as not being a clinician at all. The results of all this is that co-ordination of preventive and curative work has been unsatisfactory. Much time and effort and money have been wasted. Four-hourly feeds and water in between are diligently recommended for babies that are dying of beri-beri and rickets, while thousands of pounds are spent yearly in hospitals and dispensaries in curing diseases that are perfectly preventable.

The third great handicap is one that has already been mentioned, the lack of a training school for health workers, so that one is faced with a double problem, of training a staff and working out a project at the same time. The problem of staff is an acute one, but local problems should guide us in the choice and training of staff. Local needs and local abilities should be the starting point, although the standard to be aimed at is a high degree of attainment.

In order to conduct welfare work in Trengganu with economy and efficiency it is necessary to bear all these arguments in mind. We can now summarize our consideration:—

(1) It is most essential to begin with a study of local conditions and of local diseases.

(2) It is necessary to consider economy, local needs and local abilities when devising methods of control.

(3) Prevention and cure must go hand in hand or both are relatively useless.

(4) Both prevention and cure must be accompanied by tireless explanation, encouragement and health teaching.

(5) Teaching must always be vigorous, idiomatic and direct. Teaching that is mechanical and perfunctory does actual harm by producing an immunity.

(6) It is relatively useless and uneconomic to concentrate on 'infant' welfare. All the family and household, and all the domestic and social and economic factors must be taken into consideration, must be cherished and educated. To attend to the infant to the exclusion of all other elements in the domestic scene is to fail to realize the surpassing importance of environment than the human infant.

(7) In introducing nutritional improvements it is essential to utilize what is available, what needs least preparation, least cash expenditure, least disorganization. To improve artificial feeding of infants would do a little good to a very small number of infants. To encourage breast feeding, to improve the technique of breast feeding would do a very great deal of good to a very large number of infants.

(8) Local customs are legion. In the past there has been a great tendency to 'let the Malays keep their customs'. To accept this policy without criticism is to destroy the race. It is necessary for educators of every description, particularly health workers, to encourage the people to examine their own customs, and keep those that are beneficial or harmless, and to destroy ruthlessly all those that are damaging to domestic and to child life.

(9) Hospital and welfare work should as far as possible be covered by the same staff and the same direction. They must be co-ordinated throughout so as to ensure continuity of treatment, of advice and of record keeping. The mother whose child has been successfully treated in hospital is more ready to follow advice from the welfare centre if she comes in

contact with the same staff. The mother who has grown to know and trust the welfare staff is more likely to seek hospital treatment for her child's illness if she knows that in hospital it will be cared for by the same individuals.

(10) The staff must be given variety of work or they invariably become stale and mechanical. Too much home visiting is exhausting and monotonous; too much sitting in clinics and handing out advice and treatment is exhausting and monotonous; too much working in hospitals is exhausting and monotonous; but let each individual concerned have work that is varied between hospitals, home visiting and welfare centres and at once there is variety of occupation, there is the interest of watching individuals through health and sickness, there is a more comprehensive attitude towards cause and effect. These are factors that have a strong influence in developing the characters of the staff, as well as their interest and efficiency.

(11) We cannot afford, nor could we obtain, a complete trained staff with which to set up the work. We have to discover local talent and make use of local abilities as we go. Bidans, midwives, nurses, and helpers of all sorts are wanted. By exploring and training and testing and teaching we will gradually manufacture our staff.

(12) Adequate supervision must at all times be maintained. Supervision means co-operation and discussion as well as inspection. For the welfare worker it is disheartening to see many cases without opportunity for discussing their progress and their special interest with the doctor. For the junior worker it is essential to spend a considerable part of the time working with those who are more experienced. For the doctor it is a great advantage to be able to obtain the co-operation of the health workers, an advantage which many of them have not yet learned to appreciate.

(13) The work itself is never static. It is always exploring and developing. It is a good thing for all workers to have too much to do, than instead of merely directing the work they are also directed by it. It sometimes develops surprisingly.

(14) Co-operation with the education, the agricultural, administrative and other departments is essential.

(b) *Establishment of clinics*

Before deciding on the set up of the centres themselves, it is necessary to keep in mind some detailed considerations as well as the foregoing general principles :—

(1) The mother who has the enterprise, who has taken the trouble to come to the clinic with her child is in a more receptive state of mind and more willing to follow advice than the one who is visited willy-nilly in the home. Therefore attendance at clinics must be encouraged.

(2) It is impossible for the women to spare time to go any long distance to a welfare centre.

The centres therefore must be sufficiently numerous to be readily accessible.

(3) Sickness and death among children is taken very much as a matter of course. Sickness in a child will not force the family through economic necessity to take the patient into hospital, as it may in an adult. Treatment for children therefore must also be readily accessible if the people are to avail themselves of it, particularly in the early stages of the work.

(4) In the clinics there is a spirit of friendly rivalry and mutual education which is lacking in home visits.

(5) One worker can supervise a very much larger number of cases if they attend clinics than if she has to visit individuals in the homes. (The orthodox system gives each health visitor a district with 250 births per year. There were 3,400 births registered in the Kuala Trengganu district in 1940.)

(6) It is unreasonable to expect people instinctively to know the value of preventive medicine, but if they see the results of effective treatment and their confidence is won, then they readily continue to attend and to follow advice. Therefore efficient treatment must be given in case of illness, not mere placebos—particularly in the early stages when people are still shy of hospitals and before they realize the necessity for keeping an apparently healthy child under supervision. In places where the people are educated sufficiently to attend hospitals when advised to do so, it may be necessary only to keep a few simple drugs. But in more primitive conditions it is essential to provide for effective treatment. There is no special virtue in treating an ophthalmia with boric lotion for six weeks. With sulphapyridine it would probably have recovered in three days.

(7) The clinic building and equipment must be as simple and as unassuming as possible. Elaborations are not merely a waste of money, they do actual harm in frightening away a timid population. A great deal can be done by merely demonstrating care and cleanliness in a building which is similar to the homes of the people themselves.

(8) Teaching to begin with must be on the very simplest lines. Such periods as posters, group teaching and any sort of elaborate display can only be employed gradually as the mothers learn to attend to this form of teaching. Much, on the other hand, can be done by habit formation. See that the mother actually wipes the child's nose with a cloth; see that she actually teaches him the 'technique of the toilet'; see that she actually gets him to take the rice congee with a spoon.

(9) To begin with the main objectives must be simplified to the bare minimum. Our advice may be summarized as follows :—

Antenatals.—Eat unpolished rice. Get treatment for yaws, worms, malaria and anæmia. Engage a reliable bidan.

Infants.—Give breast milk only. No other food for six months. Do not shave the head. The baby must not be adopted by anyone else for at least six months.

Children.—Vaccination. Get yaws and worms treated. Give unpolished rice. Teach clean habits. Avoid worms.

Everyone.—Fresh air, sunshine, unpolished rice. Use latrines. Grow more foodstuff. Use more soap.

(c) Home visiting

With a very small staff this is necessarily on a restricted scale. It is the side of the work which is most difficult for an untrained staff. It is not possible for an untrained worker to undertake much home visiting, or it brings discouragement and distaste. Still more serious, the visit is perfunctory, the advice is inept and actual hostility may be aroused.

New-born babies and special cases are the first considerations. The bidans (untrained midwives) are instructed to notify the health nurse when a baby is born, or if there is any case of abnormality in pregnancy. Visits are paid as soon as possible after the notification is received, a careful examination is made and advice is given.

Home visiting does not generally include any medicine or treatment. It is felt that if treatment is necessary it is better for the people to make the effort of going to ask for it. Medicine, like anything else what is too easily come by, is not treated with the respect that it deserves. Bottles that are too readily handed out are left untouched or else are casually broken. Some coloured water in a bottle with a gaudy wrapper bought from a pedlar is treated with more reverence than good medicine all because a price has been paid for it.

(d) Supervision of bidans (native midwives)

From our enquiries it was evident that the large infant mortality was due, not so much to the poor obstetrics as to malnutrition and disease in the mother, small and weakly babies and to ignorant child management.

We could do very little and at very great expense by providing government midwives who mostly receive their training in the management of labour under hospital conditions. So it was decided not to try and supersede the old village handy woman or 'bidan', but to try and teach her some very simple rules of conduct. Also we made no attempt to interfere with the 'adat Meleyu', on local customs except in as far as they were definitely harmful to mother or child.

Cases of difficult labour were always advised to come into hospital. The bidans are asked to use all their influence to have the cases brought in time. It is no more advisable to send a doctor into kampongs to conduct cases of difficult labour than to send a surgeon to conduct amputations and laparotomies in a native hut.

The full instructions to bidans may be found elsewhere. The main points are these :—

(1) To bring antenatal cases to be seen by the health nurse.

(2) To insist on the antenatals eating unpolished rice and to get treatment for worms and yaws and anæmia.

(3) To wash their hands with soap and a nail brush (made of coco-nut husk) and to keep their nails short.

(4) To keep a basket with bottles, basins, towels, etc., total outlay about two dollars. To bring it regularly to be inspected by the health nurse who will keep it supplied with cord ligatures, eye lotion, swabs, etc.

(5) To use scissors for cutting the cord and an antiseptic dressing, instead of bamboo or a bit of old glass followed by sireh and spit.

(6) To realize the importance of breast feeding.

(7) To report all births and all abnormalities and anxieties to the health nurse.

(8) To bring all complications of labour to be treated in the hospital. The delay that is caused by sending to fetch the nurse or doctor is always much greater than would be the case if the woman is taken straight into the hospital.

(e) Hygiene in schools

One of the most depressing things about our civilization in the past is that education for a thousand years has been dominated by the monastic and the celibate minded. This has resulted in more attention being paid to academic subjects than to those that are of practical value in life. The consequence is that one sees that children of the educated classes may be even more unhealthy than those of the uneducated. Too often one finds the teacher's children just as unhealthy as any in the village, artificially fed, overclothed, eating sophisticated food, infected with worms, and, in addition, fed on a variety of patent medicines. This is true of many countries in the world. Now in Britain there is loud demand for more training in mothercraft for girls, more insistence that the child should be taught in school how to regulate his life and his adjustments to his own personal problems, his family, industry, community and state.

The efficiency of the teaching and practice of hygiene in schools varies considerably. On the whole, and with some very marked exceptions, it would seem that hygiene is indifferently taught and the methods used are not sufficiently practical.

There are four methods of learning :—

(a) by receiving information,

(b) by experiment,

(c) by observation, and

(d) by formation of habit.

All these should be made use of in teaching hygiene. As at present only the first is used in many schools and there seem to be few teachers who impart knowledge of hygiene with

that pure passion that they can pour into geography and literature.

The teaching is based on the four methods mentioned. Lessons are given on essential subjects—unpolished rice and how to cook it, worms and how to avoid them and so forth. They actually do the cooking and eat the rice. They actually look at the worms and they actually form the habit of washing their hands before food. There is a row of bamboo pitchers in the manner of the Health School in Java, and they are in daily use. They learn to make their own tooth and hand brushes from coco-nut husks and stems. There are also lessons and demonstrations in the care and feeding of babies.

School medical inspections take place yearly and efforts are made to get medical treatment for those who need it. It is hoped in future to link up these inspections with more health work, both curative and preventive. It is hoped also that the dental work among school children may be extended.

Ultimately school health work should link up with lectures on economics and the best way of spending money, and with agricultural work and with all the factors that go for rural and for urban improvement. There is no reason why fathercraft and citizenship should be counted of less importance than mothercraft.

Probably some of the most valuable lessons will be learned in the schools where welfare centres are actually being held once a week. In these and in the lectures given by the health staff the teaching is made as simple and as practical as possible.

(f) *Education of the medical staff and others*

An important part of the programme was to permeate the medical department with more ideas of preventive medicine.

The doctors as a whole in this country have shown little interest in pædiatrics, either curative or preventive. In the final examination at the College of Medicine, Singapore, there may or may not be one question set on some pædiatric subject. There is never more than one, and there is no practical examination. It also appears that people in this country have not developed any abounding faith in the ability of Western practitioners to look after their children. When one remembers that infancy and childhood are periods of great mortality and morbidity, it is curious to consider how little attention has been paid to these age periods.

Lectures were given to dressers and nurses on the subjects that seemed to be most essential to the health of Trengganu and most neglected by orthodox medicine. As these subjects are often inadequately described in the usual textbooks, the notes were cyclostyled and circulated. Lectures on welfare work and on the care of children were given by the health nurse. Throughout the teaching and demonstrations and in the actual management of the hospital and medical department, every effort has been made

to emphasize the importance of good food, cleanliness and fresh air and on all the factors that are important in the prevention of disease.

The nurses and some of the dressers took it in turn to work with the health nurse in the welfare centres and at the visiting. In this way the staff became interested in the objects and in the methods of welfare work, and the welfare centres became associated with the hospital. The result of this is that people coming into hospital are often given some instruction in the prevention of disease.

Improved methods in the care of children has been popularized not only in the hospital and clinics but also in the homes of the staff, with the most gratifying results.

The people of Trengganu have a misguided idea of the use of medicines.

Efforts have been made to get the population to realize the importance of healthy habits and food rather than to put their trust in bottles of medicine, but little progress has yet been made in this respect.

It was hoped that first-aid classes might lead to increased interest in health, and after a couple of false starts they were finally given to members of the police force and to senior boys at the English school.

Among those most in need of health education are the educated. The current 'popular biology' and 'popular medicine' result in numbers of Europeans and others believing that there is danger in child welfare as it may interfere with the jungle law of the survival of the fittest. These archaic conceptions have to be remedied, while the 'educated' among the local people have to be reclaimed from the heresies of artificial feeding, overclothing and sophisticated food which generally seem to go with literacy.

(g) *Costing*

The total amount spent on the health survey was \$4,500 in 1940 and \$10,000 up to June 15, 1941.

The welfare work has been under the supervision of Dr. Scharff, the medical officer, and the health staff, but the only specific outlay on welfare work has been as follows:—

Senior health nurse \$260 per month salary and allowances.

Two bidans in training at \$12.50 each per month salary.

Minor expenses at \$20 per month.

Otherwise the work has been done by the already existing medical staff, sanitary inspectors, dressers, etc. Treatment costs at the centres were met from the medical vote, but there was no increase in the quantities of drugs used, but merely a redistribution.

The total amount that has been spent on buildings up to the present is \$156.

It has been our object to spend every available cent on personnel and as little as possible on buildings and non-essentials.

(h) Results

It is now ten months since the survey was first started.

It is impossible to give any accurate or statistical appraisal of the results at the present stage.

We are trying to introduce a system of education, not to perform a conjuring trick, so that instantaneous results are not to be expected.

Numbers of attendances are in themselves some indication of the popularity of the centres. The numbers of vaccinations and injections for yaws are a contribution towards the health of the state. It must be remembered that about 70 per cent of these attendances are Malays, and that Trengganu is supposed to possess the most backward and timid Malay population in the peninsula. And our only bribes are medical treatment and good advice. The attendance at the welfare centres in August 1941 totalled over 4,000.

The teaching in the schools has made a start. The health nurses' lessons in hygiene and mothercraft at the girls' school seem to be appreciated and both the dressers and the pupils seem to be interested in the teaching in the boys' schools. The syllabus is made as practical as possible—details of it may be found elsewhere. Travelling dressers are encouraged to centre more and more of their work on the schools.

There has been some increase in the number of Malay women and children coming to hospital, both for treatment and for admission.

The supervision of bidans is a slow method of improving the midwifery, but it is the best that we can manage under the circumstances. Even if a large staff of highly trained midwives were suddenly imported, they would not as yet be patronized by the people.

As far as the education of the medical staff and others is concerned, I think there are definite signs that interest has been aroused, and there is no reason why this should not increase very considerably. At any rate there has on all sides been the most kind co-operation, and often enthusiasm.

It has not been possible yet to do much in the way of 'pushing the work into the kampongs' because we want to make quite certain of what we are pushing. We want all the workers to learn the lessons of prevention not only in theory, but to know them in practice. We want them to know the results so well that they will speak and act with conviction. When the foundations are sure, then the whole structure will rise easily and certainly.

The most important result is that it has been definitely proved that Malays will attend welfare centres, they will listen to advice, they will follow rational methods of bringing up their children, they will come for medical treatment and injections if and when they are convinced that the exponents of these things know their jobs, and secondly, if and when they themselves

are sufficiently healthy to react normally to a normal stimulus.

September 1941

Postscript—January 1942

Since this was written, many things have happened which affect the work and Trengganu.

My term of service in the state ended in October. But the work had reached a stage when it was on the point of 'spreading out into the kampongs', and the health nurse was due for her holiday. It seemed better not to leave at that juncture, when another three months might put the whole scheme on a better footing, might do much to establish the methods of working the centres, and the methods of expanding into new areas. For example there was Besut.

Then came December 8, 1941.

Besut was the first part of Trengganu to be bombed by the Japanese; on December 10 we were ordered to evacuate. The medical officer, Dr. A. L. Shield, refused to leave, but two days later he was also forced to go.

To have to abandon the work, the workers and the patients, particularly when everything was developing so superbly, was a sort of nightmare. Everyone of us leaving Trengganu had the same feeling of overwhelming deprivation. We shall live in the hope of returning.

Political cataclysms will pass away, but the world will still seek better ways of guarding its children. This monograph is offered in the hope that the pattern on which the work was built will again be of service to the children of Trengganu, and perhaps to others.

Current Topics

Some Factors Affecting the Incidence of Post-Anæsthetic Vomiting

By R. M. DAVIES, M.R.C.S., D.A.

(Abstracted from the *British Medical Journal*, Vol. II, 25th October, 1941, p. 578)

THE author has presented in this article some facts about post-anæsthetic vomiting which are well recognized and others which have not in the past received due attention.

The findings are based on a consecutive and unselected series of 1,000 cases, which had been submitted to anæsthetics and surgical procedures of every type, and they are compared with findings obtained in four series of one hundred cases, which had been submitted to the following anæsthetic sequences:—

Nitrous oxide, oxygen and ether.

Pentothal sodium, nitrous oxide, oxygen and ether.

Pentothal sodium, cyclopropane, nitrous oxide, oxygen and ether.

Pentothal sodium, nitrous oxide and oxygen.

Consideration of the findings obtained revealed the following facts:—

(1) The sequence nitrous oxide, oxygen and ether provided the highest incidence of post-anæsthetic vomiting.

(2) This figure was reduced by one-third by the preliminary addition of pentothal sodium.

(3) The addition of cyclopropane to the anaesthetic sequence did not raise the incidence of post-anaesthetic vomiting.

Consideration of sex incidence showed post-anaesthetic vomiting to be more frequent in females than in males, and that preliminary pentothal reduced the incidence by a greater proportion of females than was the case with males.

A study of the relation between operative procedure and anaesthetic revealed the following:—

(1) Oro-nasal operations had no effect on the vomiting rate, although it has often been said that patients always vomit after tonsillectomy.

(2) The procedure of dilatation of the cervix in gynaecological operations caused a rise in the post-anaesthetic vomiting rate, while the type of anaesthesia employed had to have little or no effect upon its incidence in these cases.

A note on the prophylaxis and treatment of the condition is added.

The Eradication of Refractory Gonococcal Infections by Combined Artificial Fever-Chemotherapy

By W. M. SIMPSON
D. L. ROSE

and

H. W. KENDELL

(Abstracted from the *British Journal of Venereal Diseases*, Vol. XVII, July-October 1941, p. 185)

THE authors of this paper report that by administration of sulphonamides for a number of hours immediately prior to a single session of artificial pyrexia, they were uniformly successful in eradicating gonococcal infection in a series of cases which had proved resistant to or intolerant of sulphonamide treatment, and that the whole period of hospitalization was reduced to 48 hours. They say 'The implications are apparent in the application of this therapeutic programme for the more prompt and certain eradication of gonococcal infection to persons engaged in vital military, naval and industrial pursuits'.

The value of artificial fever in the treatment of gonorrhoea was established before sulphonamide treatment was introduced. It was used mainly for complications. Improvements in the apparatus for inducing pyrexia and for care of the patient during it have made it possible to increase the length of each sitting and so to reduce the number of sittings; at the same time the treatment has become safer, and therefore applicable to a wider range of cases. The present report relates to 105 patients who had proved either intolerant of or resistant to sulphonamide treatment, and were each treated with a single session of fever with or without supplementary chemotherapy. The variations in the application of this principle of treatment with the number of cases and cures were as follows:—

- (a) Eight hours at 106.6°F. (about 41°C.), 9 cases and 1 cure.
- (b) Ten hours at 106.6°F. (about 41°C.), 11 cases and 7 cures.
- (c) As (b) but with sulphanilamide orally for 18 hours immediately before the fever, 20 cases and 20 cures.
- (d) As (b) but with sulphanilamide administered intravenously once immediately before the fever, 16 cases and 13 cures.
- (e) As (b) but with Promin (the sodium salt of pp'-diamino-diphenylsulphone - NN'-didestrose-sulphonate, a very soluble sulphonamide compound given intramuscularly during the fever, 11 cases and 7 cures.
- (f) As (b) but with Promin given intramuscularly for 18 hours before the fever, 11 cases and 11 cures.

(g) As (f) but temperature 106°F. (about 41°C.), 7 cases and 7 cures.

(h) Eight hours at 106°F. (about 41°C.), with either Promin (4 cases) or sulphathiazole (11 cases) orally for 18 hours before the fever, 15 cases and 15 cures.

Thus, whereas fever alone and fever with sulphonamide therapy in one dose immediately prior to the fever or administered during the fever was not always successful, fever with sulphonamides for a number of hours immediately prior to the fever eradicated the infection in every case. This method of administration enabled the pyrexia to be reduced in degree and duration which had the advantage of reducing the post-pyrexial malaise and enabling the patient to be discharged from hospital within 48 hours of admission. The dosage of Promin given orally for 18 hours was 0.5 g. six times; that of sulphathiazole was 2 g. at once followed by five doses of 1 g. The methods of diagnosis and the tests of cure were irreproachable.

The Use of Riboflavin in the Treatment of Corneal Diseases

By K. W. COSGROVE, M.D.
and

PAUL L. DAY, Ph.D.

(Abstracted from the *American Journal of Ophthalmology*, Vol. XXV, May 1942, p. 544)

THE first careful study of the ocular manifestations of a condition that is now recognized as uncomplicated riboflavin deficiency in the rat was reported in 1931 by Day and others. They reported the following incidence of ocular manifestations in the rats observed: alopecia of the eyelids, 68 per cent; lacrimation, 60 per cent; conjunctivitis, 96 per cent; discharge, 92 per cent; thick, swollen, inflamed lids, 92 per cent; cataract, 94 per cent; and anterior interstitial keratitis, 100 per cent.

In 1937 they demonstrated that pure riboflavin, natural or synthetic, would prevent the keratitis, cataract, and other ocular manifestations of 'vitamin-G' deficiency. The following year the same laboratory reported that the parenteral administration of pure riboflavin to rats with ocular manifestations of riboflavin deficiency resulted in the rapid disappearance of the keratitis, and in many cases the arrest of the cataractous changes. Not all investigators have observed such a high incidence of cataract in riboflavin deficiency. Keratitis and vascularization of the cornea were more consistent ocular changes than cataract and were improved by addition of riboflavin to the diet.

Recent reports on human riboflavin deficiency indicate that the ocular manifestations are almost the exact counterpart of the picture that is seen in the eye of the rat with regard to the pathologic alterations in the cornea and related structures. Up to the present time no conclusive evidence has been presented that would show whether any cases of human cataract are the result of riboflavin deficiency.

In 1939 Pock-Steen reported the ocular symptoms of patients suffering from sprue and related disorders. He found that the administration of riboflavin resulted in improvement of the visual acuity in such patients who had a condition which he termed 'twilight blindness'.

Sydenstricker and associates stated in 1940: 'Photophobia, dimness of vision, and actual impairment of visual acuity were promptly, even dramatically, relieved by the administration of riboflavin in some cases before visual changes occurred in the cornea. Congestion of the sclera, vascularization and opacities of the cornea, and abnormal pigmentation of the iris responded rapidly to the administration of riboflavin'. Further effectiveness of riboflavin in the treatment of nutritional keratitis has been presented by Spies and associates and by Sydenstricker. The latter report stated: 'At the present time it seems that superficial vascular keratitis is the earliest and most common

visible manifestation of riboflavin deficiency as well as a rather reliable index of early deficiency of the B group of vitamins.

EXPERIMENTAL

Twenty-eight patients with corneal disease have been treated with riboflavin. The results were varied, dependent upon the aetiology. Cases of interstitial keratitis associated with hereditary syphilis responded much more rapidly when riboflavin was administered than when antiluetic treatment alone was given. Two cases of phlyctenular keratoconjunctivitis improved rapidly under this therapy. One patient had previously been treated for two months without improvement. Cases of corneal disease in which no definite

aetiological factor could be determined were presumed to be possible cases of ariboflavinosis. Some of these responded miraculously upon the addition of riboflavin to the diet. Recurrences were noted in one case when the vitamin was omitted from the diet. Allergic cases did not respond; the conjunctival irritation and the steaming of the cornea were not greatly affected by the administration of riboflavin. In one case of linear keratitis of obscure aetiology there was no improvement; in another, in which the keratitis was associated with mature cataracts, the keratitis was improved but no change was observed in the cataract or visual acuity. Riboflavin cannot be considered a specific for all types of keratitis, but it seems to facilitate the healing of some corneal lesions.

Reviews

1. **CLINICAL ATLAS OF BLOOD DISEASES.**—By A. Piney, M.D., M.R.C.P., and Stanley Wyard, M.D., F.R.C.P. Fifth Edition. 1942. J. and A. Churchill Limited, London. Pp. viii plus 134 with 46 illustrations, 43 in colour. Price, 16s.
2. **SYNOPSIS OF BLOOD DISEASES.**—By A. Piney, M.D., M.R.C.P. 1942. William Heinemann Medical Books, Limited, London. Pp. ix plus 120. Illustrated. Price, 10s. 6d.

DR. PINEY is one of the best known writers on anaemia in Great Britain. He has contributed some books that are very popular amongst students and practitioners. It is true that his books are not always well received by the more advanced haematologists but perhaps it is for this reason that they appeal to the practitioner and student. Whether or not they advance the cause of haematology we are not prepared to say.

His *Clinical Atlas of Blood Diseases* which he has written in conjunction with Dr. Wyard is certainly one of the most popular of his publications, and deservedly so. It contains a very large number of plates which are well reproduced and will certainly help the student to recognize the different forms of red cells he will encounter in the blood in various blood diseases and in the sternal puncture material. Another feature of this book is the very useful glossary which we feel should always be included in any book on a specialized subject, but seldom is. The fifth edition of this book will certainly enhance the reputation of the writers. It has been brought up to date in a number of ways; the addition of the method of calculating haematological constants, and of the percentages of the different cells in normal sternal puncture go some way to refute the criticism reviewers in the past have made about Dr. Piney's books.

Altogether it is a book that we can strongly recommend to the student and practitioner. The price is 16s., high for a small book, but in these days paper is scarce and plates probably very expensive to produce.

In his other book, *Synopsis of Blood Diseases*, we feel that Dr. Piney has overstepped the mark. This book does not seem to us to fill any want. In peace time, the publication of a book is a matter between the publishers and the author, but in war time it is a matter between the publishers, the author, and Lord Woolton, or whoever it is that rations paper. In this particular case, I am very surprised that he allowed the paper to be used for the purposes of this superfluous book. The book contains some accurate information, a certain amount of inaccurate information, and a very great deal of very inadequate information on a number of subjects. Let us take one example:—

On page 104, under 'Leishmania' (sic) the following statements occur:—

'Progressive hypochromic anaemia falling as low as a million corpuscles per c.mm.'

Comment. This is quite untrue; the anaemia is usually orthochromic, or sometimes slightly hyperchromic, but seldom hypochromic, unless there is some complicating factor. Further, it is not progressive and seldom drops to the level of one million red cells. On the contrary, the anaemia tends to stop at about three million red cells, even in the more advanced cases.

'The most striking character of the blood picture is leucopenia which may be as low as 500 per c.mm. (Death may occur with all the signs of agranulocytosis.)'

Comment. This is perfectly true.

'There is great reduction of neutrophils (but those present are often moderately immature), considerable relative lymphocytosis and well marked increase of monocytes.'

Comment. This is also true.

Rarely the organisms can be found inside monocytes in the blood.

Comment. This is a most inadequate statement. The meaning is not clear. Does he mean, 'they are sometimes found inside monocytes but usually outside', or does he mean 'they are rarely found in the blood and, if they are, they are found in monocytes'? In neither case is the statement true. The frequency with which they are found depends on the persistence of the searcher. They will be found in 60 per cent of cases of kala-azar if a thorough search is made; not at all if the search is a casual one. They are usually in monocytes, but may be in polymorphonuclears.

The parasites are usually easily found in films made from material obtained by liver puncture, less commonly from the marrow and still less often from the spleen (spleen puncture in this disease is not free from danger).

Comment. This is the exact reverse of the truth, that is to say, parasites are usually found in the spleen, with more difficulty in the marrow, and with still more difficulty by liver puncture. Reference to any experienced writer on kala-azar diagnosis will confirm this statement. Spleen puncture undoubtedly is dangerous, but so is crossing the road, if you don't do it in the proper way. The reviewer's score in spleen punctures is approaching five figures, without mishap.

Treatment. See textbooks of tropical diseases. Here it is enough to indicate that antimony is essential, either tartar emetic or one of the less toxic modern preparations, e.g. neostibosan.

Comment. It is difficult to see why this paragraph was put in at all if reference is to be made to other textbooks. It is not true that antimony is essential, and tartar emetic is practically never used these days.

L. E. N.

DEMONSTRATIONS OF PHYSICAL SIGNS IN CLINICAL SURGERY.—By Hamilton Bailey, F.R.C.S. (Eng.). Eighth Edition. 1942. John Wright and Sons Limited, Bristol. Pp. xii plus 336, with 455 illustrations, a number of which are in colour. Price, 25s.

THE production of the eighth edition of this book, after fourteen years and in the middle of a war, speaks well for its popularity. This edition has been made under considerable difficulties as explained in the preface but, in spite of these, it can be confidently stated that it is as good as ever—in particular the reproductions in colour deserve special mention and one looks forward to the day when all photographs, in this and other medical books, will be in colour.

Throughout the book the various physical signs are lucidly described—in the text and by pictures, of which there is an abundant supply. For the most part simple tests are described, which can be applied by anyone having the minimum of diagnostic armamentarium.

Certain chapters, such as the ones describing the examination of the abdomen and those on the genito-urinary system, deserve special note, being both very clear and concise. The chapter on the breast is also particularly well done and emphasizes the importance of comparison of the normal and the abnormal side—a method of examination which the author strongly advocates.

By way of comparison, the chapters on the examination of the central nervous system (i.e., the head, spine and peripheral nerves) are not up to the high standard maintained elsewhere in the book and might to advantage be more detailed. Such tests as the anvil test for the spine and the numerous signs connected with exophthalmos might well be omitted, as the author almost suggests.

In conclusion, this book can be strongly recommended to all medical students starting as surgical dressers and to those working for final examinations. A periodical perusal by practitioners would probably enhance the value of their clinical examination and remind them that in diagnosis it is the examination of the patient which comes before other tests such as the laboratory and x-rays.

G. C. T.

PATHOLOGY AND TREATMENT OF WAR WOUNDS.—By Sir Almroth E. Wright, M.D., F.R.S. 1942. William Heinemann Medical Books Limited, London. Pp. viii plus 208. Illustrated. Price, 21s.

CONTAINED in the 205 pages of this book is much of the work which has formed the basis of the treatment of wounds during this war and, for this reason if for no other, it should be read by all those who are scientifically interested in to-day's war surgery.

The chapters on wound infections stress the importance of the simple saline dressing—denouncing the use of antiseptics and encouraging the adoption of aseptic principles by thorough wound débridement and dependent drainage.

The chapters on gas gangrene are of particular interest. Although antitoxin treatment combined with chemotherapy by sulphapyridine (or sulphanilamide) appear to be distinct modern advances, the treatment recommended by the author was a definite advance on any in vogue at that time and even now the alkalization of the patient might be adopted more often to combat the toxæmia of gas gangrene.

Throughout the book it is delightful to study the simple experimental ways that the author and his co-workers adopted to study their problems as also is the formulating of the simple questions he asked himself and then proceeded to answer—indeed it is an inspiration for present-day research workers.

G. C. T.

THE FOOT AND ANKLE: THEIR INJURIES, DISEASES, DEFORMITIES, AND DISABILITIES: WITH SPECIAL APPLICATION TO MILITARY PRACTICE.—By Philip Lewin, M.D., F.A.C.S. Second Edition. 1941. Henry Kimpton, London. Pp. 665, with 304 illustrations. Price, 42s.

IN the second edition of this book the author deals in a comprehensive way with the various conditions, both pathological and non-pathological, of the foot and ankle. Besides this, other matter, e.g. gynaecological conditions and lesions definitely confined to the leg, is included and so, with a section on the military aspect and a certain amount of repetition, the book is increased to 620 pages.

One feels that for a work of this standard a mere 15 pages for the description of the embryology and anatomy of the foot and ankle is insufficient and that perhaps it would have been better to have omitted this section—and on the same score some parts of chapter 3.

In the prefaces it is stated that the book is meant for the student, general practitioner, industrial surgeon, younger orthopaedic surgeon and the army medical officer. With guidance for such doctors in view it would seem unnecessary to give detailed description of alternate techniques of operations, e.g. in the treatment of hallux valgus. Surely it would be better adapted to the purpose of the book if the operation which in the opinion of the author is the most suitable were described and at most one other?

More detail might have been given to local anaesthesia and fractures—both being important subjects in these times.

The orthopaedic and operative sides, as also the dermatological, are very well done and repay study. The various steps in the operations are lucidly described and good illustrations are provided throughout. The chapter on anterior poliomyelitis is one of the best in the book—the treatment of the various stages being given in detail.

A full bibliography is given which together with the book itself forms a sound basis for the study of the conditions of the foot and ankle.

G. C. T.

MEDICAL RESEARCH COUNCIL. SPECIAL REPORT SERIES NO. 243. CHRONIC PULMONARY DISEASE IN SOUTH WALES COAL-MINERS. I—MEDICAL STUDIES. A—REPORT BY THE COMMITTEE ON INDUSTRIAL PULMONARY DISEASE. B—MEDICAL SURVEY.—By P. D'Arcy Hart and E. A. Aslett, with contributions by D. Hicks and R. Yates. C—PATHOLOGICAL REPORT.—By T. H. Belt with assistance from A. A. Ferris. 1942. Published by His Majesty's Stationery Office, London. Pp. xiv plus 222. Illustrated. Price, 10s. 6d.

SINCE 1929, when compensation for silicosis first became payable to men in the coal mining industry, the number of disablement cases has increased rapidly, and there has been greater mortality from respiratory disease among coal miners in South Wales than elsewhere in Great Britain.

In 1936 the Medical Research Council were asked by the Home Office and the Mines department to investigate the problem. A committee was formed, and investigations began in 1937. It involved mainly clinical and radiological examination of about 2,000 miners and 500 coal trimmers.

A convenient classification of pulmonary changes caused by dust in coal mines has been devised. There are two main divisions: (a) consolidation and (b) reticulation. The former includes discrete nodulation and various forms of conglomerate shadow, and corresponds to the changes which generally go under the name of silicosis in coal miners.

The latter is an important form of roentgenographic abnormality that has been detected among the South Wales coal miners. This may be associated with respiratory disability, but usually does not conform to the criteria indicating silicosis for compensation

purposes. As a result of histological study it has been termed 'dust-reticulation'. It is characterized by retention of silica as well as carbon, and increase of reticular tissue in the lung, silica being present mostly in the form of silicates and the reaction being proportional to the amount of dust. Thus this condition differs from classical silicosis.

The data collected suggest that none of the methods and processes used in mining coal is the main causative factor, although reduction of exposure of the collier to dust produced in rippling, relegation of short-firing at particular times, and chilling of spakes would be desirable.

HANDBOOK OF APPLIED PHYSIOLOGY OF THE NERVOUS SYSTEM, THE SPECIAL SENSES, MUSCLE AND NERVE.—By Harendra Nath Das, Ral Bahadur, M.A., M.D. Das Gupta and Co., Calcutta. 1942. Pp. 443. Price, Rs. 6

In this work, written by an Indian for Indian students, Dr. Das has set himself a monumental task. How well he has carried it out, the reader must judge for himself.

The whole ground is well covered and the arrangement of the subject-matter is excellent. There is hardly a detail which is not adequately dealt with.

The book is interspersed with clinical notes and references to Applied Physiology which should help to supply the connecting link between Physiology and Medicine.

There are numerous excellent illustrations accurately reproduced which should prove of great help to the student.

The author is to be congratulated not only on the energy displayed in collecting and arranging such a mass of information in a form particularly acceptable to the Indian student. The use or misuse of the definite article, which is so characteristic of the writings of Indian scholars, may be neglected as it does not detract from the scientific value of the work.

J. A. S.

MEDICAL RESEARCH COUNCIL. SPECIAL REPORT SERIES NO. 245. REPORT OF THE COMMITTEE ON BED-BUG INFESTATION, 1935 TO 1940.—Published in July 1942 by His Majesty's Stationery Office, London. Pp. 64. Illustrated. Price, 1s.

No disease has yet been laid at the door of the bed-bug, yet it is undoubtedly an objectionable parasite. At the least, it is liable to disturb sleep.

The report of this committee gives valuable information regarding the bionomics and control of the parasite.

ANTENATAL AND POSTNATAL CARE.—By Francis J. Browne, M.D. (Aberd.), D.Sc., F.R.C.S. (Edin.), F.R.C.O.G. Fourth Edition. 1942. J. and A. Churchill, Limited, London. Pp. viii plus 592, with 84 illustrations. Price, 24s.

THE 4th edition of Mr. Browne's book offers in little bulk one of the best textbooks on prenatal and postnatal care offered in the past five years not only because the material is sound, well presented and succinct, but also because the book has been planned in the modern manner. All essentials have been shed, each chapter carries its own bibliography, important advances in pathological research and in harmonology have been included.

Much new material has been added in this edition but so carefully has the selection been made, especially in regard to the influence of hormones upon female physiology, upon pregnancy and upon abnormalities, that one may say that although five years hence it may be possible to add much to this chapter it is unlikely that anything will be contradicted or withdrawn.

The chapter on the history and development of antenatal care and that on the 'Uses and Value of Radiology in Obstetrics', by Salmond, are valuable additions to the text. The diets of the pregnant and the nursing woman have received due attention.

In appendix 'A' are given type-forms for record of prenatal and obstetric cases.

In short, this is a book which every medical student and obstetrician will find useful.

L. G.

ANNUAL REVIEW OF BIOCHEMICAL AND ALLIED RESEARCH IN INDIA, VOL. XII FOR 1941.—By the Society of Biological Chemists, Malleswaram P. O., Bangalore. Pp. 84. Price, 6s. or Rs. 3

THIS review is divided into the following sections: (1) enzymes, (2) general nutrition, (3) vitamins, (4) protein, carbohydrate, fat and mineral metabolism, (5) pharmacology, (6) animal nutrition, (7) chemistry of plant products, (8) plant physiology, (9) soils and fertilizers, and (10) technical mycology. Each section has been compiled by one or two authors who have experience of the subject and a study of the book gives a fair idea of the type of research carried on in the different laboratories in India. The book is pleasant to read and should be welcomed not only by biochemists and chemists but also by others who are interested in the growth of science in India.

Abstracts from Reports

ANNUAL REPORT OF THE UNION MISSION TUBERCULOSIS SANATORIUM, AROGYA-VARAM, NEAR MADANAPALLE, SOUTH INDIA, FOR 1940-41

DURING the year 471 patients were admitted and 465 patients discharged, leaving on 30th September, 1941, 259 patients. The total number of patients treated during the year has been 724. The daily average number of patients treated has been 255.76 for the whole year.

The number of beds available during the year varied from 249 to 253, but at times extra beds have been fitted in temporarily.

Of the 465 patients discharged, 335 were men and 130 women. Hindus numbered 229 or 49.3 per cent, Christians 182 or 39.1 per cent and Muslims 38 or 8.2 per cent; in addition, there were 11 Buddhists, 4 Chinese and 1 Jew.

Of the 465 patients, 400 were found to be suffering from pulmonary tuberculosis. Of the remainder, 8 were found to be suffering from other tuberculous conditions, namely 3 from glandular tuberculosis, 3 from intestinal tuberculosis, 1 from tuberculosis of the hip, and 1 from tuberculosis of the spine; 18 patients were found to be suffering from non-tuberculous lung diseases, namely, 4 from bronchiectasis, 6 from lung abscess, 3 from actinomycosis of the lung, 5 from lung disease associated with eosinophilia; 23 patients were found to have no active tuberculosis; 13 patients were proved to be non-tuberculous and not suffering from any serious disease; 1 patient was found to be suffering from chronic malaria and 2 from heart disease.

Of the 400 patients suffering from pulmonary tuberculosis, 337 are included in the medical statistics.

Twenty-five, or 7.4 per cent, were in first stage or early cases, 42 or 12.5 per cent in second stage or medium severe cases, and 270 or 80.1 per cent in third stage or advanced cases.

Of the 337 patients, 253 or 75.1 per cent were discharged with positive results, viz. 28 as 'arrested', 168 as 'much improved' and 57 as 'improved'. Among the patients discharged with negative results, 40 were discharged as stationary, 16 as worse and 28 died.

The training of doctors for the Tuberculous Diseases Diploma of the Government of Madras has continued during the whole year.

The senior class of the Vellore medical students came as usual for a course of two weeks in the diagnosis and treatment of tuberculosis.

Owing to the large increase of operative work, an extension of the post-operation rooms in the operation block became an urgent necessity. A wing of six new rooms has been added. Four additional special wards have been built.

In August the sanatorium had the honour of a second visit of Her Excellency the Marchioness of Linlithgow. Her Excellency opened the Lazarus Memorial Building in the ex-patients' colony.

ANNUAL REPORT OF THE COMMITTEE OF THE INDIAN CHEMICAL MANUFACTURERS' ASSOCIATION, CALCUTTA, FOR THE YEAR 1940-41

The third annual session of the Indian Chemical Manufacturers' Association was held at Bombay on the 19th and 20th September, 1941. Delegates from different parts of the country participated in the session.

Raj Mitra B. D. Amin in his presidential address emphasized that industries in this country faced immense difficulties after the outbreak of war, due to dislocation in supplies of essential and basic materials, but things got themselves adjusted to a certain extent later on. Sodium dichromate, potassium dichromate, liquid chlorine, zinc chloride, soda ash, tannic acid, carbolic acid, oxalic acid, acetic acid, etc., for which the country was completely dependent on foreign supplies, are being produced to a considerable extent in this country. Projects for the production of caustic soda, bleaching powder, sodium bicarbonate and for further production of soda ash, zinc chloride, several sulphates, acetic acid, etc., are under way. Besides, India is now almost self-sufficient in respect of sulphuric, hydrochloric and nitric acids, naphthalene, copper sulphate, alum, aluminium sulphate, magnesium sulphate, glycerine, etc.

In the manufacture of drugs, pharmaceuticals and proprietary medicines also, the progress has been to a certain extent satisfactory.

Most of the provincial and State governments have expressed readiness to make available to the manufacturers the facility of clinical trial in hospitals under their control. It is now for the manufacturers to take advantage of the facility and make Indian products more popular. The time has come when the industrialist and the scientist should realize the utmost importance of closer co-operation.

Interview with Lieut.-General Sir Gordon Jolly.—The committee arranged a meeting of the local members of the Association with Lieut.-General Sir Gordon Jolly, Director-General, Indian Medical Service. Mr. J. N. Lahiri was in the chair. Besides members of the Association, the meeting was attended by Major-General J. Taylor, Director, Central Research Institute, Kasauli, Colonel W. C. Paton, Surgeon-General to the Government of Bengal, Brevet-Colonel Sir R. N. Chopra, Dr. J. N. Ray and Major S. P. Bhatia. The following subjects were discussed at the meeting:—

(1) Purchase of medical supplies from England over a long forward period, (2) manufacturing and importing activities of the Government Medical Stores Depots, (3) purchase of vaccines and sera by the Government from Indian manufacturers, (4) difficulties experienced in exports of drugs and medicines out of India and (5) necessity of giving permission to private manufacturers to undertake the manufacture of opium alkaloids. General Jolly explained the position and the Government's policy in purchasing drugs and medicines and stated that he would try to maintain closer touch with the manufacturers.

ANNUAL REPORT OF THE CHEMICAL EXAMINER'S DEPARTMENT, GOVERNMENT OF MADRAS, FOR THE YEAR 1941

The number of articles examined fell from 9,474 in the previous year, to 8,630 in the year under review.

Cases of human poisoning examined increased from 427 to 432; but the percentage of cases in which poison was detected fell from 55 to 53.2. The vast majority of the poisons detected were organic poisons. The commonest poisons detected were opium or its alkaloids in 43 cases, oleander in 26 cases, copper or its salts in 20 cases, alcohol in 20 cases, datura or mydriatic alkaloid in 15 cases, and cyanide in 12 cases. A few cases of interest are reported.

Animal poisoning cases examined numbered 33, as against 23 in the previous year. Poison was detected in 13 cases. The number of stain cases examined decreased from 1,081 to 1,004. Miscellaneous medico-legal cases involving the examination of fire-arms, bombs, explosives, bones, etc., decreased from 142 to 115.

ANNUAL REPORT OF THE BRITISH EMPIRE LEPROSY RELIEF ASSOCIATION, MADRAS PROVINCIAL COUNCIL, FOR 1941-42

In spite of the difficulties due to war the work of the Association has proceeded with comparatively little interruption. One of the important activities was investigation of childhood leprosy. The total number of cases on the register is now 617. It is being realized that possibly 50 per cent of the cases becomes abortive and is innocuous, and much information has been gathered to estimate whether a leprosy lesion in a child is serious or not. Survey work was carried out by the rural and urban centres. The total urban population so far examined is 16,304 with a gross incidence of 26.4 per thousand, a child rate of 26.6 per cent and open case rate of 14.0 per cent. This indicates a less serious condition than in the rural areas so far investigated, but greater difficulty is experienced in segregating the open cases. Research work on various aspects of leprosy have continued. The 470 leprosy clinics in the presidency have functioned throughout the year with varying success.

Correspondence

TREATMENT OF MALARIA IN THE PRESENT EMERGENCY

SIR,—Now with the restriction on the use of quinine coming into force, doctors, especially in tea estates practices, where a large percentage of their cases are malaria, have been hard put to in not being able to get enough of this most important weapon in their armamentarium to fight this dreadful disease. It is high time that some one in authority should lay down a definite line of treatment for treating cases of malaria with this short ration of quinine. An immediate and authoritative direction is all the more necessary because of the spate of recent unseemly controversial letters as regards use and misuse of quinine which appeared in the lay press. These are being used as weapons to snub doctors by dubbing them 'fools who have no common policy for treating even such common cases of every-day occurrence as malaria'. One also feels the unexpressed opinion from the members of the public that when the doctors do not agree amongst themselves about the treatment of simple malaria cases they should not be trusted to treat more difficult cases and should be kept at arm's length!

One cannot blame the public for forming such an opinion about doctors after going through the letters appearing in the daily papers under the signatures of eminent doctors.

One asks in dismay if these letters should have appeared in the lay press at all. Was this display of

knowledge or lack of it, by the eminent signatories, before the public within the bounds of medical ethics?

However, we doctors in the malarious districts look up to you for laying down a definite direction as to the best method of treating malaria (both acute and chronic) with the minimum expenditure of quinine and which will cure our patients with minimum number of invalid days.

B. CHATTERJEE,
Medical Officer.

THE CHARGOLA VALLEY MEDICAL
ASSOCIATION,
DULLABCHERRA P. O. AND T. O.,
SYLHET,
18th September, 1942.

Note.—In our opinion the action of certain doctors in writing to the lay press on technical matters, such as the treatment of malaria is most unseemly, and calls for strong protest.—EDITOR, I. M. G.

Service Notes

APPOINTMENTS AND TRANSFERS

COLONEL J. B. HANCE, C.I.E., O.B.E., V.H.S., Inspector-General of Civil Hospitals and Director of Public Health, Central Provinces and Berar, was appointed Officer on Special Duty in the Office of the Director-General, Indian Medical Service, with effect from the 27th July, 1942.

Lieutenant-Colonel C. M. Ganapathy, M.C., C.I.E., I.M.S. (Retd.), is appointed to officiate as Port Health Officer, Bombay, with effect from the afternoon of the 11th August, 1942, *vice* Major M. Sendak.

On return from leave, Lieutenant-Colonel E. Cotter resumed charge of the post of Public Health Commissioner with the Government of India, with effect from the 27th August, 1942.

Lieutenant-Colonel R. V. Morrison. Dated 1st September, 1942.

Lieutenant-Colonel B. T. Eminson. Dated 24th September, 1942.

Lieutenant-Colonel J. C. De. Dated 23rd August, 1942.

Major A. W. West. Dated 13th May, 1942.

Notes

B.D.H. MEDICAL PRODUCTS (INDIAN EDITION), 1942

THE British Drug Houses Limited have sent us a copy of their recently published price list of medical and miscellaneous products, injections, pharmaceutical specialities and tablets. The list is concise and simple and will be found useful for reference. Its pages show at a glance the names of the preparations with short descriptive notes, indications, methods of administration, packings and prices. There are also two useful indexes—one of diseases and another of medical products. Medical practitioners who have not received copies of the list may apply to the Firm, Imperial Chemical House, Ballard Estate, Bombay.

BOVRIL LIMITED

MANY members of the Forces of the British Empire and Allied Nations attended a Welcome Party given by Messrs. Bovril Limited at the Overseas House, London, on the 1st August, 1942.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-3 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

OBSERVATIONS ON INGUINAL HERNIA, ITS TREATMENT AND OPERATIVE TECHNIQUE

By F. A. B. SHEPPARD, O.B.E., F.R.C.S.
MAJOR, I.M.S.

Professor of Surgery, and Principal, Andhra Medical College, Vizagapatam

THE subject of inguinal hernia is one of some antiquity and there are constant references to it throughout the whole period of surgical literature. Nevertheless a proper understanding of the underlying causes and the principles of treatment were not arrived at until the end of the 19th century. Since then a considerable variety of procedures, aimed at so-called repair of the inguinal canal, has been described. This insistence on adequate surgical repair of the region implies that the risk of recurrence is always with us. Despite this implication, it is curious to find that cases of inguinal hernia are frequently relegated to the end of the surgical list for unsupervised operation by a junior house-surgeon. In these circumstances, operative treatment is apt to become a matter of determination rather than of skill, and to result in a large recurrence rate. Statistics collected from groups of public hospitals have been collected from time to time to show a recurrence rate which compares most unfavourably with that of individual surgeons especially interested in the subject. For example, Max Page (quoted by Keynes), during an investigation of a selected group of individuals (policemen), found a post-operative recurrence rate of 20 per cent for indirect inguinal hernia, and 25 per cent for direct inguinal hernia, whereas Keynes himself had only 4 recurrences (two in one patient who had 'enormous' bilateral hernia but who had undergone sudden violent exertion soon after operation) from amongst a group of 94 of his own patients.

It is obvious that the subject is a difficult one calling for a thorough understanding of the inguinal region and for an individualized care of the patients.

The inguinal canal

The key to the problem of hernia lies in the inguinal canal, and a thorough understanding of its anatomy and its normal mechanism are essential. The canal is an oblique channel in the abdominal wall, in the adult about $1\frac{1}{2}$ inches long, through which the spermatic cord passes down to the scrotum. In the infant up to the age of 2 years, the canal is so short that the internal abdominal ring almost underlies the external abdominal ring. Gradually, however, the length and obliquity of the canal increases until the internal abdominal ring comes to lie

at a point approximately half an inch above the middle of the inguinal ligament. The external ring remains opposite the pubic crest.

The internal abdominal ring is a structure of considerable importance.—The vas deferens, spermatic vessels and lymphatics which form the spermatic cord enter the inguinal canal and leave the abdomen through it. From the margins of the 'ring' which is a somewhat oval slit in the *fascia transversalis*, fibres are prolonged down the cord as the *internal spermatic fascia*. The size of the ring is a matter of considerable importance, for any increase in its size must necessarily weaken the posterior fibrous wall of the canal to a degree which varies with the extent of the enlargement. It is evident that the presence of an indirect inguinal hernia, which leaves the abdomen through the ring, will inevitably exert such an effect. In fact, cases are frequently observed in which this has proceeded to such an extent that the posterior fibrous wall of the inguinal canal can hardly be considered to exist at all. *Attention to the internal ring, and its restoration where necessary to a normal size, must be considered an essential step in all operations for indirect hernia.*

The posterior wall of the inguinal canal consists entirely of the *fascia transversalis*, reinforced medially by a lateral expansion of the tendon of insertion of the *rectus abdominis* muscle along the pectinal line of the pubic bone. This expansion is somewhat variable in length. Thus muscle fibres play no part in the make-up of the posterior wall.

The roof of the inguinal canal is formed by the arched fibres of the internal oblique as they pass from their origin along the outer half or two-thirds of the inguinal ligament to their insertion into the *linea alba* and the pubic tubercle. The *transversalis* muscle is usually fused with the internal oblique in this situation and cannot be separately defined from it. The internal oblique muscle is of great importance for it protects the internal ring, and has an important sphincter-like action on the inguinal canal as a whole, for when it contracts the arch straightens out and approximates itself to the inguinal ligament. The significance of this muscle and the importance of preserving it intact was stressed by Hamilton Russell forty years ago.

The conjoined 'tendon' consists mainly of muscle fibres of the fused internal oblique and transversalis muscle approaching their attachment to the pubic bone.

The *cremaster muscle* is a part of the internal oblique muscle continued down the anterior aspect of the cord as a series of looped fibres. These muscle fibres of the cord can, in nearly every case, be seen to have an attachment of variable strength to the more medial end of the inguinal ligament. In effect, therefore, there are muscle fibres attached to the inguinal ligament throughout practically the whole length of the inguinal canal, viz, the internal

oblique muscle and its continuation, the cremaster muscle. The fibres of the cremaster muscle continue down the cord for a variable length and then loop upwards to rejoin the internal oblique just before its attachment to the pubic tubercle. On incising and opening out the external oblique aponeurosis through the full length of the inguinal canal, in operating for inguinal hernia, the underlying space is seen to be occupied by muscle fibres which, in the area between the *rectus abdominis* muscle and the cord, show a varying degree of development. In early cases of indirect hernia, it is so much the rule for these muscle fibres to show a full development, that such may be taken to be the normal arrangement. It has been noted, however, in the few cases of Malgaigne's swellings operated upon, and in all those cases of direct hernia with an overlying, stretched but otherwise intact layer of *fascia transversalis*, that the muscle in the area referred to is greatly thinned, and in some cases even entirely absent. It is difficult to assert that this absence of normal development is of congenital origin, for it may often represent a pressure atrophy of muscle fibres superimposed on the underlying hernia. Since, however, the earliest response of muscle to strain is an hypertrophy, and as such has never been observed at operation on really early cases of hernia of this type (*i.e.*, direct hernia covered by a bulging *fascia transversalis*), I am inclined to the view that a congenital deficiency in the region does in fact play an important rôle in the development of certain varieties of direct hernia. Attention should be given to this region in all exposures of the inguinal canal, and the degree of muscle development should be noted. Should it be poor, even in early cases of indirect hernia, the necessity for a reinforcement operation in addition to a simple excision of the sac would be indicated on the assumption that such patients are liable to the later development of a *direct* hernia.

The anterior wall of the inguinal canal is particularly strong, for it is in reality formed by the internal oblique muscle for part of its extent, and by the cremaster muscle, as well as by the aponeurosis of the external oblique muscle. The external abdominal 'ring' is a triangular opening through which the cord covered by cremaster fibres passes to the scrotum, and is situated just above and lateral to the pubic crest, and precisely opposite to the lateral expansion of the tendon of insertion of the *rectus abdominis* muscle which reinforces the extreme medial end of the posterior wall of the canal. In operation for the relief of hernia, the normal size of the ring should be restored in order to preserve the full strength of the inguinal canal.

The inguinal ligament of Poupart forms the floor of the canal. As it is firmly attached to the *fascia lata* of the thigh, it forms a useful and reliable sheet-anchor in all reinforcement procedures for strengthening the inguinal canal.

Ætiology

The occurrence of two main varieties of inguinal hernia has long been recognized, the *indirect* hernia which enters the inguinal canal through the internal abdominal ring, and the *direct* hernia which enters the canal through its posterior wall. The essential differences between these two varieties are of great importance and have a bearing on treatment and prognosis.

1. *Indirect inguinal hernia* depends for its occurrence on the presence of a preformed congenital sac. This is the basic conception of the origin of all such hernias. The process of peritoneum which accompanies the testicle in its passage through the inguinal canal to the scrotum, is normally obliterated entirely except for that portion which surrounds the testicle. In certain cases its obliteration up to the internal abdominal ring is incomplete, or fails to occur at all, and there remains a patent process of peritoneum which extends for a variable distance down to the testicle. As no amount of force or trauma has ever been shown to result in the escape of a process of peritoneum and intra-peritoneal contents through the internal abdominal ring, the congenital origin of indirect hernias may be assumed with some confidence. The unvarying situation of the sac within the spermatic cord, its direct relationship to the *vas deferens* which *always* lies closely applied to it *posteriorly*, the frequency with which thickening and signs of obliteration are to be observed at the apex of hernial sacs, and especially of that variety of sac which extends down to and invests the testicle, all these findings supply strong evidence of its congenital nature. The fact that most indirect hernias do not occur until early adult life is due to the anatomy of the inguinal canal, which even in the presence of an unobliterated peritoneal process is able effectively to resist the escape of gut or omentum into it. To most individuals with such a sac, however, a time is sure to come when gut or omentum will enter it, either suddenly, as a result of unexpected or overwhelming strain, or insidiously. Once such an event has occurred, the walls of the sac are opened out and the inguinal canal operates under an ever-increasing disadvantage. Furthermore, the posterior wall of the inguinal canal is greatly weakened by the stretching and dilatation of the internal abdominal ring which follows the birth of the hernia. It has been noted previously that this dilatation of the internal ring may progress to a degree which amounts to almost complete destruction of the posterior wall of the canal. The protective sphincter-like control of the internal oblique muscle is similarly lost in time through stretching of the muscle fibres. The overlying aponeurosis of the external oblique muscle is also progressively stretched and the external abdominal ring dilated, with increase in the size of the hernia. A vicious circle is thus established. With the passage of the internal ring medially and the external ring laterally, a

time may come when the patient has an aperture in his abdominal wall which will admit directly two or more fingers.

2. *Direct inguinal hernia.*—The important essential difference between this variety of hernia and the indirect variety is the absence of a preformed sac: The hernia thus depends for its occurrence on (a) a weakness of the inguinal canal, either developmental or acquired or (b) on an actual rupture of, or aperture in, the fibres of the *fascia transversalis* forming the posterior wall of the canal.

These important differences, which have not always been clearly defined or recognized, require further consideration.

(a) *Primary weakness of the inguinal canal, congenital or acquired.*—Reference has already been made to Malgaigne's swellings in which has been observed a poor development of muscular tissue in the area between the rectus abdominis muscle and the cord. A similar poor development is occasionally observed in patients operated on for indirect hernia too early in origin or too small to have caused secondary weakness.

The general bulge of the lower abdomen which occurs with increasing age is evidence of a loss of postural tone of the lower abdominal musculature. The protective efficiency of the muscles guarding the inguinal canal is thus reduced, so that any increase of intra-abdominal pressure such as is brought about by intra-abdominal adiposity, a chronic persistent cough, the straining of constipation or of urinary difficulties, is apt to lead to a bulge forwards of the poorly protected posterior wall of the canal, and to the development of a direct hernia. In hernias consequent on primary weakness of the inguinal canal, the sac is always covered by the greatly stretched and bulging *fascia transversalis* of the posterior wall of the canal. It is thin-walled, it never descends into the scrotum and in consequence of its wide neck has little, if any, tendency to strangulation. In the aged, it is characteristically bilateral.

(b) *Rupture of the posterior wall of the canal.*—Direct hernias are seen in which the sac has clearly come through an aperture in the posterior wall of the canal. The margins of the aperture are well defined, and it is constantly situated close to the lateral border of the rectus muscle. This constant situation of the aperture, and the unlikelihood of any force from within the abdomen rupturing an intact posterior wall, point to its congenital origin. The sac is not covered with *fascia transversalis*; it is thin-walled and may be surrounded by a considerable mass of extra-peritoneal fat. In one case, an asthmatic, admitted with severe pain and tension in the swelling, and operated on urgently, the mass of extra-peritoneal fat was in a condition of strangulation, the hernial sac being congested but empty. Such hernias are usually unilateral, and occur in young men. It is of importance to note that the narrow neck of the

sac and the rigid margins of the opening through which it emerges, predispose the patient to the risk of strangulation. This variety is relatively uncommon and is usually indistinguishable pre-operatively from an indirect hernia.

Treatment

Indirect inguinal hernia.—In all cases, provided general and local considerations permit, early operation should be advised. The narrow neck of the sac which exposes the patient to the constant risk of strangulation, and the fact that with increase in the age and size of the hernia the muscles of the inguinal canal are progressively weakened, are the two factors which dominate the situation.

In patients suffering from gross cardiac or renal insufficiency, operation must, of necessity, be avoided unless there is reason to fear the onset of strangulation, or unless strangulation has actually occurred. The hernia in such patients must, ordinarily, be controlled by a truss which should be carefully measured and adjusted by the surgeon, and its efficiency constantly checked. Operation also is best postponed, if possible, in infants up to the age of two years, for not only are the tissues delicate and less easy to define, but the lack of urinary control increases the risk of wound sepsis. The question of fitting a truss to an infant should receive consideration, for there is reason to hope that, at least up to the age of one year, obliteration of the sac may still occur. Such consideration should only be given if the parents are sufficiently intelligent to grasp the rules of application of the truss, and to appreciate the necessity for cleanliness. There will therefore be many cases in which operation will have to be performed, even in infancy. Fortunately, in infants the surgical procedure necessary for the cure of the hernia is minimal, complete removal of the sac being all that is required. The shortness of the inguinal canal renders it possible to do this without incising the external oblique muscle. In all other cases up to the age of twenty-five years, in addition to complete removal of the sac, it is necessary carefully to define and examine the internal abdominal ring, and to reduce it by suture to a normal size, snugly enclosing the spermatic cord.

In judging whether reinforcement of the posterior wall of the inguinal canal is a further necessity, the age and occupation of the patient, as well as the age and size of the hernia, and also the actual appearance of the muscles, internal oblique and cremaster, as seen at operation, have all to be taken into account. All adult labourers and, generally speaking, most patients over the age of thirty, will require reinforcement and 'repair' of the inguinal canal, for while removal of the sac and closure of the internal abdominal ring to a normal size will guarantee cure of an indirect hernia, the presence of primary or secondary muscular weakness predisposes the patient to the later development

of a direct hernia. A few hernias are encountered of such a gross size that destruction of the inguinal canal has reached a degree where cure can be obtained only by castration and obliteration of the canal.

Direct hernia

(a) *Primary weakness of the inguinal canal.*—When this variety of hernia is seen in 'pot-bellied' old men, operative treatment is often not advisable. The hernia is caused by loss of tone of the lower abdominal musculature plus the increasing intra-abdominal pressure of age. These causes are for the most part irremediable. Moreover, it never reaches a large size and, by virtue of its wide mouth, never strangulates. The fitting of a truss is preferable to an operation for such patients, and provided that care is taken with regard to its efficiency, the hernias will be completely controlled. In the less common cases in which the hernia is unilateral and has occurred in middle aged or younger patients, operation is worth while. The redundant and stretched *fascia transversalis* enclosing the thin-walled sac should be excised, but the sac itself need not be removed. Reinforcement of the posterior wall of the canal is the essential step in such cases.

(b) *Rupture of the posterior wall of the inguinal canal.*—Such hernias occur in relatively young men, are unilateral and relatively rare. Early operation is a necessity in all cases of this nature, for the narrow neck predisposes the hernia to strangulation. If the overlying muscular development is good, and the hernia is of recent origin, removal of the sac and closure of the aperture through which it has come are all that is required. If muscular development is poor, or secondary weakness is judged to be present, further reinforcement of the posterior wall of the canal will be necessary.

Technique

Operation for hernia requires a delicacy of execution which it does not always get. Exposure of the sac should be achieved by a deliberate dissection with the knife through each successive layer of tissue. It is then possible to lift up the sac and clear it of internal spermatic fascia with a minimum of destruction to the tissues. The internal spermatic layer of fascia is often so closely adherent to the sac in the region of its neck that a few touches with the knife are necessary in order to effect its complete clearance, and to define clearly the internal abdominal ring. It would seem unnecessary to mention the need for a complete opening of the inguinal canal (in all but infants) by an adequate incision of the aponeurotic external oblique muscle, but for the fact that operations have been witnessed in which no attempt was made to open the canal at all. The inguinal canal *must* be opened for its full length in order to permit inspection of the underlying muscle tissue and to allow complete

exposure of the sac. In many cases, in addition to the original indirect hernial sac, it will be found that superimposed secondary weakness of the canal has resulted in the formation of a small direct hernia.

DESCRIPTION OF PLATES XXXII AND XXXIII

Fig. 1.—The external oblique aponeurosis has been freely incised to show the underlying internal oblique and cremaster muscles. The ilio-inguinal nerve is not shown and, as illustrated, the incision in the external oblique is somewhat longer than necessary. Note that the cord and any hernial sac are covered by muscle tissue. The varying degree of development of this muscle tissue and its importance have been noted in the text.

Fig. 2.—The cremaster muscle and its fascia have been incised to display the underlying cord and fascia. An indirect hernial sac lies immediately beneath the muscle. A direct sac will lie above and medially to the cord.

Fig. 3.—An indirect sac has been transfixed and ligatured at its neck. Note the moderately dilated internal abdominal ring.

Fig. 4.—The sac has been excised. The internal oblique muscle is retracted upwards to fully display the internal ring.

Fig. 5.—The internal ring is being reduced to a size snugly enclosing the cord, by a continuous suture (of fine silk or nylon).

Fig. 6.—The suture of the internal ring has been completed. In hernia in which no further repair than this is considered necessary, the cord would not be displaced (as shown also in figures 3, 4 and 5). It would be left undisturbed, and the operation completed by suturing the cremaster muscle back in front of it, and by similarly suturing the external oblique muscle.

Fig. 7.—The less common variety of direct hernial sac proceeding through an aperture in the posterior wall of the inguinal canal is shown, transfixed and ligatured.

Fig. 8.—The aperture in the posterior wall of the inguinal canal is in process of being closed with a continuous suture (of fine silk or nylon). In early cases with well-developed internal oblique and cremaster muscles no reinforcement would be required. The operation would be completed by suture of the cremaster muscle in front of the cord.

Fig. 9.—In cases requiring reinforcement the cremaster muscle is sutured *behind* the cord. Unless this is done it is not possible to bring down the upper leaf of the external oblique muscle to the inguinal ligament, without injury to or destruction of the cremaster muscle.

Fig. 10.—The upper leaf of external oblique muscle is in process of approximation to the inguinal ligament for the full length of the inguinal canal, the first and most medial suture passing through the thickened periosteum of the pubic tubercle. A continuous silk or nylon suture is used.

Fig. 11.—The suture completed, the cord has been allowed to drop back into place.

Fig. 12.—The inguinal canal, with two layers of tissue added to its posterior wall, is reconstituted by suture of the lower leaf of external oblique muscle to aponeurosis above the cord.

Fig. 12.

Many variation in technique for the reinforcement of the posterior wall of the inguinal canal are in use, the most popular being the use of free fascial sutures derived from the thigh, a flap of rectus sheath, or 'darning' with silk sutures. The Bassini operation in which the internal oblique muscle is sutured to the inguinal ligament is still commonly performed, but the support which it gives to the posterior wall of the canal is most unreliable. In most cases of recurrence following this operation, I have observed that the sac has found its way through a split in the fibres of the muscle, just above the site of its fixation to the inguinal ligament. The operation which I favour for the reasons that it is sound in principle and gives excellent results in practice, is based on that of Andrewes.

The inguinal canal is approached through a somewhat transversely oblique incision one inch above the inguinal ligament. The aponeurosis of the external oblique muscle is cleared of fat by a sweep of gauze and incised, so as to open out the inguinal canal for a little more than its full length. The internal oblique and the cremaster muscles are inspected and their development noted (figure 1).

In operation for indirect hernias, the cremaster muscle is then picked up with a pair of artery forceps and incised in the direction of its fibres and of the underlying cord, care being taken to avoid the ileo-inguinal nerve, which is subsequently retracted to one or other side (figure 2).

Incision of the thin internal spermatic fascia then enables easy dissection and delivery of the sac, which is twisted off, transfixed at its neck, and excised (figure 3).

If the neck of the sac is relatively wide-mouthed, a running suture of catgut is a preferable and more efficient means of closure than simple transfixion and ligature. Retraction of the internal oblique muscle upwards then enables the internal ring to be inspected and, if enlarged, reduced to a normal size with a silk suture. The importance of this manoeuvre, which restores the posterior wall of the canal to its normal degree of completeness, is again stressed (figures 4, 5 and 6).

In operation for direct hernia, incision in the thinned and poorly developed cremaster muscle is made over the site of the hernia, above and medial to the cord. In that variety in which the sac is covered by the stretched fascia transversalis of the posterior wall of the inguinal canal, the fascia is incised and the sac stripped off it, care being taken not to damage the bladder which is so often in close relation. Redundant fascia is then excised, and the edges are brought together with a fine silk suture. It is not necessary, and even inadvisable in most cases, to attempt excision of the sac, because it is so delicate that sutures simply cut out.

Where the hernia has passed through an aperture in the posterior wall of the canal, the

sac is, as before, defined by incision of the covering cremaster muscle, above and medial to the cord. It is then excised after transfixion of the neck in the usual manner (figure 7).

Sacs of this nature are sometimes enclosed in a considerable quantity of extra-peritoneal fat, which has to be carefully peeled off. The bladder also is occasionally in close relation in the region of the neck. The aperture in the posterior wall of the canal is next closed with a silk stitch. In early cases with good muscle development, no further repair is necessary (figure 8).

Should reinforcement of the posterior wall of the canal be deemed necessary for the reasons previously given, the cord is held aside with a Lane's forceps which encloses it and the cremaster muscle sutured behind it, so as to enable the upper leaf of the aponeurosis of the external oblique to be drawn down and sutured, also behind the cord, to the inguinal ligament for the full length of the canal (figure 9).

Approximation of the external oblique aponeurosis to the inguinal ligament is effected with a continuous suture of fine silk or nylon. It is considered essential that the first stitch be passed through the thickened periosteum covering the pubic tubercle so that no gap is left at the medial end of the canal through which a hernia may pass. In order to effect this, the upper leaf of the external oblique aponeurosis should be clearly defined, particularly in the region of the superior crus of the external abdominal ring. In this situation, the cremaster muscle is often to be observed closely adherent to the under-surface. Similarly the under-surface of the lower leaf of the external oblique has to be cleared down to the inguinal ligament, and especially medially so as to define the pubic tubercle (figure 10).

In practically every case the stretching already suffered by the external oblique aponeurosis through the presence of the hernia will permit its ready approximation without tension to the inguinal ligament. In the occasional instance where such approximation of the aponeurosis to the inguinal ligament could be effected only by the exercise of a certain amount of tension, the gap between it and the ligament should be bridged by a series of very closely placed silk sutures, to act as a darn and to supply the foundation for the development of firm fibrous tissue in the region. There are no real grounds for the view that retention and suture of the cremaster muscle behind the cord leave a gap medially through which a recurrent hernia may pass down along the cord. No such gap is left if the first suture passed through the external oblique is correctly placed. The further argument that posterior reposition of the cremaster muscle interferes with its function of drawing up the cord and testicle is of little importance. In adults this function is not apparent, and, furthermore, in practice no disability follows alteration in the position of the muscle.

Not only do I consider it wrong to excise the cremaster, but I regard its preservation and suture behind the cord as an additional protection to the posterior wall of the canal. As soon as the reinforcement of the posterior wall of the canal is completed, the cord is allowed to drop back into place, and the lower leaf of external oblique aponeurosis is sutured in front of it (figures 11 and 12).

Separate suture of the superficial fascia and the skin completes the operation. Hæmostasis should be perfect throughout.

This reinforcement technique has been employed in more than six hundred operations, and has given complete satisfaction. The addition of two layers of tissue, the cremaster muscle, and a leaf of the external oblique aponeurosis to the posterior wall of the canal can be considered to provide a most effective means of support. The extensive use of silk or nylon, which is considered the most satisfactory suture material in this type of operation, does not increase the incidence of wound sepsis, and only the ordinary rules of asepsis and pre-operative preparation, applicable to any surgical procedure, need be followed.

Post-operative care.—All adult patients should be confined to bed for twenty-one days following operation, and forbidden to resume heavy work, if such is their occupation, earlier than two months from the date of discharge from hospital. Sedentary workers may resume duty after one month. For patients with lax abdominal muscles, a course of simple strengthening exercises of the leg-raising or body-bending type should be prescribed. Any tendency to excess weight should be kept in check by attention to the diet and by suitable exercise.

Recurrence.—It has been found possible to maintain contact with only a few cases after discharge from hospital, and it is therefore impossible to form a really accurate opinion regarding recurrence. No case of recurrence following the above operative treatment has yet come to my notice. As is well known, conditions are such in India, that one should be certain to see at least some of the cases if recurrence was occurring in even 5 per cent. I therefore feel justified in holding the belief that the incidence of recurrence must be really low, provided a careful and individual study is made of each patient, and a meticulous attention to detail followed at operation.

Summary

The inguinal canal has been described with special reference to the surgical significance of each layer.

The underlying causes of each variety of primary hernia and the principles governing treatment are discussed.

An operative technique practised in a large number of cases has been described, and the conclusion is drawn that, provided an individual study is made of each patient and a strict

NOTES ON THE USE OF COTTON IN SURGERY, AND ON PLASTER TECHNIQUE

By A. T. ANDREASON, F.R.C.S.

MAJOR, I.M.S.

(A) THE USE OF COTTON AS SUTURE AND LIGATURE MATERIAL IN PLACE OF CATGUT

IN the present crisis the supply of catgut is likely to become a problem, particularly when it is considered that so many different types are used for various types of work, and when it is realized that it is not prepared in any large quantity in India. A further difficulty with catgut is the elaborate manufacturing apparatus required to ensure a supply of any size and reliability.

Any material which will cause no more tissue reaction than catgut and which is available in good quantity, easily sterilized by boiling, available locally and requiring no extra factory installation than at present available would very certainly be an ideal material for general use in war time at least. Such criteria are fulfilled by cotton.

Cotton has been in use by reputable surgeons in various parts of the world, according to publications available at the moment, since 1913 when Halsted (1913) wrote on its use. From that time there has been a steady stream of literature on the use of cotton. A number of the more informative are listed for reference at the end of this note. The trend of the reports appearing since 1939 has been to show that cotton is in many respects more nearly the ideal suture material than is catgut.

Catgut seems to hold its place as a suture material on the basis of its being absorbable, and upon the teaching that foreign bodies are to be feared in wounds. It seems to have been forgotten that catgut itself is a foreign body and that it is one of those foreign bodies which will excite no mean reaction since it is absorbable. It has been shown experimentally that when catgut, silk, linen and cotton were carefully graded for the reaction they caused in tissues, catgut caused most reaction with the slowest healing and after it in order with less and less reaction and quicker healing were linen, silk and cotton (Meade and Ochsner 1939).

The ideal suture should be pliable, easily prepared, easily available, inexpensive, should tie securely, should not excite tissue reaction, should maintain its strength for a predictable length of time in all patients, should cause no tendency to infection or sinus formation. In my experience

(Continued from previous column)

attention is paid to the operative detail, highly satisfactory results may be expected.

My thanks are due to Professor R. Krishna Rao and Dr. T. V. Mathew, of the Anatomy Department, for their help in dissections of the inguinal region, made in order to clear up certain points in the anatomy of the inguinal canal.

with all types of suture material, cotton most fully fulfils these requirements. Cotton is pliable, is available in any bazar, is easily sterilized by boiling for 20 minutes, and does not lose strength by reboiling, is inexpensive (400 yards for four annas), has a secure knot when properly tied, the ends may be cut on the knot without fear of the knot slipping, and has proved to be one of the most inert suturing materials that has so far come into use.

Cotton maintains its strength for a known predictable period in all patients. Its tensile strength is increased 10 per cent. after boiling for 20 minutes. When placed in the tissues it loses 10 per cent of its strength in ten days, which fact contrasts favourably with catgut which loses 50 to 70 per cent in ten days, and which will be absorbed more quickly in one patient than in another in an unpredictable manner.

Cotton shows a low incidence of infection and has not caused any tendency to sinus formation in infected cases.

My own experience of cotton extends over five years, including a large number of abdominal operations involving intestinal anastomosis and gastric resections in a centre where 20,000 new cases of peptic ulcer were seen each year, and where some 3,000 cases of intestinal obstruction were admitted yearly. I have used it in operations on the head and neck, and upon the extremities. I have come to use it exclusively for all surgical work, including suture of the kidney, ureter and bladder.

(a) The main points of the technique of the cotton suture are :—

1. Use interrupted sutures only except for the peritoneum.

2. Sutures are pulled only tight enough for comfortable approximation of the structures under suture. Tightness of the knot does not ensure more certainty of union, in fact it is the reverse. It must not be forgotten that catgut does not maintain its tensile strength for more than two or three days, whereas that of cotton is permanently maintained. Hence too tight a suture with cotton will lead to cedema and cutting out of the cotton; with catgut this will not occur since its strength is not maintained.

3. Never use buried absorbable and non-absorbable sutures side by side.

4. Always use the finest available material compatible with the strength required. Coarse material does not do well.

5. Avoid mass ligatures; pick up the very point to be ligatured.

6. Never leave enclosed dead space.

7. Always close the superficial fascia separately.

8. Use 40, 6 cord thread for all work. I have never used anything but 40, 6 cord, for all purposes, doubling it when extra strength was necessary.

9. Sutures are cut 18 inches long and threaded on needles ready for use, placed between layers

of lint or gauze and sterilized by boiling. A glass reel with some forty yards wound on it is also boiled for extra sutures and for ligatures. Cotton is always served up under saline in a tray or bowl, and kept wet until required for use.

10. Black cotton is used, for if white were used it would soon be invisible when once stained with blood.

11. All knots are so placed that they are directed downwards.

12. With the superficial fascia sutured the skin sutures may be removed in 24 to 48 hours in the face and neck, and in 5 to 6 days elsewhere.

13. Cotton may be used in contaminated wounds with as much safety as any other material. (The old surgical rule here is not to use any in the presence of sepsis whatever the material.)

14. Cotton is an excellent intestinal suture material provided that the three layer technic is used. In this way the mucosa is never perforated by a suture appearing at the serous surface.

(b) The cotton knot is not tightened with a jerk, but by a steady and gentle sliding of the first turn into position at the point to be tied off with the two forefingers taking a steady strain in opposite directions on each of the two lengths of thread coming from the knot being tied. Once firmly and evenly tied the first turn will not slip unless it has become slippery in fat. Hence in general it is not necessary for more pull being maintained than that required to allow the second turn of the knot to be taken. This second turn should be tied and tightened in the same manner as the first.

(B) A SIMPLE METHOD OF REMOVING PLASTER OF PARIS CASTS

Recently there have been described in the medical press several ingenious methods of removing plaster of paris casts. The following method does not appear to have been mentioned. It has the advantage in that it is applicable even under service conditions since no special gadget or appliance is required. All that is necessary is two lengths of rubber tubing of about 8 mm. external diameter and a little vaseline to grease

the tubing with. The tubing should be of such a length that it can be laid along the external aspect of a large adult thigh, leg and body from the axilla to the small toe with six inches over at each end. This is the longest cut required in any plaster cast. The tube should be kept this length and not cut for shorter plaster; its length in the shorter plasters is no disadvantage, and economy is observed by the need of only two lengths of tubing—one for each side of a double spica or a spinal cast—instead of many lengths for the many different sizes of plaster cast in use.

The method of application is as follows :—

(a) In an arm or a leg, the posterior slab having been laid in position, the site for the slit in the plaster, either for immediate slitting or for removal after the required period of immobilization, is chosen, and the vaselined rubber tubing is laid in that position and held by one or two turns of the wet bandage used for holding the moulded slab in place. The plaster is then completed as usual. After completion and hardening, the tubing is pulled tight and stretched at each end where it projects from the plaster, and in this way it is eased out of the cast. A tunnel is left of sufficient dimension to allow the toe of the plaster shears to be inserted freely without catching up the skin as the cutting progresses. The bends and angles are easy to cut by this method, and, if they are likely to be acute and difficult to turn with the shears, a little ingenuity in the placing of the tubing will give a less acute angle to cut through.

(b) In large lower limb casts involving the thigh and trunk the casts can be removed more easily if two tubes are inserted, one externally and one internally. The same applies to spinal casts.

(c) By using two tubes in suitable position any cast may be bivalved very rapidly.

I have used the method for over five years now with satisfaction. The idea may be of use in this present time when plaster is in such general use, and much time and energy are lost in the removal of heavy plasters put on to ensure that a case may be evacuated with safety.

(C) A SIMPLE METHOD OF PLASTERING A LIMB LIKELY TO SWELL

Treating an injured limb which is already swollen or is likely to swell is a serious problem to all who have the responsibility of treating injuries to limbs. In more normal times it is possible for the surgeon or his deputy to supervise the plastered limb and to give it his personal attention should the swelling occur and require relief. Thus the stability of the plaster cast is not destroyed and the position of the bones is not disturbed, but in the present crisis such close supervision is not always possible. Attempts made by inexperienced staff are likely to be disastrous to the stability of the cast and

to the position of the bones. In order to overcome this difficulty and to provide my hard working staff with a plaster cast which they can deal with confidence in my absence, I have for some time now used the following type of cast for such difficult cases.

After surgical toilet and manipulation of the bones into position, the usual posterior slab is applied and gently and evenly moulded on with a broad wet bandage. This posterior slab should encircle two-thirds of the limb. Next an anterior slab is applied to cover half the circumference of the limb and is bandaged in position with a wet bandage. The limb is now elevated as usual with any swollen limb. Should it later become necessary to release pressure on account of the swelling having increased greatly, all that is now required is for a nurse or an orderly to cut through the two layers of ordinary bandage holding the two slabs in place, and the pressure will be at once released evenly throughout the whole length of the limb under plaster. The slabs are maintained in position by tying two or three loops of bandages over them at equal distances along the limb. The slabs adhere sufficiently to the calico bandages to prevent them falling apart when the bandages are cut, and in any case the posterior slab covers two-thirds of the limb and will not fall off if the limb has swollen up. As the swelling goes down all that is required for some time to maintain even firm immobilization is to tighten the two or three loops of bandage holding the slabs in position. The slabs may be thus kept in position for about four weeks. About this time it is better to carefully replaster the limb for the remainder of the time that immobilization will be required.

(D) A SIMPLE METHOD OF SETTING AND PLASTERING UNCOMPLICATED ANKLE FRACTURES

All three degrees of abduction-external rotation fracture and fracture dislocation of the ankle joint, i.e.: Pott-Dupuytren types, and all three degrees of abduction fracture and fracture dislocation of the ankle joint can be treated by this simple method. It is not recommended that the method be used for the vertical compression fracture dislocation of the ankle joint where there is so often an anterior marginal fracture of the tibia with forward displacement of the astragalus.

Anæsthesia having been produced by injecting 1 per cent novocain—5 or 10 c.c.—into the sites of fracture, skiagrams are taken in two planes. By the time that the plates have been developed, the anæsthesia will be complete. The patient is assisted to kneel on a chair with his knees well separated, and facing the back of the chair. In this position both the feet will hang free over the edge of the seat of the chair. He is instructed to let both feet hang loose. The fractured ankle will now take up very nearly its normal relations by virtue of its own weight and

TREATMENT OF CARBUNCLE WITH EXCISION

By S. P. WANCHOO, M.B. (Pun.), M.R.C.S. (Eng.),
L.R.C.P. (Lond.)

In charge, Alexandra Hospital, Alwar

THOUGH most experienced surgeons operate on carbuncles in this way, I thought of writing this article, based on records of my cases this summer, purely for the benefit of the general practitioner and the beginner in surgery, who is apt to be lead away by the textbooks, most of which still advocate crucial incision and removal of flaps.

This line of treatment, besides being irrational, does not give good results, as the growing margin of the carbuncle remains untouched.

A carbuncle is infective gangrene of the subcutaneous tissues. Just as in the case of gangrene of a limb, the line of treatment is to amputate through the healthy tissues, so in the case of this type of gangrene, the line of incision should be through the healthy area. Hence the practice of incising into the gangrenous area, as in the case of the crucial incision of the textbooks, appears most unscientific, for there is danger of introduction of sepsis into the systemic circulation.

(Continued from previous page)

the anæsthesia induced. The correctness of the position of the injured foot can easily be checked by reference to normal alongside of it. Any minor correction that may be necessary can then be easily and gently made and maintained by movements directed to the toes and/or the heel. Sometimes it is necessary to wait a few minutes for the injured foot to relax and for the damaged part to fall into place. It is always well worth while to wait patiently for this to happen and for the correction to attain the maximum of its own accord before undertaking any manipulation, for such an exercise of patience is usually well rewarded and any tendency to undue speed and rough handling is avoided.

With the position corrected there is only the posterior slab to be applied. This should be broad enough to cover two-thirds of the circumference of the limb from the toes up to the bend of the knee. In the position in which the patient is on the chair it is an easy matter to apply the posterior slab, mould it carefully, and allow it to dry with the foot in very good position. Once dry the post-reduction skiagrams can be taken to confirm the correctness of the position. The plaster may be completed then either by the rubber tube method, or by the anterior slab method, whichever may be the more applicable to the condition of the limb.

The method is simple and accurate, and is capable of application by even a novice in the art of fracture treatment. It is most gentle and removes any excuse for the use of force in the manipulation of these fractures.

There seems to be a prevailing idea, not only amongst the lay people, but also amongst some medical practitioners, that operative removal should not be carried out in the old, diabetic and/or debilitated patients, because they are not likely to stand the operation. This is contrary to the general principles of surgery and has not been borne out by practical experience. Whereas a young healthy man is likely to recover from a carbuncle even if it is not excised, because of his good general power of resistance in combating septic absorption, this is not the case in the old, diabetic and debilitated individuals. In such persons, the disease is likely to spread more rapidly with the resultant severe toxic symptoms and even fatal results, if the focus of infection is not eradicated early.

Thus early excision is the only rational treatment of carbuncle and is even more important in debilitated individuals. This method not only reduces the mortality rate but also shortens the period of sickness, thereby preventing much unnecessary suffering and pain. This point is clearly brought out from the appended summary of records of my cases treated during this summer. It will be seen that, whereas an average sized carbuncle after operation heals up perfectly in about 6 weeks' time, a case without operation takes much longer.

It will also be noted that out of 9 patients, two refused operation. Out of the latter one died and the other took 3 months to recover.

From the point of view of treatment the carbuncle may be divided into two stages :

1st stage.—A hard painful swelling in the subcutaneous tissues, often on the back, the skin over which becomes dusky and cedematous.

2nd stage.—Swelling still more prominent, the skin over the area becomes purplish and usually ulcerates in several spots near the centre, exposing to view the ashy slough of the subcutaneous tissue, allowing exit to thin sero-pus.

An average Indian patient, who is apt first to resort to the homely remedies, usually comes to the doctor in the second stage of the disease. This really should not matter as the line of treatment in the first stage consists of applying fomentations to relieve pain and promote hyperæmia, and this is what most of the homely remedies, whether in the form of a poultice, a hot water-bottle, etc., aim at.

The only rational treatment in the second stage consists of excision, as soon as possible.

Choice of anæsthesia.—If the patient is young and his urine does not contain sugar and albumin, gas and ether are the best. If general anæsthesia is contraindicated on account of diabetes, nephritis or old age, then local anæsthesia is used. The exact procedure I follow is as under :—

Morphia $\frac{1}{4}$ gr. is given about forty-five minutes before the operation. Infiltration of the healthy tissues is done all round with 1 per cent novocain or 1 in 1,000 percain with a Lobat's syringe. This type of syringe with its lock for

TABLE

Summary of case records of carbuncle cases treated in Alexandra Hospital, during summer 1942

Case number	Age	Date of admission	Summary of clinical notes	Urine report	Treatment	Date of discharge from hospital	Condition on discharge	Date of final cure	Total number of days in treatment	Result
1	50	14-6-42	Carbuncle on the back 4" X 4" on the surface, duration one month.	Albumin present, a trace. Nil else abnormal.	Patient refused operation, was put on infra-red ray exposures.	12-8-42	On discharge had an ulcer 2" X 2".	10-9-42	86	Cured.
2	80	26-6-42	Carbuncle on the back 5" X 5" on the surface, duration 2 months.	Normal	Excision under local anaesthesia.	28-7-42	Clean granulating wound.	10-8-42	45	Cured.
3	33	26-6-42	Carbuncle on the back 4" X 4" on the surface, duration 7 days.	A trace of albumin. Nil else abnormal.	Excision under general anaesthesia on 7-7-42 as he refused operation earlier.	19-8-42	Wound completely healed.	19-8-42	55	Cured.
4	72	28-6-42	Carbuncle on the back 5" X 5", duration 15 days. Developed rashes of acute pemphigus all over the body on 18-7-42. Became intensely toxic. Developed fainting attacks which became more and more frequent.	Normal	Refused operation. Was put on infra-red exposures and sulphathiazole internally.	29-7-42	Died	Died.
5	59	30-6-42	Carbuncle on the back 4" X 4", duration 12 days. Also had an abscess in the finger, duration 25 days. Other abscesses developed in the body later on. Also developed dry gangrene of the terminal phalanx of finger.	Sugar present 5 per cent.	Carbuncle excised and abscess in finger incised. Terminal phalanx of finger amputated; other abscesses were opened.	9-9-42	All wounds healed.	9-9-42	69	Cured.
6	50	8-7-42	Carbuncle on the back 4" X 4" on the surface, duration 7 days.	A trace of albumin. Nil else abnormal.	Excision under local anaesthesia.	8-8-42	Wound healed except for an area $\frac{1}{2}$ " square, and was covered up with elastoplast.	18-8-42	40	Cured.
7	50	9-7-42	Carbuncle on the back 4" X 4", duration 8 days.	Normal	Excised under general anaesthesia. Infra-red rays during convalescence.	13-7-42	On discharge had an ulcer 4" X 4".	9-8-42	30	Cured.

TABLE—*concl'd.*

Case number	Age	Date of admission	Summary of clinical notes	Urine report	Treatment	Date of discharge from hospital	Condition on discharge	Date of final cure	Total number of days in treatment	Result
8	45	12-7-42	Carbuncle on the back of neck 4" × 4", duration 7 days.	Sugar a trace, albumin a trace.	Excised under local anæsthesia.	29-7-42	Wound 3" × 3".	21-8-42	40	Cured.
9	65	30-7-42	Carbuncle on the back 6" × 6" on the surface, duration 20 days. Deep muscles were involved.	Sugar a trace, albumin a trace.	Excision under local anæsthesia on 31-7-42. Involved muscles also excised. Thiersch grafting on 19-8-42.	9-9-42	Wound completely healed.	9-9-42	40	Cured.

the needle is almost indispensable for such work, especially as the tissues are very hard, and proper infiltration with an ordinary syringe is very difficult. Soon after finishing the local infiltration, further morphia $\frac{1}{2}$ gr. is given. After 10 minutes the operation is started and except in very hyperæsthetic persons, there is no trouble during the course of the operation.

Operation.—The growing margin of the carbuncle is first felt all round, and the incision is made just outside. The cut skin along with the carbuncle on one side is caught in Lane's tissue forceps and the carbuncle is dissected out like a tumour. If by any chance the knife cuts into the carbuncle itself, then one must go deeper or wider and excise the whole thing *en bloc*. Most of the hæmorrhage stops with hot sponges but if any vessel still bleeds, it is ligated. The wound is dressed with concentrated solution of magnesium sulphate in glycerine for 3 or 4 days and later with B.I.P.P. or mercurochrome (or acriflavine) in liquid paraffin.

Convalescence.—After having been sleepless for so many days, the patient has a very restful night following the operation and the next morning one finds that the wound is clean and quite healthy. In 10 or 15 days the wound becomes smaller and is covered up with healthy granulations and all one has to do is to apply a strip of stretched elastoplast, to enable the wound to heal undisturbed under it.

If the area is very big, skin grafting may have to be done (as in case 9 of my series). The diabetics are given a carefully planned nutritious diet with adequate units of insulin, the diet being controlled by daily urine examinations.

Other cases including the old and debilitated are given liberal diet. Tonics are very useful. The convalescence is usually uneventful except in diabetics who may develop abscesses on other parts of the body. These abscesses are opened as and when they occur.

SURVIVAL OF *VIBRIO CHOLERÆ* IN GASTRIC JUICE

By L. EVERARD NAPIER, C.I.E., F.R.C.P. (Lond.)
and

S. K. GUPTA, M.B., D.T.M.
(School of Tropical Medicine, Calcutta)

Introduction.—In a paper on the gastric acidity in cholera convalescents Pasricha and others (1940) found that 36 per cent of cases had achlorhydria, 52 per cent a low acid content, and 12 per cent a normal curve; none had hyperchlorhydria or even a high normal curve. They made three suggestions for the cause of this low acidity in their series, namely (a) that it might be the result of acute gastritis and quoted Sir Arthur Hurst's well-known views on this subject, or (b) that the loss of water, acid, and chlorides might have caused a depletion from which the patient had hardly recovered. Neither of these explanations for the low acid curve in these cases seems to us to be very probable, for (a) the 'gastritis' of cholera is scarcely comparable to the chronic gastritis to which Sir Arthur Hurst refers, and even then many people do not accept his views on this subject, and (b) the bio-chemical balance of the cholera patient would usually have been re-established by the time the samples were taken in this investigation.

The third explanation, not of the low acid curve in these particular patients but of the writers' findings, seems to us to be a much more probable one, namely. (c) that persons with a low acid curve were more liable to get cholera and that therefore these writers' clinical material had been subjected to a degree of natural selection.

We decided to carry out a very simple investigation to test further the probability of this last explanation.

Experimental.—We took the gastric juice from a number of patients in hospital, in whom

gastric analysis was being done in the routine investigation of the condition from which they were suffering. A definite amount of fresh cholera culture was added to each tube containing gastric juice and after different intervals the gastric juice was plated to see whether the vibrios were alive or not.

The fasting juice and several other samples were taken in sterile test-tubes in measured quantities and a 24-hours' broth culture of 'smooth' *Vibrio cholerae* was added to the tubes so that the culture added amounted to one-fifth of the volume of gastric juice present in the tubes. The tubes were then thoroughly shaken and plated on 0.5 per cent bile-salt agar; subsequently they were again shaken and plated after intervals of 15 minutes, half an hour, 1 hour, 2 hours, 3 hours, 24 hours, 48 hours, 72 hours, and so on until the vibrio colonies failed to appear. This procedure was carried out with the gastric analysis samples of 10 patients.

Free acid.—The full results in two cases, one a case of hyperchlorhydria and the other a case hypochlorhydria, are given in detail in tabular form below (tables I and II). The contrast is most striking. It will be seen that, in the hyperchlorhydric case, the vibrios

the rest survived for various period, from 96 to 370 hours.

Thus, as far as free acid is concerned, it is apparent that the vibrios survive for a very long time in the absence of acid, that if any acid at all is present they survive for only a short period, and that, if there is more than the equivalent of 22 c.cm. of N/10 HCl in 100 c.cm. of gastric juice, they are always killed immediately.

Total acid.—From table II there is a suggestion that in the absence of free acid the combined acid has some influence on vibrio survival; for example, in the fasting juice and in sample 8, the total acid is 16 degrees, and the maximum survival is 24 hours, whereas in samples 3 and 4 when the total acid is 10 and 8, the vibrios survived for 264 and 192 hours, respectively.

The same suggestion is conveyed by table III, in which, while in cases 1 and 7, the 'total' acid is 16 and 18, respectively, the survival period is 24 hours and *nil*, whereas in the other samples with less 'total' acid the mean survival rate is just about 200 hours. The data on this point are, however, not sufficient to warrant any conclusions.

Discussion.—Panja and his co-workers (1942) showed that vibrios are only found in

were killed immediately in every sample, whereas in the other case they survived up to 24 hours in 8 out of 10 samples, and in one sample up to 264 hours.

Table III is a summary of the findings in all the ten cases. It will be observed that in every case the vibrio was killed immediately if the free acid was over 25 degrees of acidity*, and, even over 5 degrees, they did not survive for more than one hour. On the other hand, in the absence of any acid at all, only one out of 13 was killed immediately, 3 within 24 hours, and

the vomitus when this is alkaline in reaction. Unfortunately these workers estimated the hydrogen-ion concentration only, whereas we estimated the neutralizing value of the gastric juice. These two values are not capable of conversion one into the other, but they are naturally closely correlated. We have been able to show that in the absence of any free acid the pH is usually between 8.0 and 6.0 and that in the presence of an acidity of 22 degrees, the pH is never above 4.75. The two sets of findings are therefore strictly compatible; Panja and his co-workers never found vibrios in the vomitus if the pH was 4.9 or less, whereas, if it was above this but less than 7.0, vibrios were present

in half the samples, and, when the pH was above 7.0, vibrios were found in 12 out of 14 samples.

Dilution of gastric juice.—It is obvious that *in vivo* there would be some dilution of the gastric juice if water were taken. In order to see how this would affect the destruction of the vibrios by the hydrochloric acid, we diluted

gastric juice with sterile distilled water before adding it to the vibrio emulsion. The results are shown in table IV.

Discussion.—As one would expect dilution has a marked effect in prolonging the time of survival of the vibrios. The fact that a one-in-five dilution, when the acidity was 30 units or

The figures in the chart indicate the number of hours of survival of *Cholera vibrio* after they have been added to the different samples of gastric juice. 0 indicates killed immediately, that is to say, there was no growth even after first plating. S indicates that the vibrios were alive at the time they were plated.

less, allowed the vibrios to survive almost indefinitely is more or less in keeping with our previous observations, and suggest that it is mainly the acidity *per se* that kills them.

This indicates that when water is the medium of infection and a large draught is taken, the vibrio will pass through the stomach in a viable form, despite a high acidity.

Conclusions.—Cholera vibrios are killed very rapidly when they come in contact with gastric juice with an acidity of 22 degrees or more, and in the presence of any free acid they do not survive long. In the absence of acid they may survive up to 15 days. Whilst admittedly the gastric juice is subjected to considerable dilution *in vivo*, the presence of even small amounts of

free hydrochloric acid is so fatal to the vibrio that it seems justifiable to conclude that the individual with a low-acid gastric juice may be much more susceptible to cholera infection than the individual with a normal or high acid content.

This seems to add support to the third reason put forward by Pasricha and his co-workers (*loc. cit.*) to explain their findings of a low gastric acidity in cholera convalescents.

VITEX PEDUNCULARIS—AN ANTIHÆMOLYTIC AGENT

By J. C. GUPTA, M.B.
B. S. KAHALI, M.B.

and

S. C. GANGULY, M.Sc.

(Indigenous Drugs Enquiry, Indian Research Fund Association)

(From the Department of Pharmacology, School of Tropical Medicine, Calcutta)

Résumé of previous work.—Vaughan (1921) found that an aqueous infusion of the leaves of *Vitex peduncularis*, Wall, var. *roxburghiana*, was being used by the aboriginal tribe of Ranchi in malaria and blackwater fever. Though the medicinal properties of the members of the Vitex family (e.g. *Vitex trifolia*, *negundo*, etc.) have been elaborately described in the Ayurvedic system of medicine, the *Vitex peduncularis* Wall, var. *roxburghiana*, had not been mentioned by the early Hindu pharmacists. Vaughan (1921) used an infusion of the fresh leaves of the plant in the treatment of malaria. Four cases of

blackwater fever were also treated 'with success'. He concludes thus—

'In vitex it may be that we shall find active principles which will give us all the power of quinine in malaria without many of the dangers and drawbacks of quinine and its allied alkaloids.'

Chopra, Knowles, and Gupta (1924) gave the drug a fair trial in malaria in the Carmichael Hospital for Tropical Diseases. They reported that 'the drug appeared to be absolutely useless in the treatment of malaria'. Measham (1940) treated eleven cases of blackwater fever with the vitex infusion (prepared according to Vaughan) 1 ounce hourly until the colour of the urine returned to normal. Some of his cases had malaria parasites in the blood: in a few cases atebirin or quinine in doses too small to influence the course of the disease was used. He found that all except one improved considerably in three days: urine cleared on the third day after vitex and the temperature came to normal within three days. He concluded that 'vitex had definite value in the treatment of blackwater fever'. Commenting editorially on this paper, Dr. L. Everard Napier wrote:—

'... it is obvious that *Vitex peduncularis* is at best a poor antimalarial drug, and we have good antimalarial drugs at our disposal.

If it is not on account of its antimalarial properties, how then does it act? In an attack of blackwater fever there is often one severe hæmolytic crisis in which all the damage is done; in such a case treatment consists in helping the body to tide over the shock, to recover its normal functions and repair the damage. Whilst it is conceivable that there are many drugs that will assist this, there does not seem room here for a 'specific'.

On the other hand, it is conceivable that there might be some specific drug that would prevent further hæmolytic crisis, and would, therefore, if used prophylactically, prevent the initial attack. Is *Vitex peduncularis* such a drug? There is no evidence that it has such an action or for that matter that it has any action at all. The clinical trials reported are not very convincing; to be so, they will have to be carried out on a much larger scale. Statistically there is no significant difference between a 10 per cent and a 20 per cent, 30 per cent, 40 per cent, or even 50 per cent death rate,

when the total number of subjects in each series is only 10, and clinical progress is so much a matter of personal opinion subject to all kinds of influences, that it is liable not to carry much weight outside the clinician's personal sphere.

Whether or not a *prima facie* case has been made out to justify pharmacological investigations . . . it is for the pharmacologists to decide'.

Since this date Roy (1941) has reported a further ten cases of blackwater fever treated with *Vitex peduncularis* with one death only. He used two preparations of vitex, one for intramuscular injection and the other a tincture for oral administration. The patients received an initial intramuscular injection of 2 to 3 c.cm. of the injectable preparation followed by the tincture in 10 to 15 min. doses thrice daily. Depending on the severity of the case the injection was repeated the same day or for the next 2 or 3 days. The oral administration was continued for 3 or 4 days after the cessation of hæmoglobinuria.

This brief résumé of the work done with *Vitex peduncularis* shows that the clinical approach for elucidating the action and use of vitex has not provided any clear cut evidence as to its uselessness. We, therefore, thought that it was worth while taking up Dr. Napier's suggestion that the next move should come from the pharmacologist, and we decided to undertake certain experiments, choosing first the investigation of the anti-hæmolytic properties of this plant.

Experimental work

We undertook work under three headings :—

I. *In vitro* experiments.

II. *In vivo* experiments.

III. Physical effect on blood and red cells.

It is proposed to publish full details of the technique at a later date when the investigations are complete; meanwhile, however, a summary of the results of our preliminary observations is given.

I. *In vitro* experiments

1. *Fragility (or osmotic resistance) of rabbit red cells.*—Average osmotic resistance of the washed rabbit red cells was found to be 0.75 per cent saline. The addition of vitex in the proportion of 1 drop per 10 c.cm. increased the osmotic resistance of the rabbit red cells. 0.65 per cent saline which hæmolyzed the normal washed cells almost immediately, could not hæmolyze the vitex-treated cell even in 1 hour.

2. *Saponin hæmolysis.*—Crude saponin 1 in 26,000 (approximately) in normal saline (0.85 per cent) hæmolyzed the washed red blood cells of the rabbit (in half an hour); 1 drop of vitex per 10 c.cm. prevented the saponin hæmolysis.

3. *Bile salt hæmolysis.*—The washed red blood cells of the rabbit were completely hæmolyzed by bile salt (sodium taurocholate was used) in a concentration of 0.5 mg. in 10 c.cm. (i.e. 1 in 20,000) of 0.85 per cent of normal saline. Addition of 1 drop of vitex per 10 c.cm. of the hæmolytic solution entirely prevented hæmolysis.

4. *Cobra venom hæmolysis.*—Vitex proved to be an efficient anti-hæmolytic agent to the hæmolysin of the cobra venom (1 drop of 1 in 500 in 10 c.cm. of 0.85 per cent saline).

5. *Acid hæmolysis.*—Addition of 1 drop of vitex per 10 c.cm. was found to resist the hæmolysis caused by

inorganic acid (1 in 1,000 of hydrochloric acid in normal saline).

II. *In vivo* experiments

(a) Osmotic resistance of the hare red blood cells was increased after vitex given intramuscularly. The effect attained its maximum after about two hours; then gradually diminished; by the fourth hour the red cells had reverted almost to the pre-injection condition of resistance. In one animal the osmotic resistance was estimated 24 hours after the injection; no effect persisted. Very little or no effect was observed within an hour of injection.

Acid and saponin hæmolysis.—Injection of vitex intramuscularly in the hare increased the resistance of the red cells against hæmolysis by both these agents.

Effect after oral administration

Osmotic resistance of the hare red blood cells was slightly increased after oral administration. The effect, more evident with the higher dose (1 c.cm.), was maximum after 2 hours and disappeared by the fourth hour.

III. Physical effect on blood and red cells

The red cell charge, packed volume of the red cells and the viscosity of the blood before and after vitex have been studied in some instances. The preliminary results strongly suggest that the action of vitex is directly on the red cells, very likely on the surface of the cells.

Discussion.—There now seems to be a *prima facie* case for testing the anti-hæmolytic property of vitex in those pathological conditions characterized by increased disintegration of the red cells. The mechanism of hæmolysis in blackwater fever has not yet been established beyond doubt, but it may be assumed that in blackwater fever, as in malaria, the red cells are less resistant to lysis (but not always to hypotonic saline). Vitex will probably make the red blood cell more lysis-resistant. It is an observed fact that in blackwater fever the hæmolytic crisis occurs suddenly without any premonitory sign and hence vitex cannot be used to cure the resultant hæmoglobinæmia with its associated symptoms, but if it were possible to use vitex prophylactically it seems possible that it would prevent the blackwater fever. It is true that we have no means of knowing beforehand those cases of fever which will develop into blackwater fever, but there is ample reason to believe that *Plasmodium falciparum* (malignant tertian) infection, if treated irregularly with quinine in endemic areas, often develops into blackwater fever. It is undoubtedly true that in many cases the use of quinine precipitates an attack of blackwater fever. We believe that the use of vitex in these cases in a prophylactic manner, before giving quinine, is justifiable. It has also been observed that, after the hæmolytic crisis the osmotic resistance of the remaining red cells is higher (Ott, 1932). This is due to the escape of the normally more resistant cells from hæmolysis. But the new cells that are being added to the circulation will have a population with the usual proportion of less resistant cells. The previously more resistant cells are also becoming less

SEARCH FOR AN ANTIMALARIAL DRUG IN THE INDIGENOUS MATERIA MEDICA

PART I—*Alstonia scholaris*, F. Br.

By B. MUKERJI

B. K. GHOSH

and

L. B. SIDDONS

(From the Biochemical Standardization Laboratory, and the School of Tropical Medicine, Calcutta)

Introduction

THE possible shortage of quinine, which has remained the mainstay of the physicians in the treatment of malaria for nearly three centuries

(Continued from previous page)

resistant. *Vitex* will possibly inhibit hæmolytic of the more vulnerable cells and will thus prevent relapse of the hæmolytic crisis, diminish the increased disintegration of red cells which is usual in this disease, and thus improve the condition of the blood.

Conclusion

We are now in a position to answer the question quoted above—'It is conceivable that there might be some specific drug that would prevent further hæmolytic and would, therefore, if used prophylactically, prevent the initial attack. Is *Vitex peduncularis* such a drug?' The plant appears to contain some substance or substances with these properties.

It would be unwise from the data given here to draw definite conclusions regarding the value of *Vitex peduncularis* in the prophylaxis or treatment of blackwater fever. So far we have studied only its action on the red cells of healthy animals. Similar work is now being attempted in man in health and disease.

Summary

1. *Vitex peduncularis* increases the osmotic resistance of the red blood cells of animals.
2. It inhibits hæmolytic by saponin, acid, cobra venom and bile salts.
3. It is absorbed when given intramuscularly, the maximum effect being attained within two hours; the injection is apparently without any toxic effect.
4. Absorption through the alimentary tract may take place but the rate is extremely slow and depends on the size of the dose.
5. It is assumed that the action is on the red blood cell surface.

since the discovery of cinchona bark, has naturally stimulated new interest in the search for substitutes which can be used with the same degree of efficiency as quinine. In view of the already established antimalarial value of synthetic derivatives, e.g., Atebrin (Mepacrine Hydrochloride, B. P. Addendum, 1940) and Plasmochin (Pamaquin, B. P. Addendum, 1940), attempts have been made in India to synthesize these products and it is reported that a certain amount of success has already been achieved in this direction. The limitation of synthetic antimalarials, as far as production in India is concerned, is obvious, in that quite a large number of basic and intermediate chemicals necessary for synthesis have to be imported from foreign countries. It seemed worth while, therefore, to explore, by modern scientific methods of investigation, the possibilities of finding a substitute, if possible, from the indigenous materia medica. A number of natural drugs have enjoyed a local reputation as febrifuges and antimalarial remedies for a long time. The present paper deals with one member of this group, *Alstonia scholaris* (N. O. Apocynaceæ), the vernacular (Hindi and Bengali) synonym of which is 'chhatim'.

General description, chemistry, pharmacology, etc.

Alstonia scholaris is a tall evergreen tree widely cultivated throughout India and found in the sub-Himalayan tract from the Jumna eastward ascending to 3,000 feet. The tree is also found in abundance in Bengal. The bark of the tree has been reputed in the Hindu medicine for ages as a febrifuge, alterative, tonic and gastro-intestinal sedative. There is hardly an Ayurvedic prescription for acute and chronic fever or diarrhoea where 'chhatim', in some form or other, is not used. It was also recognized in the B. P. 1914.

An uncrystallizable bitter principle called 'ditain' was isolated and the febrifugal properties of the drug were ascribed to this principle by earlier workers. Later investigations showed that the following constituents were probably present: (1) an alkaloid, ditamine, (2) a substance resembling an alkaloid, (3) a crystallizable acid and (4) a fatty acid and resinous substances. Bacon (1906) found the presence of two alkaloids, 'ditamine' and 'echitamine'. Goodson and Henry (1925) reported that the principal alkaloidal constituent of *A. scholaris* and other allied species such as *A. congesta*, *A. gillettii*, *A. angustiloba* and *A. spathulata* was 'echitamine', ($C_{22}H_{28}O_4N_2$). This alkaloid, however, was found to be absent in other representatives of the Alstonias, e.g., *A. constricta*, *A. macrophylla* or *A. villosa* (Goodson, 1932). Sharp (1934) reported the presence of 4 alkaloids in *A. constricta*, of which 'alstonine' was considered the chief one and was obtained in crystalline form as sulphate.

Bacon (*loc. cit.*) studied the pharmacological action of echitamine on unicellular protoplasm represented by amœbæ. Exposed for 2 hours in a 1 per cent solution, amœbæ were reported to have thrived well and the conclusion was drawn that echitamine would not act as a protoplasmic poison like quinine or emetine. Goodson, Henry and Macfie (1930) tried the alkaloids, 'echitamine', 'ditamine', 'akuammine' and 'harmine', in bird malaria and found them inactive, except 'echitamine' which produced feeble action in doses of 5 mg. per dose. Buttle (mentioned by Sharp, *loc. cit.*) recorded the inactivity of alstonine sulphate in bird malaria.

Experimental

(a) *Separation of total alkaloids.*—In view of the conflicting and partly inconclusive data with regard to the efficacy of individual alkaloids of the *Alstonias*, it was decided to carry out our investigations first with purified total alkaloids of *A. scholaris* obtained from Bengal and, in the event of positive findings, to follow up the work with various related individual alkaloids which could be isolated in a pure state, by following the detailed method employed by Sharp (*loc. cit.*) in the case of *A. constricta*. The method followed for the extraction of total alkaloids is given below :—

About one and a half kilograms of powdered bark were moistened with rectified spirit and extracted in a percolator for several days until exhausted. The solvent was removed and the black viscous residue was extracted with 0.5 per cent H_2SO_4 . The aqueous extract was filtered from insoluble resinous and fatty matter, diluted with water, allowed to settle and again filtered. The filtrate was shaken out with ether several times in order to remove the soluble impurities. The aqueous layer was then transferred to a second separator, chloroform was added, the solution made alkaline with Na_2CO_3 , and extracted several times with fresh chloroform. It was then made strongly alkaline with 20 per cent $NaOH$ solution and further extracted with chloroform until completely exhausted. The mixed chloroform extract was then evaporated to a small bulk and the total alkaloids were taken up by acidulated water (0.5 per cent H_2SO_4). This process was repeated again for purification. Finally, the chloroform extract was evaporated to dryness in a vacuum and neutralized with alcoholic sulphuric acid. The yield was found to be approximately 0.3 per cent of the bark.

(b) *Pharmacological studies.*—A 1-2 per cent solution of the sulphate of the total alkaloids (TAS) was used in these investigations. The important point to find out was whether the toxicity of the total alkaloids would lie within such dose range as to enable it to be used therapeutically without the possibility of any untoward toxic reactions and no attempt was therefore made to work out systematically the minimum lethal dose. It was found that a dose of 20 mg. per kilo. could be well tolerated in the monkey and about 10 mg./kg. in the cat.

Administered intravenously in the anesthetized cat (chloralose or urethane) in a dose of 4-8 mg. per kilo., a slight fall followed by a rise in blood pressure is produced. The fall in blood pressure is not much affected by atropinization. In spinal cat preparations, a distinct but temporary rise of about 10-15 mm. Hg. is noticeable. This points to a predominance of the central effect to the parasympathetic effect of the drug in bringing about the fall of pressure. The muscular effect of TAS may also be important, as will be evident from the fact that an increased tone and contraction is often observed in isolated rabbit or guinea-pig uterus in as low a dose as 1 in 20,000 to 1 in 10,000. Isolated rabbit intestine also gives indications of stimulation in a concentration of 1 in 20,000. Isolated frog heart is

mildly stimulated in 1 in 10,000; in higher concentrations, a depression with measurable diminution of the outflow of the perfusate is observed.

(c) *Chemotherapeutic studies.*—These were carried out on rhesus monkeys (*Sillemus rhesus*) weighing between 2.5 to 3.0 kilo. infected with *Plasmodium knowlesi*. The inoculum consisted of 1 c.cm. infective blood given intraperitoneally. Injections of TAS in different dosages were given intramuscularly at various stages of the infection. Regular parasite counts were made once a day and sometimes twice a day. Control experiments were run side by side with quinine administered by the intramuscular route. It was found that TAS failed either to retard or to control the progress of infection. If the injections were made when the infection was fairly advanced (say, about 2,000 parasites per 10,000 red cells), the monkeys died invariably, as would have been the case had no treatment been administered at all. Contrary to the findings of Goodson, Henry and Macfie (*loc. cit.*) with echitamine, even a prolongation of the period of survival (when compared with control animals) could not be noticed. Attempts were made to save the animals by intravenous quinine in the late stages but this was ineffective in most cases. In some of the later experiments, quinine was given earlier when the infection was milder (about 1,000 parasites per 10,000 red cells) and in such instances, it was possible to save the animals or establish a chronic infection. The results of a representative series of experiments are given in the following table on the opposite page.

(d) *Clinical studies.*—It is a popular belief in Bengal and some other parts of India that genuine 'chhatim' (dita bark), if administered in the form of a decoction ('pachan') according to strict Ayurvedic principles, is almost as effective as quinine. In Manila Hospital, the results of trials in malaria cases were reported to be very satisfactory and it was opined that it would completely replace quinine in malignant tertian fevers (Chopra, 1933). The drug was also tried in India in 14 cases of malaria at the instance of the Indigenous Drugs Committee, Madras, 1921, in all of which it caused the temperature to fall steadily to normal in a short time. Treatment for a few days only was sufficient to cure the patients. In all these early reports, no definite proof was given that the cases treated were truly malarial in origin. Presumably purely clinical spot diagnosis was the criterion employed without any laboratory examination of the blood for the presence of parasites. It is therefore difficult to give much credence to such findings.

During the period that the chemotherapeutic studies were proceeding, a tincture (1 in 10), containing approximately 1.3 gr. TAS per ounce, was prepared from the powdered bark of *Alstonia scholaris* and this was administered in doses of one ounce thrice daily in a few patients suffering from malaria. Authentic records of only 6 cases are available, but more than a dozen patients were treated. In 4 cases, malarial infection was definitely proved by the demonstration of parasites (BT parasites in one and MT parasites in three). In 2 cases, the presumption was drawn from symptoms and previous history associated with palpable spleen but parasites were not detected in the peripheral blood, at the time of admission. In none of these cases, according to the opinion of the physicians in charge, did the tincture of alstonia produce any remarkable febrifugal effect or alter in any significant way the course of the disease. The temperature chart of 3 patients, however, showed a distinct drop in fever almost immediately following or about half hour after doses of the tincture were administered. The patients appeared during these periods to be comparatively free from subjective symptoms such as headache, nausea, etc. On critical examination, this mild reduction in temperature has been ascribed by the physicians to simultaneous coincidence rather than to any direct effect of the drug. At any rate, no demonstrable anti-malarial action could be proved. It is possible that the slight reduction in temperature may be the result of central action of TAS contained in the tincture, as is

TABLE

Alstonia scholaris alkaloids in monkey malaria (*P. knowlesi*)

Serial number	Weight of monkey and date of inoculation	Date of commencement of treatment	Daily dosage in mg. and number of daily doses	NUMBER OF PARASITES PER 10,000 R.B.C.		REMARKS
				Before treatment	During treatment	
I	2.5 kilo, 23-5	27-5	(1) 50 (2) 50 (3) 60 (4) 80 4	840	(1) 3,590 (2) 5,600 (3) 6,820 (4) 6,920	Quinine gr. 2 given on 1-5. Monkey found dead 2-5 morning.
II	2.5 kilo, 12-6	14-6	(1) 50 (2) 50 (3) 50 3	5	(1) 220 (2) 460 (3) 2,430	Quinine gr. 1 given on 17-6. Monkey found dead 18-6 morning.
III	2.6 kilo, 17-6	20-6	(1) 50 (2) 50 2	50	(1) 350 (2) 1,410	Quinine gr. 1 given daily 22-25-6. Parasite counts:—1,840—130 (26-6), 230 (30-6)—70 (9-7) chronic infection established.
IV	3.0 kilo, 20-6	22-6	(1) 60 (2) 60 2	120	(1) 320 (2) 1,220	Quinine gr. 1 given daily 24-28-6. Parasite counts:—1,440-120 (1-7), 60 (2-7)—nil.

observed after the administration of centrally-acting antipyretics.

Summary and conclusions

Careful investigations in the laboratory and in the clinic of the total alkaloids isolated from *Alstonia scholaris* (N. O. Apocynaceæ), and also of a tincture (1 in 10) made from the powdered bark show that, contrary to popular belief and the earlier records of clinical trials with the drug, *Alstonia scholaris* has little or no demonstrable action in malaria induced in monkeys or naturally occurring in human patients. It cannot therefore be recommended as a substitute for quinine and other cinchona alkaloids.

Acknowledgment

The authors would like to record their thanks to Dr. L. E. Napier, Director, School of Tropical Medicine, for permission to carry out this collaborative study, and to Professors S. Ghosh and B. M. Das Gupta for placing the facilities of their respective laboratories at the disposal of the workers.

ECONOMY AND SIMPLIFICATION IN THE STAINING OF BLOOD SLIDES

By A. T. W. SIMEONS, M.D.

(Medical Officer, Satara Parole Camp)

With the Technical Assistance of E. Koechler

THE stains commonly used for staining blood films (Giemsa's, Wright's, Leishman's, etc.) have become expensive, and in many cases difficult to obtain. In order to get the best results with these stains, acetone-free alcohol and distilled water of a specified pH are necessary. This again increases costs and complicates technique. Furthermore, films, and particularly thick-drop slides, are usually stained by flooding, which means that the stain is discarded after having been used for a single slide only.

It is the object of this paper to show how a stain devised by Boyé (1940)—during the present campaign in North Africa—for the staining of thick drops can be used in such a way as to make it suitable for routine laboratory blood-film staining in all cases in which the Romanowsky stains are generally used.

The advantages of the methods we are about to describe are that:—

- The stain itself is 'home-made'.
- It contains no alcohol.
- It is suitable for staining by immersion instead of flooding.
- It does not appear necessary to be fastidious about the pH of the distilled water employed in its manufacture.
- It improves with use.
- It reduces the time required for processing drops and films to a matter of seconds.
- The results are perfectly satisfactory for all routine clinical work.

The stain consists of two solutions which, following Boyé's (1940) and Stévenel's (1918) directions, are prepared as follows:—

Solution 1 (eosin solution)

Eosin pure	1.0 gm.
Distilled water	1,000.0 c.cm.

Solution 2 (Stévenel's blue)

1. Medicinal methylene blue .. 1.0 gm.
Distilled water .. 75.0 c.cm.
(Dissolve completely.)
2. Potassium permanganate .. 1.5 gm.
Distilled water .. 75.0 c.cm.
(Dissolve completely.)
3. Mix (1) and (2) in a flask. A massive precipitate forms at once. (In the abstract of Stévenel's paper, it is said that almost complete decolorization of the liquid takes place. If this is meant to imply that it becomes colourless, we must mention that we have never observed this. The mixture changes colour through various shades of violet, but we have never seen it become colourless; perhaps *discoloration* is meant.)
4. The flask is kept in a water-bath at boiling point for half an hour during which the precipitate re-dissolves.
5. Filter. The stain is now ready for use: it requires no further dilution.

For staining single slides, we use small glass cylinders $1\frac{1}{2}$ inches in diameter and $3\frac{1}{2}$ inches high, which, when not in use, are closed with greased watch-glasses to prevent evaporation. The contents of these cylinders decrease very slowly through the lifting out of wet slides. The loss is replaced by adding from stock. Apart from these small additions, we have stained more than a hundred slides with about 60 c.cm. of each stain before we have noticed the slightest evidence of deterioration. In fact, the more the stain is used, the better it appears to become. This does not seem to be due to 'ripening', as old stock is not as good as well used solution. The improvement is possibly due to the transfer, in spite of rinsing, of traces of eosin to the Stévenel solution, and *vice versa*. The water adhering to the slide after rinsing appears to be sufficient to counteract any change in concentration of the stain due to evaporation.

With this stain we have been able to discontinue altogether the use of distilled water for rinsing. We use boiled or stored tap water only. Water, as it comes from the tap in Satara, cannot be used as it is too highly aerated after passing through a hydro-electric plant before distribution, and therefore covers the slides with a layer of air-bubbles.

We fix our thin films by immersion for one minute in a cylinder—similar to those used for the stain—containing ordinary rectified spirit. We have found that, in an emergency, commercial methylated spirit serves the purpose almost as well, the same spirit being used repeatedly. We have found that a satisfactory dehaemoglobinization of thick drops can be obtained by immersion in tap water without risk of the 'drop' becoming detached from the glass.

It is, however, necessary that the following precautions be scrupulously observed:—

(a) The slides must be perfectly cleaned by boiling in soapy water, and subsequently rinsed

(b) They must be kept quite free from finger-prints, by handling at the edges only.

(c) Care must be taken to avoid touching the patient's finger with the slide when charging it with blood.

(d) The drop must be evenly and finely spread and allowed to dry properly in a horizontal position.

The time required for dehaemoglobinization depends on the thickness of the drop and on the time it has been allowed to dry. If it is dehaemoglobinized as soon as it appears dry, one minute is usually sufficient. If some hours elapse after taking the blood, or if the film is very thick, it may take 5 to 10 minutes. Dehaemoglobinization is complete when the blood has lost all colour and is hardly visible.

We always clean the skin for puncture with commercial petrol which, apart from its cheapness, has better cleansing properties and is a more effective grease solvent than alcohol.

We have found the ordinary lance eraser no. 4 manufactured by Perry & Co., and widely used for retouching photographic negatives, by far the most satisfactory instrument for puncturing the skin. These erasers can be bought from any stationer like ordinary nibs and are so cheap that they can be discarded as soon as they get blunt. They are readily sterilized in any number which saves time in mass work. They make a superficial, clean cut which produces a far better flow of blood, and hurts less than a prick. They are very suitable for spreading thick drops. It is impossible to spread a thick drop evenly with a needle.

For the immersion method of staining, the end of the film should be well in the second half of the slide as this is the most important part, both for differential counting and malaria parasites (see figure 1-a).

Fig. 1.

A. Correct shape and position of thin film. The slides are immersed up to the dotted line, and identified with grease pencil beyond the line.

B. Correct position and size of thick drops. Two drops should be made. In the figure, the first drop shows the correct size before spreading as it should be taken from the puncture. The second drop shows the size to which it should be spread with the lance eraser.

The thick drops should be placed and spread as shown in figure 1-b. It is important that the drop should be small, and left to dry in a horizontal position flat on a table.

Procedure for staining thin films

1. Fix by immersion in spirit ..	1 minute	4 seconds
2. Rinse with tap water ..		
3. Immerse in eosin solution ..	10	"
4. Rinse with tap water ..	4	"
5. Immerse in Stévenel blue ..	15	"
6. Rinse with tap water ..	4	"
7. Immerse again in eosin solution ..	5	"
8. Rinse with tap water ..	4	"

Total time required .. 1 minute 46 seconds

Allow to dry in upright position.

Procedure for staining thick drops

1. Dehaemoglobinize by immersion in tap water in beaker no. 1 ..	1 minute	
2. Immerse in eosin solution ..		20 seconds
3. Rinse by dipping into tap water in beaker no. 2 ..	4	"
4. Immerse in Stévenel's blue ..	30	"
5. Rinse by dipping into tap water in beaker no. 3 ..	4	"
6. Immerse again in eosin solution ..	10	"
7. Rinse by dipping into tap water in beaker no. 2 ..	4	"

Total time required .. 2 minutes 12 seconds

The microscopic appearance of such slides is almost the same as we obtain with the Romanowsky methods, the only difference being that eosinophil leucocytic granules have an orange tinge instead of the usual brick-red. All nuclear and protoplasmic characteristics of leucocytes and lymphocytes are beautifully clear and typical. Malaria chromatin appears a bright ruby colour, and the protoplasm pale blue. The latter stands out clearly from the red cells. Malaria pigment is black, and crescents are indistinguishable from those obtained with a perfect Giemsa's stain.

In the thick drop, malaria parasites usually appear somewhat different from those in thin films, owing to the process of dehaemoglobinization. MT rings look like a semicolon with the comma lying in a horizontal position. The dot is bright red, and the comma light blue. Crescents appear the same as in thin films. BT parasites are irregularly shaped and frequently show no clear outline, but they are very easy to recognize by the combination of blue protoplasm, red chromatin, and black pigment. In quartan, the pigment has a golden tinge. The characteristic band-forms do not appear in the thick film. There is for practical purposes no difference between a really good Giemsa-stained thick drop and the result of the method we have described. As the thick-drop method is still not very popular in India, we may be permitted to remark that its great advantage lies in the fact that it makes a positive malaria diagnosis possible with a single glance through the microscope. Even in a very mild infection in which it may be necessary to make a long search in the ordinary film, 1 to 2 parasites are usually found in every field in the thick drop. In medium and heavy infections,

they are correspondingly more numerous, 20 to 40 parasites per field being quite common. It has been our experience that if 15 fields show no parasites in a properly made and well-stained thick drop, a negative report may be returned with confidence. When examining a thick drop, it is advisable to work from the edge towards the centre, because at the edge there is no visible red corpuscular residue so that the malaria parasites and the leucocytes appear on a clear background. With a little practice it is possible to examine and diagnose correctly 25 thick-drop slides in 15 minutes; if the percentage of positives is high this can be done in still less time. Hitherto the disadvantage of the thick film was that really good slides could be obtained only by Giemsa's method, and this required half an hour for staining. With the rapid method here described this drawback has been overcome.

The present necessity for strictest economy in the prescribing of antimalarial remedies makes it necessary to explore every route by which antimalarial drugs can be saved. One very important source of waste is the indiscriminate prescribing of quinine for undiagnosed fevers. In places where microscopic facilities are available it should be possible to insist on an exact diagnosis by blood examination and to restrict the prescribing of quinine to those cases in which parasites are found. This would result in a very considerable saving of quinine. Caplan (1942) in this journal has already called attention to the importance of parasitological diagnosis as a method of saving quinine. He compares statistics which are so illuminating that we cannot resist the temptation of quoting him:—

'Hospitals A and B dealt with an equal number of patients from the same localities. Hospital A performed about 80 blood examinations every year and B about 5,000. During the same year Hospital A reported over 11,000 cases of malaria and Hospital B under 800.'

This means that in Hospital A over 10,000 cases were unnecessarily treated with quinine in a single year. If we calculate that each case received the quite inadequate dose of 5 grammes, the total waste of quinine would amount to about 5 kilograms (or over 10 lb.) of quinine. If each case received an adequate quantity of quinine the waste in a single hospital would amount to 15 to 25 kilograms (over 30 to 50 lb.) per annum. The quantity usefully employed in actual cases of malaria would be less than one-tenth of the total consumption. It can be fairly said that, in India, Hospital A is the rule and Hospital B the exception. The resulting stupendous waste of a priceless drug could be eliminated to a great extent if microscopes were used to capacity for parasitological diagnosis.

Such a proposal is, however, usually met with the objection that in busy out-patient departments there is neither sufficient staff nor time

to do blood examinations. In order to counter this argument, we have worked out a method by which large numbers of blood slides can be taken, stained, and examined in minimum time at nominal expense.

Fig. 2.—Tank 1. Tap water for dehaemoglobinizing. Tank 2. Eosin solution. Tank 3. Tap water for rinsing eosin. Tank 4. Stévenel's blue. Tank 5. Tap water for rinsing blue.

The necessary equipment (figure 2) consists of two small (9 inches \times 2 inches \times 3 inches) and three large (9 inches \times 5 inches \times 5 inches) enamel tanks (ours were very kindly made to specification, and supplied gratis by Messrs. Ogallie Glass Works, Ogalliewadi) and a clasp to hold 25 slides which are simultaneously processed. We have experimented with and constructed a large variety of clasps, and have found the following the most satisfactory:—

Twenty-five ordinary wire paper clips are threaded on to a snugly fitting metal core. The clips are separated from each other by $\frac{1}{4}$ -inch thick rubber washers cut from ordinary thick pressure tubing (such as is used for stethoscopes). The metal core must be 11 inches long, so that it can rest on the edges of the enamel tanks. It has a thread cut at each end over which a large winged nut is screwed. A steel washer is inserted between the rubber and nut. The nuts when screwed down compress the rubber washers so that they grip the paper clips firmly. This arrangement makes it possible to replace clips that have become worn out or bent.

Contrary to expectation, thin slides are so firmly held by these clips that the clasp can be shaken without any slides falling out. The slides should be inserted into the clasp sideways as shown in the illustration (figure 2). The large tanks contain tap water for dehaemoglobinizing and rinsing. The small tanks contain the staining solution. The tap water should be renewed after every 50 slides. The stains (600 c.cm. for each tank) should be renewed after every 1,000 slides. The staining process is the same as described above for single thick-drop slides.

Let us suppose that on a given day 25 patients, suspected to be suffering from malaria, attend an out-patient department. The procedure of blood examination would then be as follows:—

1. Collect the patients. Prepare 25 slides numbered with grease pencil 1 to 25, and place in rows on a table.

2. Take each patient in turn. Paint the number of his slide on the back of his hand with gentian violet (this saves paper and clerical work). Puncture finger after wiping with petrol swab. Wipe with dry cotton-wool. Charge slide with two drops. Spread drops with eraser and replace in row to dry (beware of flies). In this manner a practised technician can take blood samples from 25 persons in less than 15 minutes
 3. When dry, the slides are inserted in the clasp, stained as described above and again left to dry. Time required (drying excluded) 4 "
 4. Remove from clasp and examine microscopically. Place positive slides apart, or mark with grease pencil. Time required for examining 25 thick-drop slides for malaria 15 "
- Total time required for 25 blood examinations 34 minutes

In other words, a complete parasitological diagnosis of malaria requires approximately a minute and a quarter per case. This may sound incredible, but actually the times we have given are generous; a practised and dexterous technician can work faster still, particularly if he is assisted by an intelligent servant. Where larger numbers of slides are processed the average time for each slide is still further decreased by working with overlapping series of twenty-five.

We feel that this amount of time can be devoted to malaria cases in every out-patient department equipped with a microscope. The thick-drop method of serial examination is so simple that it does not require the attention of a senior medical officer. Even unqualified technicians can be most reliable if properly instructed.

If a shortage of antimalarial remedies forces us to popularize the parasitological diagnosis of malaria, it will at least have one welcome consequence.

Summary

1. Preparation of a new, simple, and cheap stain devised by Boyé is described.
2. Measures for economy in the preparation of slides are discussed.
3. Procedures for staining thin films for differential leucocyte count and malaria parasites are described.
4. Procedures for staining thick drops for malaria parasites are described.
5. General remarks on thick-drop examination are made.
6. A quick, cheap and simple method of serial blood examination for malaria is suggested with the object of encouraging parasitological diagnosis as a means of economizing anti-malarial remedies.

[Note.—This method of staining has been tried by us, and found excellent for thick films, and useful but not ideal for thin films.—EDITOR, I. M. G.]

AN INVESTIGATION INTO THE TOXICITY OF SULPHANILAMIDE IN ALBINO RATS AND THE PROTECTIVE EFFECT OF NICOTINIC ACID

By B. B. ROY, M.B. (Cal.)

*Demonstrator of Pharmacology,
Carmichael Medical College, Calcutta*

THE introduction of the sulphonamide group of drugs of which the parent substance is sulphanilamide (p-amino benzene sulphonamide) marked a renaissance in chemotherapy and these drugs have a wide clinical applicability to-day. As to every other chemotherapeutic remedy a number of toxic reactions has been ascribed to them. These reactions are many and varied and, in some instances, of a serious nature. Most of the symptoms, *e.g.*, headache, vertigo, anorexia, nausea, vomiting, general malaise, palpitation, prostration, cyanosis, etc., are relatively mild. More serious are skin reactions with the occasional occurrence of exfoliative dermatitis and lesions of the hæmopoietic system such as agranulocytosis, acute hæmolytic anæmias, jaundice, etc. A number of other symptoms has been reported which include stomatitis, diarrhoea, peripheral neuritis and psychoses.

Various measures have been advocated to guard against the danger of undesirable toxic effects following the administration of sulphonamides. Of these the following may be mentioned: avoidance of sulphur in any form and purgatives in general (except liquid paraffin) with the object of preventing the formation of sulphæmoglobinæmia; methylene blue (Wendel, 1939) has been of value in removing the cyanosis due to methæmoglobinæmia; the administration of sodium lactate (Hartmann, Perley and Barnett, 1938a) and sodium bicarbonate (Lucas and Mitchell, 1939) has been suggested to prevent fall in CO₂ capacity and to counteract acidosis and renal injury, but the use of the latter as a routine measure has been criticized (Hartmann *et al.*, 1938b); acute toxic symptoms produced by sulphanilamide have been found to be reduced by the simultaneous administration of sodium acetate (James, 1939, 1940); vitamin C (ascorbic acid) has also been reported to be effective in preventing undesirable reactions (Dainow, 1939); vitamin B₁ (thiamin chloride) has been suggested by Findlay (1939). According to McGinty, Lewis and Holtzclaw

(1939) and Cottini (1940), nicotinic acid (β -pyridine carboxylic acid) has been successfully used for the same purpose.

The object of the present investigation was to observe the effect of the administration of nicotinic acid on acute toxic reactions produced by sulphanilamide in rats. It is now known that patients treated with sulphanilamide excrete porphyrin in the urine which has been found to be chiefly porphyrin of type III (Rimington and Hemmings, 1938). Rimington and Hemmings (1939) after further work have tentatively suggested that sulphanilamide, by causing methæmoglobinæmia and increased destruction of erythrocytes, brings about an increased excretion of type III porphyrin derived from the broken-down blood pigment, and have pointed out that the porphyrinuric action of drugs of the sulphonamide group appears to run parallel with their toxicity. The toxic reactions produced by sulphanilamide bear a certain resemblance to the manifestations—both the premonitory symptoms and the diagnostic syndrome—of pellagra. In pellagra there is also an increased excretion of porphyrin type III (Editorial, 1939) and nicotinic acid has a curative action in this disease. These facts indicate that nicotinic acid may have a protective effect against the toxic manifestations produced by sulphanilamide.

Experimental

Various doses of sulphanilamide were used to determine the lethal dose for rats. The 'characteristic mortality' produced by different doses was studied, and the median lethal dose (LD 50) was ascertained. The latter is the dose which will kill 50 per cent of a sufficient number of animals (Trevan, 1927). The possibility of modifying the mortality of rats receiving LD 50 by the administration of nicotinic acid was then studied. In one group of experiments, the median lethal dose was given as a single dose preceded and followed by the administration of nicotinic acid. The latter was given 2 to 3 hours before, and 4 to 6 hours after, the dose of sulphanilamide. In another group of experiments, the median lethal dose of sulphanilamide was given in three portions within a period of 24 hours, each administration being preceded by a dose of nicotinic acid given 2 to 3 hours before. The idea underlying the second group of experiments was that the sudden administration of a heavy dose of sulphanilamide might exert a toxic effect too rapidly for an antidote to exert a protective action.

The animals used were rats of the albino stock of the Nutrition Research Laboratories, Coonoor. Both male and female rats were used, the body weights varying from 60 to 150 grammes. The animals were fed on a diet consisting mainly of rice and poor in nicotinic acid. Sulphanilamide tablets (Parke, Davis & Co.—p-amino benzene sulphonamide) were pulverized, and the requisite quantity, calculated on the basis of body weight, was given orally

STEVENEL, L. (1918) .. *Bull. Soc. Path. Exot.*, **11**, 870.

to fasting animals in the form of a pellet made with a little sugar and water. There was no difficulty in giving the animals sulphanilamide in the manner described. The amount of nicotinic acid given daily as an antidote was 625 μ g. throughout the investigation. This was administered in solution by mouth through a graduated pipette. The choice of this average dose was reached after a consideration of doses in cases of human pellagra as suggested by Spies (500 mg. daily) and also depended on the fact that preliminary observations showed a dose of this order to be innocuous.

Median lethal dose

The toxic effect produced by the oral administration of various doses of the drug was studied in 104 rats. The results are shown in table I and represented graphically in figure 1.

TABLE I

Mortality resulting from various doses of sulphanilamide

Dose per kg. of body weight.	Number of rats used	Number dying	Percentage mortality
3.5 grammes	10	0	0.0
4.5 "	24	5	20.8
5.5 "	30	15	50.0
6.5 "	25	19	76.0
7.0 "	15	13	86.6

Fig. 1

The expected mortality from any given dose, and vice versa, can be ascertained from the figure. The LD 50 was 5.5 grammes per kilo

of body-weight. Statistical calculations indicate that the actual range of the number of expected deaths at this level of dosage was 15 ± 8.22 , or, expressed as a percentage, 50 ± 27.4 , with an approximate probability of 0.9973. Conversely, the range of possible doses which give rise to a mortality of 50 per cent is 5.5 ± 18.15 per cent, i.e., from 4.6 to 6.6 g. per kilo of body-weight.

These figures for lethal doses are not in agreement with those obtained by other workers for rats. Halpern and Mayer (1937) reported LD 90 to be 4 g./kg. In the experiments of Murayama and Leake (1938) doses of 4, 5, 6, 8 and 10 grammes per kg. produced mortality rates of 20, 29, 36, 40 and 50 per cent respectively. The results of the present investigation correspond, in general, to those of Molitor and Robinson (1939), who found LD 50 to be 6.2 g. It is difficult to explain the cause of these wide variations. Age has been mentioned by Molitor and Robinson (*loc. cit.*) as a possible factor in variation. It is possible that the strain of rats used and their diet may have some significance. In one experiment (not reported in this series) it was found that a group of rats receiving a diet of wheat and milk was definitely less susceptible to the toxic action of the drug than rats fed on the rice diet.

Acute toxic reaction.—The signs of the acute toxic reaction leading to death were as follows :—

The effects of poisoning appeared in 2 to 8 hours, usually between 3 and 4 hours. The animals became less active, but showed suggestions of 'agitation'. They refused food. Thirst developed. Even in the early stages the rate of respiration was obviously increased. Later, the animals became more restless, showing diverse purposeless incoordinated movements. Weakness and paralysis of the limbs followed. At this stage severe clonic convulsions lasting a few seconds usually occurred. The convulsions gradually diminished in frequency, and the animals passed into a comatose state with limbs extended and rigid, with very rapid respirations. Death ensued. Some animals showed bleeding from the gums and the nose. Most of the deaths occurred between 24 and 48 hours after administration of the drug. The earliest time was 12 hours and the latest 74 hours.

The protective effect of nicotinic acid in rats receiving 5.5 g./kg. of sulphanilamide (LD 50)

Further experiments were carried out in which the protective effect of nicotinic acid was investigated. In these experiments, groups of animals similar in age and sex composition were observed, one group receiving 5.5 g./kg. of sulphanilamide only and another group nicotinic acid in addition to this dose of sulphanilamide. The results obtained in experiments in which sulphanilamide was administered as a single dose are shown in table II.

TABLE II

Effect of nicotinic acid on mortality from sulphanilamide poisoning

Group	Number of animals	Number of deaths	Percentage mortality
Receiving sulphanilamide only.	30	15	50.0
Receiving sulphanilamide + nicotinic acid.	30	7	23.3

The difference in the percentage mortality in the two groups is statistically significant at a 0.03 level of significance.

In another group of experiments, the median lethal dose of sulphanilamide was given in three portions. Here a distinction was made between severe and mild toxic reactions and the groups were compared on this basis. The absence of convulsions and recovery was taken as the criterion of a mild reaction. The results are shown in table III. Animals showing mild manifestations include those showing no toxic signs at all, while a number of animals dying (figures in parenthesis in table III) is included in the group showing severe reactions.

TABLE III

Effect of nicotinic acid on the exhibition of mild and severe reactions to sulphanilamide poisoning—LD 50 administered in divided doses

Group	Number of animals	Mild reaction	Severe reaction	Percentage of severe reactions
Receiving sulphanilamide only (divided doses).	30	9	21 (6)	70.0
Receiving sulphanilamide + nicotinic acid.	30	16	14 (3)	44.6

N.B.—Figures in parenthesis indicate deaths.

Statistical analysis showed the difference in the percentage of severe reactions in the two groups to be statistically significant, at 0.01 level of significance.

It will be observed that the mortality in the 30 animals receiving sulphanilamide in divided doses (table III) was 6, while that in the 30 animals receiving the same amount in single dose without any nicotinic acid (table II) was 15. The difference is striking and shows that the administration of a single heavy dose of the drug is more dangerous than the same dose given in divided portions. In clinical practice, the drug is usually given in small and divided doses, and deaths during therapy are rare. In

the second group of experiments, in which sulphanilamide was given in divided doses, conditions thus correspond more closely with those obtaining in clinical practice, and here the efficacy of nicotinic acid in preventing severe toxic reactions was strikingly apparent.

Discussion

The following lethal doses of sulphanilamide for different animals have been reported by various observers :—

Animals	LD 50 g./kg. (oral)	Authors
Rabbit ..	2.0	Raiziss <i>et al.</i> , 1937.
Guinea-pig ..	2.5	Domagk, 1935.
Mice ..	3.5	Marshall <i>et al.</i> , 1938.
Rats ..	6.2	Molitor and Robinson, 1939.

A similar figure (LD 50) for dogs is not available; the number of dogs used in experiments in sulphanilamide poisoning has been small. Halpern and Mayer (1937) found the oral toxic dose to be 1 g./kg. Molitor and Robinson (1939) reported that 2 g./kg. by mouth produced severe symptoms in all animals, but mentioned the important fact that after large doses the dogs usually vomited early and the experiments had to be discontinued. In general it may be stated that dogs are quite susceptible.

It is an interesting fact that rats should have a tolerance for the drug which other animals, especially dogs, have not. The fact that rats can synthesize nicotinic acid (Shourie and Swaminathan, 1940) may be of significance.

Reference has already been made to clinical observations on the beneficial effects of nicotinic acid on acute sulphanilamide poisoning. The results reported in the present investigation, as far as they go, support these clinical findings.

Summary

1. In oral toxicity experiments the LD 50 of sulphanilamide was found to be 5.5 (\pm 18.15 per cent) grammes per kilogram in rats.
2. Nicotinic acid when administered along with this dose of sulphanilamide (LD 50) to rats reduced mortality to a significant extent and limited the occurrence of severe reactions.

Acknowledgments

This investigation was carried out in the Nutrition Research Laboratories, Indian Research Fund Association, Coonoor, while the author was attending the nutrition class in 1941. He wishes to express his gratitude for the facilities offered and for help and encouragement. He acknowledges the help of Dr. W. R. Aykroyd in the preparation of the paper.

A CLINICAL SIGN IN SANDFLY FEVER

By J. C. SHEE, M.B., M.R.C.P. (Lond.)

CAPTAIN, R.A.M.C.

THE purpose of this paper is to describe a clinical sign which is easily elicited, and which appears to be present in the majority of cases of sandfly fever, and which, as far as I am aware, has not been recorded before. The sign consists of choking of the optic discs, which varies in its slighter manifestations from blurring of the edges of the discs, with distention of the retinal veins, up to a papilloedema with a swelling of about 2-2.5 D. Exudates or retinal hæmorrhages have not been observed.

The sign was observed in cases occurring in a non-immune group of British troops recently arrived from Britain, amongst whom the disease was of frequent occurrence.

Cases.—Of a total number of thirty cases which presented the clinical criteria of sandfly fever, the sign was present in twenty-seven. The three cases in which it did not occur were very mild with only very slight headache.

(Continued from previous page)

chief, again, for his constant encouragement and valuable advice in connection with this work.

The clinical criteria applied were (1) sudden onset often with rigor, (2) flushing of the face limited by the collar line, (3) injection of the conjunctivæ, (4) supra-orbital or post-orbital headache, with tenderness on pressure over the globes, (5) backache and stiffness in the back of the neck, (6) pyrexia of from 48 to 96 hours' duration, (7) bradycardia, (8) slight leucopenia, or normal white cell count (4,000-7,000 cells per cubic mm.), (9) Vesication of palate and fauces, thought to be inconstant and rather unreliable, (10) slow convalescence seen in some cases, (11) exclusion of any other infection, especially malaria.

Cases were seen within 6 to 48 hours of onset; the sign was present in the earliest cases seen, although it sometimes became more marked on the second day. The swelling of the disc was usually most obvious in the eye in which the globe was most tender, or on the side with the most severe supra-orbital or post-orbital pain. In the slighter cases the swelling subsided rapidly; in the more severe cases it was still apparent on the day after the patient had become apyrexial.

One case not included in the 30, which was considered clinically to be sandfly fever, and which showed papilloedema after a protracted convalescence, developed catarrhal jaundice on the 15th day. Another case also not included in the series, which showed the typical clinical picture with papilloedema, tenderness of the globes and a negative blood film, and in which the temperature showed a tendency to rise rather than settle, was then found on the third day to have subtertian ring forms in the blood. These cases I consider to have been possible examples of sandfly fever, with a concurrent or consecutive other disease, although cerebral malaria has been described as sometimes showing papilloedema associated with amaurosis.

Discussion

Visual acuity tests were not carried out in any case, but it was noticed that sandfly-fever cases were photophobic and generally averse to using their eyes, as in reading.

The papilloedema is probably due to the associated rise in cerebro-spinal fluid pressure which has been reported in this disease by Le Gac and Albrand (quoted in Manson's *Tropical Diseases*, 11th edition, 1941). Owing to the conditions (Indian Frontier) under which I saw the cases, cerebro-spinal manometry was not practicable, and as morphia gr. 1/6 hypodermically was invariably found to relieve the headache, lumbar puncture was not instituted in any case for the relief of this symptom.

Summary

(1) Some degree of papilloedema was observed in twenty-seven out of thirty cases of clinical sandfly fever.

(2) This sign taken in conjunction with the other clinical findings should be of assistance in the early diagnosis of the disease.

A Mirror of Hospital Practice

A CASE OF DIPHTHERIA OF THE GLANS PENIS

By JAGDISH SINGH, F.R.C.S. (Eng.), F.R.C.S.E.,
D.L.O. (Lond.)

First Surgeon to the Rajindra Hospital, Patiala

THE common sites for the occurrence of local lesion of diphtheria are the fauces, laryngeal and nasal mucous membranes. It is mentioned in books, however, that diphtheria may involve the genitals and the skin on any part of the body. I have not read the description of a case of diphtheria of the glans penis in the literature. The case described below is, therefore, of unusual interest.

History.—B. K., a Hindu boy of 5 years, was sent by his parents for an ulcer on the glans penis and sleeplessness. The ulcer was of 12 days' duration. Constant irritation interfered with the child's sleep.

Clinical examination.—On examination the child did not look seriously ill. There was slight sanious discharge from the orifice of the prepuce. Inguinal glands on both sides were moderately enlarged but not tender. The prepuce could be retracted without difficulty but it caused a good deal of pain to the little patient. There was an area $\frac{3}{4}$ by $\frac{1}{4}$ inch on the dorsum of the glans penis extending from the corona glandis to within a short distance of the external urinary meatus, covered with the typical greyish false membrane. The case was diagnosed clinically to be one of diphtheria. There was no lesion in the throat. The temperature was 98°F. and pulse 100 per minute. Smears were examined microscopically and bacilli morphologically resembling diphtheria bacilli were identified. No other micro-organisms were seen.

Treatment.—Anti-diphtheritic serum 30,000 units was administered intramuscularly but no local treatment was carried out.

Subsequent progress.—The symptoms began to subside gradually. The child had better sleep the same night. The following morning when the child was examined, the membrane was found to be broken up and thinner. It cleared up completely in 5 days. On account of satisfactory progress the serum was not repeated.

Summary and comments

1. Diphtheria of the genitals is mentioned in books but cases involving the glans penis are very rare.

2. There seems to be very little toxæmia associated with such lesions.

3. A single dose of anti-diphtheritic serum of 30,000 units was followed by healing.

4. The possibility of an ulcer being diphtheritic should always be kept in mind.

Acknowledgment

I am thankful to Dr. Amarjit Singh for bacteriological examination.

A BRIEF NOTE ON THE USE OF CONGO RED IN PROTOZOAL DYSENTERY

By L. S. F. WOODHEAD

CAPTAIN, I.M.S.

Specialist in Pathology, British Military Hospital, Shillong

During the epidemic of protozoal dysentery among troops evacuated from Burma, most of

whom had come through the so-called 'Dry Belt', some had severe hæmorrhage *per rectum*. These cases had vegetative forms of *Entamoeba histolytica* in large numbers in the stools and these could be found even in the almost-pure blood passed. The usual routine treatment of emetine, bowel washes, salines, etc., had no effect on the hæmorrhage nor had the ordinary hæmostatic serum. In one case, the patient had had thirty-four motions in twenty-four hours, all of which were pure blood containing a few amœbæ.

It was decided to try the effect of intramuscular Congo red in the abovementioned case. 10 c.cm. of a 1 per cent solution in water were injected deeply into the buttock, 3 inches below the iliac crest, in the evening. The following morning there was a distinct improvement and the hæmorrhage had practically ceased. The injection was repeated the next evening (10 c.cm.) and again the next (5 c.cm.), a total of 25 c.cm. being given. By this time the general condition had greatly improved and there was no fresh blood in the stools, which had greatly decreased in number. The patient has improved since that time and is now almost fit for discharge—one month after the injections. There was slight discomfort at the site of injection but no real inflammation or abscess formation.

Another case was admitted in a bad condition, generally bleeding profusely. The same treatment was given with exactly similar results so far as hæmorrhage was concerned, but the patient died from pure exhaustion.

A third case admitted in a serious condition improved remarkably under the same treatment, and it almost fit for discharge.

Three other cases less serious than the others, and requiring less Congo red (15 c.cm. or 1 per cent solution), have been cured.

In none of these cases has any other treatment been used, and there has been no reaction of any kind, apart from some local tenderness over the site of injection.

It is now proposed to try the effect of Congo red on all types of protozoal dysentery in order to find out if it has any effect in controlling the diarrhoea. It is also intended to try the effect of this drug on the living amœba, and on cysts.

My thanks are due to Lieut.-Colonel J. A. C. Kidd, R.A.M.C., Officer Commanding The British Military Hospital, Shillong, for permission to publish this note.

A CASE OF MULTIPLE FRACTURES

By A. L. SOM, F.R.C.S. (Ed.)

MAJOR, I.M.S.

A SEPOY, aged 36, was involved in a lorry accident, as a result of which he sustained 25 fractures involving 18 bones. He was admitted to a field ambulance and treated for shock, and splints were applied. On the fifth day after the accident he was evacuated to a casualty clearing station and came under the care of the author.

Condition on admission.—Pulse 116, respiration 24, temperature 100.8°F. General condition poor. Respiration abdominal in type, and patient was coughing out blood-stained sputum. He complained of pain in the chest, right leg and left forearm. Surgical emphysema was present over both sides of chest which on examination showed diminished breath sounds and dullness at the bases with a pleuritic rub on either side. There was tenderness and rigidity of right hypochondrium.

Clinical examination followed by x-rays showed the following injuries :—

(1) Comminuted fracture of the lower one-third of shaft of right femur with posterior and medial displacement of the lower fragment.

(2) Fracture at the junction of the middle and lower one-third of right femur.

(3) Fractures of shafts of left radius and ulna with forward, upward and medial displacement of lower fragments.

(4) Fracture of left clavicle with upward displacement of the medial fragment.

(5) Fracture of ribs, first to ninth inclusive (right) and third to seventh (left). Right first rib fracture 1 inch from the vertebral end. Second to seventh ribs (right) were fractured near vertebral ends and also at lateral convexities.

(6) Bilateral hæmo-pneumothorax.

Treatment.—Antiphlogistine to chest. Morphine grain $\frac{1}{4}$. Brandy 2 drachms six hourly.

Next morning under-chloroform and ether anaesthesia, skeletal traction was applied to right femur by Kirschner wire through upper end of tibia. Put up on modified Braun splint. A plaster slab was fixed to posterior surface of thigh and knee. Forearm fracture was reduced and put up in plaster. Chest was strapped. Fractured clavicle was reduced and fixed by pad in axilla and strapping. Morphine grain $\frac{1}{4}$ given twice and brandy at night. Antiphlogistine applied to chest.

Progress.—Patient had slight continuous temperature for 10 days and during this period his chest condition gave rise to anxiety. After that he was afebrile till the 24th day when blood smears showed malignant tertian rings. Malaria was controlled by conservative methods and his general condition gradually improved.

Six weeks later, x-ray examination showed good position of radius and ulna with well-marked callus formation. Movements were good and rapidly became full except for slight limitation of pronation and supination which improved with active exercise.

There was slight posterior angulation of femur. The extension was removed and plaster spica applied with knee and hip in slight flexion.

Patient was evacuated to a General Hospital on the 47th day after admission in a very good general condition and with every prospect of full recovery of functional power in all limbs.

Points of interest

(a) Recovery from as many as 25 fractures in one patient is considered unusual.

(b) Fractures of 14 ribs, 6 of them double, with accompanying damage to the lungs and pleura leading to hæmo-pneumothorax, surgical emphysema, hæmoptysis and fever.

(c) Fracture of the first rib is very unusual owing to its protected position. The clavicle of the same side was not fractured but the opposite one was fractured.

(d) General anaesthesia caused no obvious deterioration of the chest condition.

(e) Relapse of malaria infection.

I am grateful to Lieut.-Colonel B. S. Dhondy, I.M.S., for permission to report this case.

AN UNUSUAL INJURY

By H. WILLIAMSON

LIEUTENANT-COLONEL, I.M.S.

THE following case seems worth recording because of the unusual injury and the easy approach to the elbow joint through rather dangerous territory :—

A young British officer, after a fall from a horse, had swelling of the right elbow and could not bend it fully. Stereoscopic x-rays showed that the base of the coronoid process of the ulna had been torn out and was in front of the joint. As the fragment could not be replaced by manipulation I decided to remove it.

Operation.—An incision was made along the outer border of the pronator teres, which was retracted inwards with the common flexors. The median nerve and the origin of the ulnar and radial arteries were drawn outwards. The branch from the median nerve to the common flexors was carefully exposed and gently retracted inwards, the dissection being deepened down to the joint in the space between the branch and the median trunk. The fragment of bone was now easily identified, cleaned of some fibres of the brachialis anticus and removed. The open joint was dusted with thiazamide powder, one stitch put in the capsule, the deep fascia sewn up and the skin closed with a subcuticular stitch.

Recovery was uneventful and movements are now normal; no weakness of the flexor muscles followed the gentle retraction of the supplying nerve.

TETANIC CONVULSIONS APPARENTLY DUE TO ASCARIASIS

By U. N. SAHA, M.B., B.M.S.

Medical Officer, Civil Hospital, Comilla

ON 1st September, 1942, at about 8 p.m., a boy, aged 6 years, was brought to the hospital. His father stated that in the morning he complained of pain in the abdomen, especially in the umbilical region. In spite of the continuous dull pain he was given ordinary rice diet which he vomited. At about 5 p.m. convulsions started which gradually increased in intensity.

On examination, the patient was found unconscious and quiet. Eyes were broadly open, pupils were equal, not reacting to light, corneal reflex was sluggish. Muscles (including neck muscles) were flaccid but lock-jaw was present, foam was coming out of the mouth. Respiration 30 per minute, irregular. Pulse 100 per minute. Temperature 99°F. Lungs—scattered moist sounds were present at the bases. Superficial and deep reflexes were sluggish on both sides.

During my examination muscular contractions began from above down; the whole body was thrown into violent tonic contraction—opisthotonos and pleurothotonus. Eyes were wide open, corners of the mouth retracted, teeth clenched. Respiration was laboured and irregular; cyanosis was developing.

The fits gradually subsided after 10 minutes leaving the patient more devitalized and relaxed, but the lock-jaw persisted.

Past and family history.—The patient had an old ulcer on the left great toe resulting from an injury about a year ago. There was no family history of epilepsy or hysteria. History also excluded poisoning. About a month ago he vomited two round worms and very often complained of abdominal pain.

Treatment.—He was given morphine grain $\frac{1}{4}$ and atropine grain 1/100, and was kept under observation in a quiet dark room. Next morning the patient was better having small contractions at long intervals.

The jaw could be opened during the interval. He regained some amount of consciousness. The abdomen was very tender.

1 Santonin 3 grains with 15 grains of sodium bicarbonate and 3 grains of calomel was given, followed after two

hours by one ounce of saturated solution of magnesium sulphate.

At noon he passed a large stool with four round worms. The stool was found full of ova of *Ascaris lumbricoides* and *Ancylostoma duodenale*.

There was no recurrence of any convulsion afterwards.

TWO RARE COMPLICATIONS OF INTESTINAL AMOEBIASIS

By GERALD H. COORAY, M.B., B.S. (Lond.), M.R.C.S.,
D.T.M. & H. (Eng.)

Surgical Registrar, General Hospital, Colombo

THE two cases which are reported below illustrate two rare complications of intestinal amoebiasis.

The first case is an example of rupture of an amoebic abscess of the liver into one of the large bile ducts and subsequently into the pleural cavity and lung.

Although rupture of a liver abscess into the peritoneum and pleura is not an uncommon occurrence in the tropics, cases of rupture into a large bile duct are rarely seen. Only a very few cases have been mentioned in the literature [Annesley (1841), Waring (1854), Roughton (1891) and Hashimoto (1885)].

M. P., male, aged 30 years, was admitted to the General Hospital on 21st November, 1941, with pain in the chest and breathlessness of 2 weeks' duration. The onset was rather sudden. He had dysentery a few years ago. On examination he was dyspnoeic, pale and emaciated. Temperature was 99°F., and pulse 102 per minute. The heart was displaced to the left, but there was no enlargement. There were signs of fluid at the right base. The spleen was moderately enlarged. The liver which was palpable three fingers below the costal margin was markedly tender. There was also intercostal tenderness over the liver area. Dyspnoea, temperature, fluid at the right base with cardiac displacement, tenderness over the liver and the past history of dysentery made it possible to arrive at a tentative diagnosis of rupture of an amoebic abscess of the liver into the pleura. As the patient was dyspnoeic it was decided to explore the right pleural cavity. About three-quarter pint of chocolate-coloured thick fluid was withdrawn. The fluid on examination was free from organisms. The dyspnoea was temporarily relieved. He was put on a course of emetine injections. On the fifth day a second aspiration was arranged to be performed in the operating theatre, but just prior to operation, the patient coughed up chocolate-coloured fluid, which indicated that the abscess had burst into a bronchus. About 40 ounces of fluid were withdrawn from the pleural cavity. The patient was fairly comfortable and the temperature kept at a low level. The emetine was stopped after 12 injections were given. The lung signs however persisted. On the 24th day after admission the temperature suddenly shot up to 103.2°F. and the patient developed a troublesome cough. The sputum was yellow in colour and the presence of bile was evident to the naked eye.

The chest was aspirated the following day and thick yellowish bile-stained fluid was withdrawn. The presence of bile in the pleural fluid as well as in the sputum was confirmed by chemical tests. A white cell count done at this time showed a leucocytosis of 10,500 per c.mm. with 81 per cent polymorphonuclears. From this time the patient's condition gradually deteriorated in spite of a second course of emetine

injections. The temperature became hectic and the coughing of sputum mixed with bile persisted. The leakage of bile in the sputum was considerable as during this stage of his illness the stools were free

CHART

from bile. His condition gradually deteriorated and he left hospital against medical advice.

Discussion

This case presents interesting features. The patient's condition on admission leaves no doubt that he was suffering from the effects of the rupture of a liver abscess into the pleural cavity. Although no amoebae were detected in the stools, the nature of the fluid aspirated, the past history of dysentery and the physical signs indicated an amoebic origin of the abscess. The further spread of the abscess appears to be as follows: On the fifth day after admission it ruptured into a bronchus and was partly emptied by expectoration and partly by aspiration of the pleural cavity. This caused considerable relief, and a temporary improvement in his condition became apparent. The temperature settled down. The improvement was not maintained. There was a sudden rise of temperature and a troublesome cough with expectoration of bile. The abscess had ruptured into one of the large bile ducts and a communication was established between the bile duct, pleural cavity and bronchus. There was considerable escape of bile by expectoration. The leakage of bile in this manner probably interfered with his digestion and contributed to the steady deterioration of his condition. The hectic temperature and the leucocytosis during the last stage of his illness were probably due to cholangitis, the infection reaching the bile ducts from the respiratory tracts.

The second case is an example of primary amoebic infection of the lung. In the majority of cases the lung and pleura are involved by the perforation of a liver abscess, but in this case it will be seen that there was involvement of the pleura and possibly the lung while the liver escaped. Karunaratne (1940) in discussing this rare type states, 'it would seem that the hepatic barrier is not able to check the passage of amoebae into the hepatic veins and so to the pulmonary circulation'. Cases of this type are very rare. Ten such cases are recorded in the literature by Lautman, Manson-Bahr and Ramond (Karunaratne, 1940). Manson-Bahr (1940) states that in this condition 'the entamoebae reach the lung by direct embolism from the gut wall. Having gained the pulmonary

circulation they form consolidated nodules, which later break down into small abscesses'.

D. E. S., male, aged 28 years, was admitted to the General Hospital on 5th December, 1941, with pain in the left chest and continued fever of 15 days' duration. Pain radiated to the left shoulder blade. He suffered from dysentery two months ago. On examination he was fairly well nourished. Temperature was 90°F. and pulse 100 per minute. There was slight displacement of the heart to the right. There were signs of fluid at the left base. The abdomen was soft. The liver and spleen were not palpable, and the liver was not tender. The patient was thought to have a simple left-sided pleural effusion and he was treated symptomatically. The diagnosis of effusion was confirmed by an x-ray. As the lung signs persisted and the temperature continued, it was decided to explore the chest. This was done on the 8th day after admission, i.e., the 23rd day of his illness. The fluid withdrawn was chocolate-coloured and microscopical examination showed red cells, pus cells and a few Charcot-Leyden crystals. There were no organisms, no amœbæ or cysts and on culture the fluid was sterile. The faeces contained both cystic and vegetative forms of *E. histolytica*. A white cell count showed 14,600 leucocytes per c.mm. with 76 per cent polymorphonuclears, 22 per cent lymphocytes and 2 per cent eosinophils. A course of emetine injections (1 grain daily) was commenced. The response was remarkable. The temperature settled down and the lung signs gradually disappeared (*vide* chart).

Discussion

The physical signs on admission suggested a pleural effusion at the left base. There were no reasonable grounds to suspect an amœbic origin on account of the absence of liver tenderness and negative x-ray findings. The treatment at first was therefore entirely symptomatic. On examination of the fluid after aspiration, the diagnosis of a simple pleural effusion had to be discarded in favour of an effusion secondary to amœbic infection, in spite of the absence of involvement of the liver. The treatment was accordingly changed.

The special features of the pleural fluid which made a diagnosis of amœbic infection possible were as follows:—

1. Chocolate-coloured fluid quite unlike the straw-coloured fluid of simple pleural effusion.
2. The presence of Charcot-Leyden crystals.
3. The absence of organisms and the failure to grow any ordinary media.

The diagnosis was clinched by the examination of faeces which showed both cystic and vegetative forms of *E. histolytica*. The blood examination was of much value as it showed a polymorphonuclear leucocytosis. The therapeutic test, namely, the remarkable response to emetine, leaves no doubt that the effusion was due to amœbic infection and the absence of evidence of liver involvement, together with the fact that the effusion was left-sided indicated that it was a primary infection. The question, as to whether the infection of the pleura is secondary to that of the lung as is usually the case in pulmonary tuberculosis, or whether it is a primary involvement of the pleura, is difficult to answer.

Acknowledgment

My thanks are due to Drs. J. H. F. Jayasuriya and B. E. Fernando, visiting surgeons of the General Hospital, for permitting me to record these two cases which were admitted under their care.

HERPES ZOSTER AND SULPHANILAMIDE

By J. C. BISWAS, L.M.F.

Assistant Medical Officer, South Dum Dum Municipality, Dum Dum

For cutting short the severe pain and the course of herpes zoster, apart from big doses of analgesics, oral administration of sodium iodide, injection of pituitary extract and even ultra-violet radiation therapy have all been tried with little good result. In April 1938, Maplestone and Ghose advocated intradermal injection of tissue-lysate, prepared from the herpetic vesicles, and according to them the treatment was uniformly successful in the forty cases they treated; but so far as my knowledge goes, it has not been possible for general practitioners to try this therapy.

As recorded in the April issue of this *Gazette*, Sarkar, failing to relieve a case of intercostal herpes zoster with conservative treatment, finally resorted to the injection of diphtheria antitoxin and attributed his success to it.

Recently, I treated about a dozen cases of varying severity with sulphanilamides with uniformly good results.

Two case notes are given below:—

Case 1.—A Hindu male, aged 40 years, a motor-bus cleaner, came to me on 8th December, 1941, with typical herpetic lesions, mostly on the back, complaining of severe pain all over the affected area. His temperature was 101°F. On another doctor's advice some of the vesicles had been ruptured and he told me that these were giving him increased trouble. I told him to dust the whole affected area with starch and zinc powder and prescribed septanilam tablets, two at a time, morning and evening, and advised him all other precautions regarding diet and general mode of living as for any acute febrile condition. He came to me again on the 10th with much improvement. His temperature went down to normal, the vesicles looked rather dried (none suppurating), his pain also disappeared to a great extent. I advised him to continue the same treatment for a few days more. When he came to me again after

three days, he was perfectly all right and looked very cheerful.

Case 2.—A Hindu boy, aged 8 years, was brought to me on 8th January, 1942, with the characteristic herpetic vesicles mostly below and behind the right axilla. He was running a temperature of about 100°F. and looked rather dull and listless, and sometimes cried restlessly from the pain. He had not been put under any recognized form of treatment. I prescribed urea sulphazide one tablet thrice daily and advised his parents to dust the vesicles with starch and zinc powder several times daily. He was put on liquid diet for a few days. I saw the boy again on the 11th, when I noted the vesicles mostly dried (none suppurated) and temperature and pain both disappeared totally. After continuing the treatment for three days more he came to me for the last time when I found him quite well.

Out of the twelve cases treated, eight were given septanilam and the rest urea sulphazide; all of them responded uniformly.

A FOREIGN BODY IN THE RECTUM FOR FIFTEEN YEARS ?

By KHAN BAHADUR AHMAD BAKSH, O.B.E., I.S.O.

MAJOR

Senior Surgeon, and Superintendent, Prince of Wales Hospital, Bhopal

GOPAL, male, aged 30 years, came in with retention of urine which he had had for 30 hours. His urine was drawn off with a rubber catheter which went in easily, and he was admitted into the ward of the Prince of Wales Hospital.

Next morning when notes of the case were recorded he mentioned that there was some obstruction in his rectum and that it was like a ball moving up and down.

When further questioned he said that he had swallowed a mango-seed last May and it has not

Fig. 1.

Radiogram of the pelvis shows a fairly large stone in the rectum.

yet come out. His rectum was examined and a foreign body like a golf ball was felt inside. His bladder also was sounded but no stone was felt.

A skiagram was taken; an opacity simulating a big stone in the bladder was detected (figure 1). If this point (swallowing a foreign body) had not been mentioned to the radiologist, he would have diagnosed it as a stone in the bladder.

The foreign body was removed with great difficulty by means of a pair of large size lithotomy forceps; it presented the appearance of uric acid calculi to the naked eye (figure 2). Its weight is 58 grammes, length

Fig. 2.

2½ inches, breadth 1½ inches and circumference 5½ inches.

After the foreign body was removed the patient was very pleased and he volunteered the true statement saying that when he was about 15 years old he had swallowed the mango-seed and since then it has been lying in his rectum and he was having a motion daily either by pushing it with his finger or with a piece of stick. He further said that due to shame he would not mention this to any one.

The points of interest in this case are :—

- (1) A mango-seed passed throughout the alimentary canal.
- (2) It never gave rise to any symptoms of obstruction of the bowel.
- (3) It caused retention of urine only once; for this he came to the hospital.
- (4) It did not produce any inflammation or ulceration of the rectum though it was lodged there for nearly 15 years, but there appeared to be a pouch on the posterior aspect of the anal canal.

SCURVY TREATED WITH TOMATO JUICE

By JOHN A. LEWIS, M.B. (Lond.), M.R.C.S. (Eng.)
and

P. C. DUTT, L.M.F.

Achabam Tea Estate, Upper Assam

THE following case of scurvy which rapidly cleared up on the administration of tomato juice may prove of interest :—

An Assamese girl, aged 8 years, the eighth child in her family, first came under observation in February with a history of weakness and lack of energy for some time previously. For the previous 2 or 3 days the little girl had suffered from bleeding from the nose

and gums, and a rash had appeared over the whole body.

On investigating the family diet, it was found that in spite of the cold weather when fruit and green vegetables are plentiful in the district, the child's main diet consisted of rice, unrelieved by any of the protective foods.

Examination revealed a well-nourished little girl, lying quietly on her back, in a listless manner; there were generalized petechiæ over the whole body, especially the back and lower limbs; and here and there on the trunk and limbs there were several large ecchymoses. The gums were swollen, spongy and easily bled, and there was marked sub-gingival hæmorrhage. No sub-periosteal hæmorrhages were found. There was a moderate degree of anæmia; the blood count was not done, but the hæmoglobin was about 60 per cent. No macroscopic blood was found in urine.

The listless apathetic attitude, history of weakness and loss of energy, and bleeding spongy gums and ecchymoses pointed to the diagnosis of scurvy. Tomato juice was given in massive doses: 8 to 12 ounces were given daily, no other treatment being given. The result was rapid and successful, the child being quite normal in 6 days from the commencement of the tomato juice.

VON RITTER'S DISEASE (DERMATITIS EXFOLIATIVA NEONATORUM) TREATED WITH SULPHAPYRIDINE

By JOHN A. LEWIS, M.B. (Lond.), M.R.C.S. (Eng.)
and

B. SAHA, L.M.F. (Calcutta)
Achabam Tea Estate, Upper Assam

THE following case of an unusual disease is reported, in view of the successful result with sulphapyridine treatment:—

A female infant, aged 5 days, and otherwise healthy, the daughter of an Assam tea garden 'babu', first came under observation with a few localized papules on the abdomen, axilla, inner surface of the arms and thighs, and neck. Slight infection in these papules resulted in the formation of pustules, the majority of which cleared up rapidly with simple treatment.

A week or so later, a generalized eruption occurred, commencing on the scalp and quickly spreading over the whole body: the rash consisted of large erythematous patches, which rapidly became confluent and passed through the stages of vesicles, pustules and later copious and extensive desquamation.

Coincidentally with this eruption, somewhat severe constitutional disturbances occurred with moderate pyrexia (100°F. to 101°F.) and marked gastro-intestinal upset with intractable vomiting. The infant became dehydrated and seriously ill, not responding to any of the usual measures which included the administration of fluid parenterally.

At this stage, the case seemed to fit well into the clinical picture described as occurring in von Ritter's disease by Mumford (1937); this disease is usually considered to be a variant of pemphigus neonatorum and is stated to show a mortality of 50 per cent. Ryan and Goldman (1940) described a case successfully treated with sulphapyridine, and it was decided to try the drug in this case.

A dose of 0.5 gramme was given by mouth crushed in milk, and subsequently 0.15 gramme every four hours to a total of 3 grammes. The effect was striking, the infant improving from

the first dose, and after 4 days the rash had nearly cleared and the vomiting disappeared. Ordinary measures were carried on while sulphapyridine was being administered.

A CASE OF PAROXYSMAL HÆMATURIA DUE TO MALARIA

By PROBODH CHANDRA DUTT, L.M.F.

Assistant Medical Officer, Tinkong Tea Estate, Assam

MALARIAL hæmaturia is not commonly met with even in endemic places, and the following case note will therefore be of some clinical interest:—

History.—The patient, a male child of four years, was brought by his mother on 15th November, 1941, with complaints of fever and bloody urine since the morning. On enquiry it was found that the child had a similar attack, lasting for a day or so, about two weeks previously.

On admission.—The child looked pale and slightly anæmic. Temperature 101.2°F. Abdomen soft and no tenderness. Spleen slightly enlarged. Liver not palpable. There was free passage of urine which was bright red in colour and intimately mixed with blood. Nothing abnormal noted in heart and lungs. Examination of blood film revealed moderate infection of benign tertian and malignant tertian malaria parasites, ring forms. Urine report showed considerable amount of albumin, red cells in abundance and a few epithelial casts.

Treatment.—He was given quinine 2 grains, half an hour after an alkaline mixture, three times a day, calcium lactate grains 5 twice daily and glucose water drinks.

Next morning the temperature came down to normal with marked improvement of the colour of urine which cleared up soon.

On 24th November blood was again examined but no parasites were found. Urine report showed no abnormality. Alkaline and quinine mixtures were now given twice daily.

On 26th the child had another febrile paroxysm—(temperature 100.8°F.) attended with hæmaturia. No malaria parasite found in the blood. Urine contained albumin, red cells and a few epithelial and granular casts.

The temperature came down to normal on the following morning with a slight rise (99°F.) in the afternoon. Urine was just smoky.

On 28th temperature normal, urine almost cleared. In addition to alkaline and quinine mixtures, he was then put on plasmoquine simplex 0.005 gm. twice daily after food for six days.

Since then the child had no other paroxysm. Urine was examined subsequently and no evidence of kidney disease was found.

My thanks are due to my chief, Dr. J. A. Lewis, for his valuable advice and kind permission to report this case.

[*Note.*—The urine in blackwater fever may contain scanty red cells, but in view of the large number seen in the urine of this patient, the possibility of malarial nephritis should be considered.—Editor, I. M. G.]

Indian Medical Gazette

DECEMBER

THE TREATMENT OF BACILLARY DYSENTERY

THE field of tropical medicine was without question the kindergarten of chemotherapy, and it was a little disappointing that when the science came of age and widened its scope, with the introduction of the sulphonamides, so few tropical infections appeared to be influenced by these drugs. It is true that sulphonylamide was advocated in sprue, but the benefit derived was not dramatic; similarly good results were claimed with these drugs in brucellosis, but again recent results have been disappointing, and the treatment of malaria by sulphapyridine was nothing more than a matter of academic interest.

Sulphapyridine soon after its introduction threatened to become a panacea, and it is very surprising that it was some years before attention was drawn to its action in acute bacillary dysentery; in fact, the writer's first reactions to a paper that was sent for publication in this journal were frankly sceptical. Experience in chronic bacillary dysentery had, he knew, been disappointing, and it seemed improbable that someone had not noticed the good results in acute bacillary dysentery much earlier, if they really occurred. However, evidence that sulphapyridine was capable of producing dramatic results in this infection rapidly accumulated, and more than one tea-estate medical officer has expressed the opinion that the drug has revolutionised the treatment of bowel diseases on tea estates and altered the whole aspect of practice in these districts.

For the drug to be effective a full therapeutic dose should be given and the treatment maintained until all symptoms have subsided—with due respect to the dangers of too prolonged administrations of this drug. If it is not given in sufficiently large doses, it is all absorbed in the upper part of the bowel and none reaches the seat of the trouble; and it has been suggested that if some really satisfactory method of preventing its absorption in the stomach and upper bowel could be adopted, the drug might be more effective.

Meanwhile, however, new compounds have been introduced, and Marshall's sulphanilyl-guanidine promises to prove an effective drug in bowel diseases. The particular value of this

drug lies in the fact that it is absorbed very slowly and even when large doses are given the concentration in the blood does not rise very high. Locally, it is entirely non-irritating and it appears to have a specific, though possibly indirect, action on pathogenic intestinal micro-organisms. The early reports from America suggested that it was very effective in diarrhoea and dysentery in children, and also in adults. Trial quantities were sent to Egypt for use amongst the British troops there, and glowing accounts of its effect in the severest forms of bacillary dysentery have been received. More recently, generous samples of the drug have been sent to India and the first indications are that it is equally efficacious against our local strains of dysentery organism, and further that it may prove a valuable adjuvant in the treatment of cholera.

The drug must be given in adequate doses and its failure in some physicians' hands can be attributed to the failure to appreciate this fact. The dose advocated is 0.1 gramme per kilogramme of body-weight of patient for the first doses and 0.05 gramme per kilogramme for subsequent doses which should be given every four hours until the stools are reduced to 3 or 4 a day, when the dosage can be reduced to 0.05 gramme per kilogramme every 8 hours. This means that an average man (European) of 70 kilogrammes will receive 7 grammes for the first dose and 3.5 grammes for subsequent doses, and the average total dosage in a severe case of dysentery will be well over 100 grammes. This is a very large amount and the cost will not be inconsiderable. The actual taking of this quantity presents no difficulties as it is added to water or milk, stirred up, and taken as an emulsion; it seldom, if ever, causes vomiting.

It is of interest that this drug has been advocated, and is, we are told, being used fairly extensively in Calcutta, as a treatment for typhoid. Drugs do surprising things and, whilst we would hesitate to condemn its use in this infection, we should require very strong evidence to convince us of its efficacy, especially in the minute doses in which it is usually given, for its whole value lies in its low absorption rate, and typhoid fever is essentially a septicæmia.

Another similar drug that is showing promise is succinyl-sulphathiazole. This also is absorbed slowly and depends on its local action in the large bowel. In *in-vitro* experiments, we believe, this drug was more effective than sulphanilyl-guanidine, and early clinical trials suggest that it is at least as effective.

It seems possible that the treatment of bacillary dysentery, which in the past has never been very satisfactory, is entering a new and more promising era.

Medical News

DRUGS TECHNICAL ADVISORY BOARD MEETING

THE first meeting of the Drugs Technical Advisory Board (constituted under the Drugs Act, 1940) was held in New Delhi on Monday, 2nd November, under the chairmanship of Lieut.-General Sir Gordon Jolly, K.C.I.E., K.H.P., I.M.S., Director-General of the Indian Medical Service and Chairman of the Board.

Fig. 1.—General Jolly addressing the meeting.

Fig. 2.—Left to right : General Jolly; Dr. Dunnicliff, Chief Chemist, Central Revenues; Major-General Sir John Taylor, Director, Central Research Institute; Dr. S. Rajagopal Naidu, Chemical Examiner to Madras Government; Dr. B. B. Dikshit, Haffkine Institute, Bombay (representative of Indian Research Fund Association); Dr. Anil Kumar Sen (Central Council of Indian Medical Association) and Professor Bires

Chandra Guha, Professor of Applied Chemistry, University College, Calcutta (representative of Indian Chemical Society).

X-RAY AND INDUSTRY

THE Institute of Physics has just held a conference at the Cavendish Laboratory, Cambridge, on x-rays in industry, to celebrate the thirtieth anniversary of the discovery by Laue of the diffraction of x-rays by crystals. The president of the Conference was Sir Lawrence Bragg, who, with his father, the late Sir William Bragg, showed how to use x-ray diffraction to analyse the structure of crystals. As nearly all solid bodies are crystalline, their methods have led to the creation of a new branch of science, which is of great industrial as well as scientific importance.

The industrial scientist can discover with the help of x-rays the size of particles in substances he is handling, their arrangement in space, and the elasticity of substances. He can use them as a help in discovering the constituents from which his substances are made. He can learn about the hardness of steel, the effects of stretching in rubber, the elasticity of wool, the composition of alloys, and a hundred other properties of industrial importance.

Three hundred industrial and academic scientists joined in the Conference, and they have decided, in view of its great success, to make such a meeting an annual feature of scientific life in Great Britain.

FACTS ABOUT FOOD FOR SCHOOL CHILDREN

AN attempt to put into simple language important facts about food and diet which the Indian high school pupil should know has been made in a 20-page bulletin 'Food and Diet' prepared in the Nutrition Research Laboratories of the Indian Research Fund Association at Coonoor. The bulletin, primarily intended for use in schools, has been written in simple language avoiding difficult technical terms.

The purpose of the bulletin is expressed in the following observations of Dr. W. R. Aykroyd, Director of the Laboratories, in his preface :

'There is one subject about which all children should learn something, namely, health. In India there is a great deal of ill-health and disease which could be prevented if people understood more about their causes and were determined to remove them. The kind of food we eat has a great influence on our health and much ill-health and disease are due to eating the wrong sort of diet. This Bulletin deals with this part of the subject of health, which is of great importance in India.'

The booklet aims at teaching children about the practical side of dietetics. Thus, while a great deal has been written about vitamins, most of it is of little instructive value to ordinary people. A little knowledge of the more important vitamins is very useful to children. Various points are illustrated by anecdotes, such as the story of how Captain Cook kept his crews free from scurvy.

The purpose of food, what it contains, the rôles of vitamins and mineral salts, the value of milk and various cereals, the importance of cooking and regular meals, and the evils that result from badly balanced and poor diets are explained and the conclusions are summarized in thirteen 'Facts to Remember'.

It is hoped that the booklet will be translated into various Indian languages for use in schools throughout India. Adult students may find its perusal well worth while as the improvement of the diet of the average Indian depends largely on education in dietetics and is a matter of the greatest importance, especially in wartime.

The Bulletin may be obtained from the Manager of Publications, Civil Lines, Delhi, and from other sellers of Government publications at annas three per copy.

Public Health Section

PUBLIC HEALTH ORGANIZATION

V. THE PUBLIC HEALTH ASPECT OF MALARIA CONTROL

By G. COVELL, M.D., D.P.H., D.T.M. & H.
BRIGADIER, I.M.S.

(Director, Malaria Institute of India)

IN his introductory paper to this series of articles, Jacocks (1942) made the following statement: 'In view of the importance of malaria in causing ill health it would be unwise for any public health department in any province in India not to have a malaria division directed by a well-trained and experienced officer'.

This principle was recognized as early as 1909, when the Imperial Malaria Conference convened at Simla passed a resolution urging the creation of local provincial organizations to work in consultation with a central committee to be appointed by the Government of India. Subsequently, a provincial malaria committee was actually formed in each province and one of its members was delegated to attend a meeting of the central committee each year. In almost every province there was appointed an officer trained in malaria research, whose function was to carry out investigations which would lead to the institution of preventive measures in his province. During the period immediately following the conference numerous valuable investigations were carried out, notably by Christophers, Bentley, Fry, Graham, Kenrick, Adie, Perry, Gill, T. S. Ross, Horne and Hodgson.

The central body originally consisted of a scientific committee, which suggested lines of investigation and drew up schedules specifying the data most urgently required. The Central Malaria Bureau, to accommodate collections of mosquitoes and a special reference library, was founded at Kasauli in 1909, and courses of instruction in malariology for medical officers were held from 1910 to 1914, first at Amritsar and afterwards at Delhi.

The war of 1914-18 had a disastrous effect on this organization, owing to the fact that individuals of the calibre and status previously available could no longer be spared for anti-malaria work. Malaria officers were still employed in some provinces, but they did not reach the high standard set by their predecessors, and with some notable exceptions such work as was undertaken was relatively unimportant.

During the post-war period a number of malaria inquiries were set on foot by the Indian Research Fund Association; but as the years went by, it became increasingly evident that a permanent organization, both central and provincial in nature, was urgently needed to carry out co-ordinated investigations in regard to the prevention of malaria in India.

At the annual Conference of Medical Research Workers of 1925 the following resolution was passed: 'The conference is impressed with the great need of a permanent organization for carrying out continuous and adequate investigation in regard to the prevention of malaria in India. It also wishes to call attention to the necessity of adequate provincial malaria organizations working in collaboration with the central organization and considers that the constitution of such organization (*which should include at least one effective malaria worker*) ought to receive urgent and early attention by local governments'.

A central malaria organization, with a director, assistant director, entomologist, two research workers, and an appropriate subordinate staff came into being in 1927. A malaria engineer was subsequently added to the cadre. This organization was known as the Malaria Survey of India until 1938, when its designation was changed to that of the Malaria Institute of India. Its functions are as follows:—

1. To be fully informed upon all malaria problems. To advise Government on all issues relative to malaria in India.

2. To initiate inquiries and investigations on malaria. To carry out such inquiries as government may for any reason require. To assist provincial organizations in the carrying out of such inquiries as may be undertaken by them, providing such assistance as desired and even, in certain cases when thought necessary, to lend officers temporarily from the staff to work under local governments.

3. To undertake systematic research in due course into all the basic facts underlying malaria transmission, prevalence and prevention, such as the study of mosquitoes, systematic and bionomical, types of malaria parasites, transmission power of different species of Anopheles, mechanism of infection including the study of endemic and epidemic phenomena, etc. Gradually to complete and organize knowledge on these subjects and to arrange for the making of such knowledge available for practical application, or such other uses as may be desirable.

4. To carry out epidemiological investigations—mapping of endemicity, study of hyperendemic and healthy areas, study of malaria statistics on modern lines—and generally to elucidate the underlying principles of malaria prevalence in India.

5. To advise upon and assist in carrying out of antimalaria measures. To study these scientifically and to judge and elucidate their results.

6. To undertake clinical work on malaria, including treatment. To study serum reactions and allied aids to diagnosis and understanding

the disease. To study relapse problems, effects of new drugs, etc.

7. To assist affiliated researches (e.g., kala-azar, filariasis, sandfly fever, dengue, *Stegomyia* work) by identification of material, provision of trained staff and subordinate personnel.

8. To teach and train officers and others in practical malaria work.

9. To publish scientific results, useful guides, bulletins, etc.

10. To keep alive interest in malaria study and prevention and to see that such interest wherever present is nursed and assisted.

In subsequent years a number of further resolutions were passed by the annual conferences of medical research workers, urging the formation of provincial malaria organizations in provinces where none was provided, and the strengthening of those already in existence.

In most of the provinces in India there exists a malaria organization of some kind, but its composition often leaves much to be desired. In some cases there is a malaria officer with no staff, whilst in others the staff provided is inadequate and insufficiently paid.

The one great lesson which has been learnt as regards the prosecution of antimalaria measures during the last fifty years is that spasmodic attempts at control are doomed to failure. Grants of money have been made to finance schemes of rural malaria control in India over limited periods, and this money has been largely wasted, simply because adequate organizations for expending it to the best advantage did not exist. Staff previously untrained in the special technique of malaria investigations had to be recruited and the only individuals available were men who had either held no previous posts or who for one reason or another were out of employment. Since their services were required only for a limited period, they were faced with the certain prospect of being once more thrown out of employment when the funds had been spent. It is not to be wondered at that they took little interest in the work and were mainly preoccupied in looking out for posts which would render their future more secure. This led to constant changes in personnel and little good was accomplished.

It cannot be too strongly stressed that the first and most important requirement for provincial malaria organizations is *continuity of effort* and this can only be attained if the terms offered are sufficiently attractive, so that the officers employed may be content to remain in their present appointments and not be continually on the lookout for more lucrative posts. The officer-in-charge of the department should be given a status and salary at least equal to those of an assistant director of public health. In certain provinces (e.g., Bengal, Bombay and the United Provinces) this is actually the case. Adequate salaries should also be paid to the remainder of the staff, which will naturally vary in number with the size of the province and the

local importance of malaria as a public health problem. The staff recently sanctioned for Bombay Presidency includes :—

- One A. D. P. H. (Malariology),
- One Entomologist,
- Two Medical Officers,
- Four Subordinate Medical Service Officers,
- Two Clerks,
- Two Laboratory Assistants,
- Eight Insect Collectors.

This staff is to be regarded as the minimum requirement for any province in India. It is intended that the Bombay Presidency malaria organization will later be expanded, its numbers having been limited in the first place by the difficulty of obtaining sufficient trained personnel at the present time.

The second requirement is that the staff employed must receive adequate training, such as is provided by the intensive courses held at the Malaria Institute of India. At the present time, these courses are necessarily restricted to members of the Defence Services, but it is intended to resume the training of civilian health officers as soon as immediate war-time requirements have been met.

The functions of the provincial malaria organizations should be :—

1. To advise the local government on all questions regarding malaria problems in the province.
2. To carry out epidemiological investigations in malarious areas and to formulate control programmes based on these investigations.
3. To direct and supervise such control measures for at least one year after they have been put into operation, and to continue investigations during that period.
4. To promote the education of government officials and of the general public in the basic principles of malaria prevention, by means of posters, pamphlets, cinema demonstrations and other forms of propaganda.

It is particularly important that the activities of the malaria department should not be restricted merely to the investigation of malaria conditions and the formulation of a control programme. It should actually initiate the control measures and should continue to carry out observations until they have been established on a proper basis. It frequently happens that considerable modifications have to be made in a malaria control programme after it has been in operation for some while, in the light of the experience thus gained. In fact, finality is never reached in antimalaria work. There is always room for further improvement, and the good malaria officer is constantly on the lookout for methods by which he can reduce still further the possibilities of transmission of the disease in the area under his control.

It is now generally recognized that no anti-malaria scheme can have any chance of success without continuous supervision by an officer.

who has received special training. This officer must be provided with an adequate salary, and in the interest of economy the scheme must be planned in such a way that supervision may be exercised where it will benefit the greatest number of people. In this connection the question of transportation becomes of fundamental importance and one of the most important factors for the furtherance of antimalaria work in the tropics is the development of road and rail communications, whereby the cost of supervision can be spread over larger areas (Covell, 1941). Antimalaria schemes should be initiated in rural municipalities in the first place. There is usually fairly good road communication in the immediate neighbourhood of such centres, so that the work may be extended into the nearby villages without much difficulty. These townships, which would normally be the headquarters of talukas, etc., with their surrounding villages, would act as foci whose activities would be linked up one with another in course of time.

The control of malaria in towns and cities and among the personnel employed by industrial concerns such as tea, coffee or rubber estates, mines, railways, etc., by modern methods has become comparatively easy. Under such conditions, large numbers of persons are congregated in relatively small areas. The interference with industry caused by outbreaks of malaria among labour forces and superior personnel renders it easy to draw up a balance sheet showing the cost of the disease to the community and demonstrating that the expenditure necessary for controlling the disease represents a paying proposition. There are many instances in India where the incidence of malaria has been greatly reduced under such circumstances by the application of antilarval measures.

The control of rural malaria, however, presents a very different problem, not only in India but in all countries where the disease is a public health problem of importance. The population is scattered over immense areas, and there are usually innumerable water collections which afford breeding places for malaria-carrying mosquitoes. The prevention of mosquito breeding under such circumstances becomes a financial impossibility and the control of rural malaria by antilarval measures is out of the question. The only measure which has been applied on a wide scale in this country to mitigate rural malaria is the provision of an adequate supply of antimalarial drugs, either by free distribution or by the sale of treatments at a price which brings them within reach of the average villager. No one will dispute that the provision of adequate treatment should supplement antimalaria measures, but as was pointed out by Jacocks (*loc. cit.*) none of the communicable diseases at present in existence has ever been controlled by such a method.

Observations carried out in India during the last seven years have raised the hope that in the

spray-killing of adult mosquitoes with pyrethrum insecticides we have at last a weapon which, when its full possibilities have been developed, will prove effective for combating rural, as well as urban and industrial, malaria. The principle involved is that a mosquito can only transmit malaria if, after feeding on an infected person, it has succeeded in living for a period of not less than ten days. If it can be destroyed within this period, it cannot convey the disease. In other words, the object of the method is not to reduce the number of mosquitoes in any great measure, but to cut short the life of the average mosquito to such an extent that it cannot become infective. A sure proof of its efficacy is provided by the results of dissections of mosquitoes in sprayed and unsprayed villages. If the method has been properly and systematically applied, no infective mosquitoes are found in the sprayed villages whilst in the unsprayed villages the infectivity rate is unchanged.

Two great advantages of the method are that (i) it is the only antimalaria measure which is universally popular, and (ii) it is the only measure which can exert an *immediate* effect on an epidemic. In addition to mosquitoes, many other insect pests such as flies, fleas, bugs, cockroaches, sandflies and eye-flies, are also destroyed.

Spray-killing of adult mosquitoes was brought into use in India in Delhi in 1936, first in quarters occupied by Government personnel and subsequently in villages (Covell, Mulligan, and Afridi, 1938). It has been practised with success in certain villages in Madras Presidency (Russell and Knipe, 1939; 1940; 1941) and in tea plantations in Assam (Viswanathan, 1941; 1942). It is now regularly employed in many parts of India for the protection of personnel, such as police, railway, forest or other Government employees, and labour forces on estates, mills and other industrial enterprises, and in the writer's opinion it represents the greatest advance which has been made in malaria control measures in recent years.

As regards costs, even under present circumstances, it is usually considerably cheaper than any antilarval measure. It has been demonstrated that pyrethrum of high quality can be produced in many parts of India (e.g., Kodaikanal, Nilgiris, the Punjab Hills, the N.W.F.P., and Mayurbhanj and Kashmir States) and it is certain that within a few years there will be an ample supply of home-grown pyrethrum to meet the country's needs. Experiments are also being carried out with a view to substituting water for kerosene as a diluent for the spray, and thus greatly reducing the cost of the method. These have given encouraging results and there is every hope that an effective mosquitocide will eventually be made available at a price that will render it possible to provide a measure of protection against the ravages of malaria for rural populations throughout the

country. The most urgent need at present is the extension of pyrethrum cultivation in India, and this should receive active encouragement from local governments in all provinces where agricultural and climatic conditions are suitable, notably in Madras Presidency.

Another matter of importance is the instruction of government officials and employers of labour and especially of engineers of all branches in the elementary principles of antimalarial sanitation. Courses in malariology for engineers were instituted by the Health Organization of the League of Nations in 1939 and in the following year by the Government of India in Delhi. At present these are held in abeyance, but it is hoped to resume them as soon as circumstances permit.

Summary

1. An essential preliminary to the successful control of malaria in India is the formation of an adequately staffed permanent malaria organization in each province, the activities of which should be linked with those of the central organization of the Government of India.

2. The status and salary of the officers-in-charge of such permanent organizations should be at least those of an assistant director of public health. Adequate salaries must also be provided for the remainder of the personnel, in order to secure continuity of service.

3. The functions of the central and provincial malaria organizations are laid down and discussed.

4. The importance of the method of spray-killing adult mosquitoes with pyrethrum insecticides as a weapon for combating rural malaria in India is stressed.

5. There is urgent need for the extension of pyrethrum cultivation in India and this should receive active encouragement from local governments in all provinces where agricultural and climatic conditions are suitable.

6. Stress is also laid on the importance of instructing government officials and employers of labour and especially engineers in the elementary principles of antimalarial sanitation.

ON AGRICULTURAL MALARIA AND ITS CONTROL WITH SPECIAL REFERENCE TO SOUTH INDIA*

By PAUL F. RUSSELL

FRED W. KNIPE

and

H. RAMANATHA RAO

Introduction

This paper presents some observations and reflections on the subject of the interrelationship between agriculture and malaria. It is based primarily on six years of intensive malaria surveys and research studies, in which medical, biological, and engineering, as well as agricultural aspects of the subject were explored by a group of specialists in South India.

Quoting Hehir (1927), 'compared with agriculture, the other industries of India, though they play a useful part in the economic life of the country, are of minor importance. Agriculture is, and always will be, the great field of industrial activity, for upon it the welfare and prosperity of the large masses of India depend'. As pointed out by Sinton (1939) it is the small farmer and the agricultural labourer who have to bear the brunt of the onslaught of malaria. This author stated that about 40 to 50 times as many 'fever' deaths occur in rural areas as in urban, and that the influence of malaria upon agriculture is 'one of the most important economic problems of India'.

There are many ways in which agriculture and malaria impinge one on the other. There is, first, the effect of malaria in retarding agricultural development. As an instance, Christophers (1924) noted the broad belt of many hundreds of square miles, called the Terai, along the foot of the Himalayas where the soil is fertile but where malaria for centuries has been, and is to-day, an effective barrier to agriculture. Again Perry (1914) called attention to the Jeypore Hill Tracts where rainfall is abundant and soil rich but where only aboriginal hill tribes are able to survive the depredations of malaria. To-day, even as this author reported in 1914, these areas are 'crying out for development', but malaria blocks the way. Many similar areas could be named.

Secondly, malaria has not only prevented development of agricultural lands but it has actually forced the abandonment of large tracts, bringing depopulation and economic disaster to extensive areas. For instance, Banerjee (1916) wrote about malaria in Bengal in these words. 'It would be no exaggeration to say that some of the fairest parts of my loved province have

* This paper is based on observations made in the course of malaria investigations in South India under the auspices of the International Health Division of the Rockefeller Foundation, co-operating with the Madras Health Department, and the Pasteur Institute of Southern India.

been decimated by this terrible scourge.... I have with my own eyes seen villages once the abode of health, happiness and plenty, now a crumbling mass of dilapidated structures, overgrown with jungle.... Other areas in India, abandoned because of malaria, could be named.

In the third place, there is the question of malaria on tea, coffee, rubber, pepper, and cardamom plantations in Assam, Bengal, Madras, and other areas, where this disease has exacted a very high tax in money and life but where one can report very considerable progress in control. This is due to the initiative of the planters, who have been aided by the Malaria Institute of India and the Ross Institute of the London School of Tropical Medicine and Hygiene, following the magnificent demonstration of estate malaria control, originated and inspired by Sir Malcolm Watson in Malaya.

Fourthly, one must cite the retarding effect of malaria on the preservation, development, and exploitation of forest resources of India. Passing note may be made of the epidemics of malaria which have often followed the opening up of a ravine where the removal of shade has allowed a vector species, like *A. minimus* or *fluviatilis*, to flourish.

In the fifth place there is the urgent problem of irrigation malaria. This has been discussed by Russell (1938) and by Sinton (1939) and will have consideration below. In some areas the water-logging which has been so detrimental to agriculture has at the same time created a malaria menace.

In the sixth place, there is the subject of man-made malaria due to mosquito vectors breeding in collections of water which the farmer or irrigation engineer creates or maintains in a state suitable for the mosquito. This phase will be discussed below (Russell, 1941).

In the seventh place, there is the fact that in many localities where the farmer has established a sort of balance with endemic malaria and succeeds in cultivating the soil, he must pay a yearly 'malaria tax' in the form of money for folk-medicines or quinine, doctors or quacks, priests or sacrificial animals. This point will be mentioned below (Russell and Menon, 1942).

Finally, in some areas of South India there is the important phenomenon, seen in a few areas in other parts of the world, that the more intensive and extensive the agricultural practice, the less the intensity and extent of malaria.

The following discussion relates primarily to South India, with reference to certain specific crops which are associated with malaria and including the last four points made above. It also considers what can be done to cope with this vital problem of agricultural malaria.

South Indian crops

The principal crops in Madras Presidency are rice, millets (e.g., *cholam*, *cumbu*, *ragi*,

korra), pulses (e.g., Bengal gram, red gram), oil seeds (e.g., ground-nuts, gingelly, castor, coconut), tobacco, tea, coffee, rubber, cinchona, turmeric, cotton, potatoes (in the Nilgiris), spices (e.g., chillies, peppers, ginger, cardamom), sugar-cane, fire-wood (*casuarina*), betel-vine, and fruit (bananas, citrus, mango, papaya, and areca nut). Of these, only rice, sugar-cane betel-vine, banana, areca nut, turmeric, and *casuarina* have been observed by the authors to be actual sources of malaria vector mosquitoes by virtue of methods of cultivation. Others, such as tea, coffee, cardamom, and rubber, are associated with natural foothill malaria because of the type of locality in which they grow best. Still others, such as cotton and the millets, are grown in such naturally malarious flat areas as one sees in the Bellary district.

Rice cultivation is the principal source of malaria due to agricultural methods but, paradoxically, the great rice growing areas of the Tanjore, Godaveri, and Krishna deltas, and the narrow rice-growing belt along the western seacoast, are not malarious. This point will be discussed below.

A sugar-cane field is in alternate ridges and furrows, the crops standing on ridges. Water is allowed into the furrows at intervals of eight to ten days. No appreciable stagnation of water is normally allowed in the furrows, as sugar-cane does not thrive under such conditions. In ill-drained soils, there may be some stagnation affording breeding conditions for mosquitoes.

Irrigation of banana gardens is through a series of trenches along the length and breadth of the field, which presents a chess board pattern. The plants are on mounds which absorb moisture from the trenches. In the Cauvery and Godaveri deltas, as elsewhere on heavy soils, such a system of irrigation is in vogue, and the trenches are never dry except in midsummer. In the Cauvery delta millions of *A. culicifacies* breed in such trenches.

Irrigation of a turmeric crop is more or less like that of a banana crop. In Trichinopoly, Karur, and Erode taluks, turmeric fields are traversed by many trenches which carry water most of the year, enabling mosquitoes to breed in thousands.

In a betel-vine garden, land is thrown into alternate trenches and ridges. The vines are planted in two rows on the ridges, and between the rows of vines are grown support plants like 'agathi' (*Sesbania grandiflora*), which also afford the necessary shade. The trenches invariably carry water which the ryot splashes on the vines. These trenches are far more numerous than in a banana garden and mosquitoes breed the year round.

In wet lands where soils are heavy, ryots grow such crops as bananas, betel-vines, and turmeric in such a way that the root zones do not get water-logged. This is achieved by cutting a series of trenches which carry water. The soil around the plants absorbs moisture from the

trenches. This system keeps the soil well drained but mosquitoes, including potential vectors of malaria, find ideal breeding conditions in the trenches.

Man-made malaria

Farmers, whatever their crop, produce a disconcerting amount of man-made malaria in certain areas because of the facilities they give to vector mosquitoes in collections of water in waste-land, wet fallow fields, ill-kept channels, uncovered irrigation wells, and miscellaneous back-yard pits. So, too, public works engineers, by heedless removal of earth and by untidy or defective irrigation construction and maintenance, create or permit many dangerous collections of water in roadside and canal-side pits, waste land, and sundry depressions. The failure of farmers, engineers, and public servants to appreciate the extent to which they actively inflict malaria on others is one of the social obstacles to the control of malaria in many lands, and especially in areas of South India (Russell, 1941).

Rice culture and malaria

The subject of rice culture and malaria has long been controversial because of a failure to analyse it into its component parts. It is basically very simple. If rice culture in an area gives rise to a sufficient number of mosquitoes of a species known to transmit malaria then in that area rice culture is malariogenic. On the contrary, if the output of malaria vectors from the rice fields of an area is so low that the required critical density for malaria transmission is not maintained, or if, as is often the case, the mosquitoes arising from rice fields are not malaria vectors, then that area will be non-malarious.

Both types of rice culture in reference to malaria are seen in South India. The fact that the greatest rice growing areas are not malarious has already been noted. On the other hand in Pattukkottai taluk, adjacent to the Tanjore delta, rice fields certainly play a significant part in maintaining endemic malaria by virtue of their large output of *A. culicifacies*, the vector.

The following types of situation may prevail as regards rice culture and malaria :—

1. Rice fields and their channels may be completely harmless because a vector anopheline is never found in them (e.g., in the Philippines, as recorded by Holt and Russell, 1932).

2. Rice fields and channels may be only potentially dangerous because, although a vector mosquito is occasionally present, it is not found in sufficient density to propagate malaria (e.g., the Tanjore delta as mentioned below. See also reference to occasional *A. minimus* in rice fields, by Rice and Savage, 1932).

3. Rice fields may be harmless but their feeder side channels dangerous (e.g., in some areas of Ceylon, as noted by Barnes and Russell, 1925; and in the Nilgiris, South India, as noted by Russell and Jacob, 1942).

4. Rice fields may be dangerous only for a part of the season (e.g., in Pattukkottai, only until the rice is about a foot high, as noted by Russell and H. R. Rao (1940). (See Manson and Ramsay, 1932, regarding *A. minimus* in fallow rice fields near coolie lines.)

5. Rice fields may be dangerous throughout the growing season (e.g., in parts of China, as noted by Robertson and Chang, 1937).

Therefore, each rice field area must be judged on its own characters as to its malariogenic possibilities and as to the measures required to curb these. In some areas, as in parts of Malaya and the Philippines, one is even justified in advocating the extension of wet rice culture as a malaria control measure; in other areas, as in the vicinity of Savannah, Georgia (U.S.A.), all wet rice culture has been forbidden as a malaria control measure. In still other areas, as in the Pattukkottai area, rice culture as now practised is a source of malaria. It would be much less malarious, possibly not at all, were more intensive cultivation and more tidy water practice in vogue.

It may be of interest to discuss some characters of Pattukkottai rice fields in reference to malaria, as they have been observed over a period of five years.

Fallow rice fields

The main rice season in Pattukkottai taluk begins in the middle of July, when water is made available for seed-bed preparation. These seed-beds form about a tenth of the entire rice area. Upon arrival of water, the ryot is expected to busy himself immediately, wetting those fields he will use as seed-beds and preparing them for sowing. This work should take about 10 days. Ordinarily, the ryot reacts in a leisurely fashion. Water floods his seed-beds and other fields as well but he is not ready with his plough and bullocks. He often allows an interval of two to three weeks to elapse before beginning work in his seed-beds. The effects of this lag is very significant as regards the output of the malaria vector *A. culicifacies* because the most dangerous stage of the fallow field is when it is wet and unploughed (Russell and H. R. Rao, 1940).

The nurseries develop for 45 days before being pulled out for transplantation. During this time water has been flooding fallow fields everywhere. The ryot is too busy with his seed-beds to do other field work, such as carting manure and preliminary ploughing. He expects to plough a fortnight before transplanting his crop, but his fields remain wet, unploughed, and fallow for over five weeks, and during this period *A. culicifacies* is produced in extraordinarily large numbers.

In another paper, the anophelids of rice fields and the estimated output of adults have been discussed (Russell and H. R. Rao, 1940). *A. culicifacies* has its highest density in unploughed,

wet, fallow fields. Subsequent cultural operations decrease its density. The ryot's tardiness and unwillingness to follow a well-defined agricultural time-table contribute towards an enormously high *culicifacies* output.

Nurseries and growing rice fields

Nurseries produce *A. culicifacies*; so also do growing fields before the rice crop is a foot tall. Fortunately, *A. culicifacies* is not found in rice fields when the plants are more than a foot tall, due apparently to obstruction to ovipositing (Russell and Rao, T. R.). The total output of *A. culicifacies* from these two habitats is not inconsiderable, and in view of the area, even low densities have practical importance and require consideration in any control scheme.

Field channels

Field channels, whether for watering rice fields or for other purposes, breed *A. culicifacies* practically throughout the rice season. In the general scheme of water distribution in Pattukkottai, the field channel is the responsibility of the ryot. He locates and maintains it. Often he has more total channel length than is necessary for efficient irrigation of his fields, and to that extent *culicifacies* numbers are increased. The channels are very often tortuous, thereby increasing breeding edge out of all proportion to optimum length. The ryot does not keep these edges tidy, not realizing, of course, that each water pocket means increased numbers of *A. culicifacies*. He pays absolutely no attention to channel gradient and frequently breaches bunds to flood adjacent land. When he takes water from the channel, he cuts open bunds indiscriminately, creating more *culicifacies* breeding conditions in the process.

Thus because of (i) long (and needless) periods when fields are wet but fallow; (ii) ill-conceived and poorly maintained channels; (iii) a natural tendency for *A. culicifacies* to breed under such conditions as well as in planted rice fields until the stalks are a foot high, the cultivation of this crop is a source of malaria in the area. But, as will be shown below, there is good reason to believe that were the first two factors eliminated the amount of breeding in planted rice fields during the early stages of growth would not by itself be sufficient to maintain malaria.

Rice culture and malaria in Nilgiris-Wynaad

The vector in the foothills of the Nilgiris-Wynaad area is *A. fluviatilis* which is found in largest numbers in small hill streams and in rice field and other irrigation or drainage channels (Covell and Harbhagwan, 1939; Russell and Jacob, 1942). In these districts, generally between elevations of 1,000 and 4,000 feet, the small channels of running water which supply or drain rice fields are definitely malariogenic. Not only do such channels menace nearby villages but frequently they tend to nullify expensive control programmes directed against the natural

streams of adjacent estates. Usually rice fields are owned by small farmers and not by estates.

Contrary to the Pattukkottai situation, it does not appear that this source of malaria incidental to Wynaad-Nilgiris rice culture can justly be attributed to imperfect agricultural practice. Nor is it clear how it can be controlled to best advantage. Possibly it can be neglected, provided spray-killing of adult mosquitoes is practised, as noted below. However, attempts have been made to employ herbage packing, sluicing, and shading in order to inhibit breeding. The last two are suitable measures if under proper supervision, such as may prevail on an estate. Elsewhere in rural areas good supervision is almost never seen.

Other foothill agricultural malaria

Both in Gudalur and in Kallar, of the Nilgiris District, for the cultivation of bananas and (in Kallar) of areca (betel) nut palms, there are irrigation systems which are malariogenic because of the breeding of *A. fluviatilis* in the supply of drainage channels, or in the depressions between rows of plants. Such sources of malaria could easily be eliminated by proper regulation of the water, providing for short drying periods.

But by far the greatest amount of agricultural malaria in the foothills has been that affecting the tea, coffee, and rubber estates. It has originated not in artificial channels, but in natural foothill streams (Measham, 1939; and especially Covell and Harbhagwan, 1939). Not infrequently the practice of clearing preparatory to planting has been responsible for opening up of ravines, so that dense jungle growth has given way to grass and open plantings along the stream edges. This has induced *A. fluviatilis* to extend into streams not attractive to it when heavily shaded, and so has presented a man-made addition to the already serious natural malaria problem.

As stated above, much progress has been made by planting communities in the control of malaria, formerly by lavish use of oil but later by such methods as sluicing and shading, and recently, by spray-killing with pyrethrum extracts. Careful siting of labourers has also been a favourable factor in some areas. But smaller and poorly organized estates, particularly if Indian-owned, are still all too frequently hotbeds of malaria.

Casuarina cultivation and malaria

There is a narrow strip of sandy sea coast from Madras City northwards for about 120 miles, where *Casuarina equisetifolia* Forst. is extensively cultivated for firewood. This tree grows readily in sandy soil, if watered regularly for two or three years, until it has put its roots into the subsoil water, which in this area is fairly near the surface (two to six feet, generally). The cheapest and easiest way of obtaining water for the young trees is by scooping out shallow wells from which water in earthen pots is carried by labourers. As reported by Russell and Jacob

(1939a) these casuarina pits or wells are prolific sources of *A. culicifacies*, the vector. By themselves they constitute a source of agricultural malaria which attains an average endemicity of over 60 per cent, measured by spleen index.

This intense malaria is nearly 100 per cent man-made and agricultural in origin, and has seriously retarded the development of such localities as Ennore.

Several times pit-filling schemes have been instituted by Government but the pits have always been redug because there is no cheaper or easier way of obtaining the essential irrigation water. So, too, pumps and special wells have been tried out and have also come up against that law of human nature, that man tends always to satisfy his needs with the least possible exertion. The authors cited above, on the basis of extended experiments, believed that this casuarina pit malaria could be controlled very cheaply by the use of *Gambusia* fishes (Russell and Jacob, 1939b).

Irrigation malaria

It has long been recognized that an irrigation system that brings vital supplies of water to a previously dry area may also bring malaria. This subject has already been discussed in detail by Russell (1938) and need only be recapitulated here.

As observed in Pattukkottai, there were certain specific ways in which irrigation produced malaria, in every case by facilitating the development of the malaria-carrying mosquito, *A. culicifacies*. These points were summarized by Russell (1938) somewhat as follows:—

1. *Defective sluice gates*, which permit water to flow when and where not required thus forming dangerous pools and unwanted channels.

2. *Seeping canal banks*.

3. *Borrow-pits*.

4. *Defective distributing chambers*, which send water in directions not indicated by requirements, so that mosquito-breeding pools are formed. Such chambers may actually block the flow and cause ponding.

5. *Excessive supply of water*, causing a great deal of mosquito breeding directly along canal banks and, indirectly, by pools and irregular channels.

6. *Improper delivery of water*, for example, into a roadway or roadside ditch, or into an open uncultivated field, or a village square, there to form mosquito-breeding places.

7. *Improperly maintained canal banks*.

8. *Improperly maintained canal beds*, which slow down the current so that it permits more breeding, or so that many mosquito-breeding pools appear at the end of the irrigation season.

9. *Absence of any planned or controlled system of field channels*.

10. *Insufficient number of bridges across canals*, thus isolating villagers from main roads so that they breach the banks, causing ponding.

1. *Absence of drainage canals*. This invariably creates a menace not only to the health of the community but to the very land itself. The evils of water-logging should not require emphasis.

12. *General untidiness*. Here a pipe is missing, there a bridge was forgotten; here is a leaky gate, there a defective distributing chamber; here a small section of canal was never dug, there two or three channels do the work of one; here a bathing ghat should have been built, there cattle protection is required. In view of the fact that these 'little things' are producing malaria, it is no proper answer to say that in time they will be corrected.

The following are some general mosquito-producing effects of an irrigation system, especially as seen in Pattukkottai:—

1. *A dry taluk becomes a wet one during the irrigation season*.

2. *Fallow fields remain wet for a longer period*.

3. *Rivers and tanks carry more water during the wet season and are empty for a shorter time during the dry season than formerly*.

4. *The subsoil water level rises because of irrigation without drainage*.

5. *Unplanned streams and channels become numerous*.

6. *Ditches are full of water throughout the irrigation season*.

7. *Borrow-pits fill with irrigation water and remain full during the season and for a varying period thereafter*.

The point was made in the paper cited (Russell, 1938) that it was not irrigation *per se* in Pattukkottai but *untidy and defective irrigation* that was a source of malaria. *A. culicifacies* is a weak vector with an infection index of only 0.1 per cent (Russell and Rao, 1940) and it has a high preference for bovine blood (Russell and Rao). It is only when this species is prevalent in very large numbers that it is an effective vector, and it is only when an irrigation system is grossly at fault that it can produce *A. culicifacies* in sufficient abundance to menace the health of a community. Finally, it is only in the absence of collaboration between Health and Public Works Departments that such disastrous irrigation malaria could arise. Pattukkottai taluk was non-malarious until 1933-34 when the irrigation system was opened. The average malaria spleen index in the taluk is now (November 1941) 56.5 per cent, and the parasite index 49.9 per cent.

Brick-pits and borrow-pits

In the villages, houses are mud-walled. The flooring is made of earth, and plastered with cow dung. Cattle sheds have raised earthen floors and granaries are earth-lined. All this earth the ryot obtains by digging borrow-pits. So it is very common to see village sites studded with such pits. Due to the rise of subsoil water,

these pits are flooded and become prolific sources of *A. culicifacies*.

The ryot also has a practice of lowering the level of his fields for easier irrigation. This he achieves by digging pits in the fields and putting the excavated soil on the bunds. At a later date he fills the pits as he levels his field. These pits often remain a long time before being levelled. They collect water which is attractive to *A. culicifacies*.

Waste land

Waste, i.e., untilled, lands collect irrigation water and breed enormous numbers of *A. culicifacies*. In most cases such land is arable and if intelligently reclaimed and cultivated would no longer be malariogenic. This procedure is discussed below.

Cost of malaria to the ryot

It is not always realized that malaria is a source of actual expense to a ryot, aside from the many indirect ways in which this disease contracts his income. There is need for many more malario-economic surveys such as that reported by Russel and Menon (1942).

In that survey it was determined in the Pattukkottai village of Tuvarangurichechi that the ryots were spending an average of Rs. 2-8 *per capita* per year to treat malarial fevers. Of course, not much of this money went to physicians but it was paid out for the kind of treatment available to or desired by the ryots, e.g. for quacks, priests, folk-medicines, candles, and sacrificial animals. In addition the lost wages due to absence from work because of malarial fevers were conservatively estimated at Re. 1-6 *per capita*. Here was a yearly loss of Rs. 3-14 *per capita*, due to malaria. Yet, as noted below, the disease could be completely controlled in this village for about As. 4 *per capita* per year.

It seems likely that these data are representative of, or are less than, the *per capita* cost of malaria to ryots in hundreds of thousands of small malarious villages throughout India. It can be deduced that malaria is a considerable direct financial burden to the ryots, whose average *per capita* annual income is probably not over Rs. 45, and in Tuvarangurichechi was only Rs. 35-3 at the time of the survey.

Control of agricultural malaria

Malaria can be controlled by (a) attacking the larvæ of malaria vector mosquitoes; (b) attacking the adult mosquitoes; (c) combining both measures. We do not believe that it can be controlled by distributing cinchona products or any other malaria remedy now available. Certainly, experiments over a half-century or more do not indicate that malaria control by drugs is possible, although, of course, no one disputes the need for better and more widely practised malaria therapy to alleviate suffering and to prevent malaria deaths.

In 1936, one of us (Russell, 1936) wrote: 'The simple truth seems to be that to-day, while prophylaxis by standardized methods is feasible in selected areas, there is not available an economical method of malaria prevention for much of rural India'. This pessimistic statement was based on the state of knowledge that existed in 1936 and was certainly true as regards the agricultural malaria of small rural villages. It was partly because of this situation that six years have been devoted to extensive investigations and experiments in methods of control of rural malaria. Now, happily, it has been proved that the above quotation is no longer true. It is now undoubtedly a fact that for much of rural India malaria control is not only feasible but financially profitable. The following sections discuss briefly some of the methods available:—

Spray-killing adult mosquitoes

It now seems beyond doubt that the method of malaria control of most promise for rural areas is that of daytime spraying of huts and out-buildings with pyrethrum sprays.

Beginning in 1938, experiments have been carried out each season under direction of the senior authors, with spray-killing of adult mosquitoes in houses and cowsheds, using a pyrethrum-kerosene extract diluted with either more kerosene, or with water. In Kasangadu village, for example, a mixture consisting of 1 part Pyroicide 20 and 19 parts kerosene was sprayed in every house, cowshed, and out-building once a week during the irrigation seasons of 1938, 1939 and 1940, but not in 1941. Since adult *culicifacies* mosquitoes rest in the daytime inside houses, cowsheds, and out-buildings, this measure has been very effective. The spleen rate in Kasangadu in November 1937 was 68 per cent. By November 1938, it had dropped to 24 per cent, in November 1939, it was 15 per cent, and November 1940, it had come to the low rate of 6 per cent, with a parasite rate of .ml. The nearby and similar village of Tuvarangurichechi was not sprayed but was subject to the same spleen tests. Here the spleen rates in November 1937, 1938, 1939 and 1940 were 55, 61, 57 and 58 per cent respectively. In other words, the transmission of malaria was completely halted in Kasangadu, and this was not the result of natural influences but of the spray-killing. The cost of the work in Kasangadu was nearly a rupee *per capita* in 1938 and 1939, but, with improved technique, had dropped to As. 7-2 *per capita* in 1940.

In 1941 Kasangadu was purposely not sprayed. As a result the spleen rate rose to 17.0 per cent and the parasite rate to 15.3 per cent. This illustrates the need for continuity of effort.

Other villages were sprayed in 1940 and 1941. In Modalcheri, for example, an extract from Nilgiris-grown pyrethrum was used. Pyrethrum has been grown in India only during the last few years and this was perhaps the first large scale

field use of an extract of Indian *pyrethrum* in South India. It is much cheaper than imported extracts. In Modalcheri the cost of spraying was only As. 4-7 *per capita*. Here the spleen rate, which was 80 per cent in November 1937, and 82 per cent in 1938, dropped to 28 per cent in November 1940, after only one season's spraying, and to 6.3 per cent in 1941, after two seasons. Villagers welcome spraying, which kills other insects as well as mosquitoes.

During 1941 a successful water-emulsion spray was developed, using a concentrated kerosene extract of Indian grown *pyrethrum* (1 gallon), an emulsifier (sodium lauryl sulphate, 184 grammes), and water (7 gallons). This spray-mixture cost only As. 7-9 per gallon, as contrasted with Pyroside 20 and kerosene at Rs. 3-1-7 per gallon. It gave excellent results in a Pattukkottai village, causing a reduction in spleen rate from 48 per cent in 1940 to 16 per cent in 1941, after only one season of spraying, and at a total cost of only As. 3 *per capita*.

It is obvious that spray-killing is as useful in South India as it has been shown to be in South Africa, and, by the Malaria Institute of India in Delhi. There are many communities that could afford to pay the annual cost of spray-killing to control malaria. Many others could do so if helped by Government agencies [Russell and Knipe (1939), (1940), (1941); Russell, Knipe and Sitapathy (1943); Russell, Knipe and T. R. Rao (1942)]. For earlier references to spray-killing successes see De Meillon (1936) and Covell *et al.* (1938).

Intermittent irrigation

Experiments, over a period of four years, with intermittent irrigation or a so-called 'turn system', to control mosquito breeding in rice fields have given as promising results in Pattukkottai taluk as have been reported from Java, Portugal, and elsewhere. The principle of intermittent irrigation as a malaria control measure is the periodical withholding of water just long enough to permit the surface of fields and channels to become sufficiently dry to cause the death of all mosquito larvæ. The sub-surface soil around the rice roots remains moist. In South India it takes a week or a little longer for the eggs of the malaria vector *A. culicifacies* to develop through larval and pupal stages, before the adult emerges. Hence a weekly drying effectively controls breeding of this species.

The experiments with intermittent irrigation have been of two kinds. First, an area of rented land was divided into uniform plots, some of which were irrigated normally, others with 5 wet days, followed by 1, 2, 3, or 4 dry days. This experiment had four seasons and at the end of each the crops of rice and straw were carefully weighed. The results have shown that in the plots from which water was excluded for only one day it was not possible to kill mosquito larvæ because the fields did not become sufficiently dry. Good mosquito control, however,

was seen in the plots kept dry for 2, 3, or 4 days, except in the rainy month of November when the plots did not always become dry. This did not matter as regards *culicifacies* because, as noted elsewhere, this species is not found in local rice fields after the rice is over a foot in height, as it generally is throughout the taluk by mid-October.

Of course, type of soil is an important factor in determining how long a period is required to dry a field. Some soils retain water closely while others are quite porous. In Pattukkottai, where one is dealing with medium sandy loam, 2 to 2½ days' drying seemed sufficient to destroy larvæ. In other areas more time might be required.

There was no significant difference in weight of weeds removed from the plots, whether normally or intermittently irrigated. Further, no significant differences in crop yield were noticed, except during the first season when, due to fungus disease, the yield was a little less in the intermittent plots. Analysis of grain at the Nutrition Research Laboratories in Coonoor showed no differences in nutritive value between the two lots of rice.

In 1940 and 1941, as a second type of experiment, intermittent irrigation was applied to two village areas, Alivalam and Senjayakollai, from the outset of the season until the November rains. Good mosquito control in fields and channels was obtained and no differences in rice crops as compared to other areas could be seen, by competent observers. Further testing is required as regards administrative technique. But here seems to be an economically feasible measure of malaria control for Pattukkottai taluk, as well as for other irrigated areas in India (Russell, Knipe and H. R. Rao, 1942).

Malaria control by attacking larvæ of malaria vectors

Complete elimination of all mosquito breeding places would seem, perhaps, to be ideal, but because of very important social, economic and (in the case of certain tanks) sentimental reasons, such complete elimination, even if limited to the vector species, is neither desirable nor practicable. Whether a given breeding place should be left alone, or be filled or drained, treated with oil or Paris green, or so modified as to make it unsuitable for larvæ, must always be determined by local conditions.

It would seem that, logically, an attack on larvæ in such an area as Pattukkottai taluk should first consist of correcting defects in the irrigation system, preventing wastage of water, filling or draining pits and ditches which serve no purpose. In order to demonstrate methods, costs and effects of such an anti-larva attack, Knipe and Russell (1942) chose an area of seven square miles, comprising the six hamlets of Senjayakollai (pop. 500), Aladikumulai (pop. 550), Enadi (pop. 1,440), Naravallikollai (pop. 400), Surankadu (pop. 300), and Veerakurichchi

(pop. 200). Over 700 large borrow-pits were filled, usually by taking earth from high level fields so that many (35.5) acres of new rice land were brought under cultivation as a by-product of the filling operations. Some 55,000 cubic yards of earth were used as fill. Numerous new field supply channels were formed (66,707 lineal feet of canals excavated or realigned), tight fitting gates (9) were installed at the sluice heads in canals, improved devices for tidy control of water in field channels were installed, fifteen culverts were provided for easy access to fields including two large highway culverts built across a canal, an inverted siphon of an improved design was put under a roadway, and many cart-tracks were put in order. Intermittent irrigation was practised in 1940 and 1941.

Gambusia fishes were put into 1,464 wells. These wells were first chlorinated to kill larger fishes which would eat small larva-destroying *Gambusia*. These fishes were very useful in wells but did not establish themselves in tanks, apparently because of predatory fishes. Several tanks were cleaned and deepened. Every one of these measures had a direct relation to mosquito control, but many also formed important means of village reconstruction and so have been of permanent benefit to the people.

The results achieved in reducing the incidence of malaria were good, as shown by the following spleen and parasite rates :—

Malaria season spleen and parasite rates in villages with experimental larva control

Description	1937		1941	
	PERCENTAGE RATES		PERCENTAGE RATES	
	Spleen	Parasite	Spleen	Parasite
Senjayakollai ...	48	42	4	Nil
Enadi* ...	54	50	19	10
Aladikumalai ..	56	49	11	3
Contrast village of Pappanadu (no control).	53	43	57	48

* Control measures in Enadi not effective until latter part of 1940.

Costs of this work in the Senjayakollai area have not been excessive. The total was Rs. 14,841-5-5 which amounts to Rs. 3-4 per acre or Rs. 4-6 *per capita*. During 1941 we provided adequate maintenance, with decreasing spleen rates, at a cost of only As. 2 per acre or As. 1-11 *per capita*, surely not beyond the financial resources of the community. (Knipe and Russell, 1942).

The best method of dealing with borrow-pits is filling. This is expensive and it is a pity that the digging of new borrow-pits under official auspices continues in the taluk almost unchecked. These borrow-pits have been proved

to be a prolific source of *culicifacies* and so of misery and even death to the inhabitants of the taluk. It seems absurd that, often merely to facilitate the measuring of earth removed by contractors, these malaria-generating pits should be tolerated.

In a number of instances, as mentioned above, filling has been accomplished with earth taken from fields too high to be irrigated. The nature of the soil is such that there is not much loss to a field by removing the top-soil and the benefits of irrigation soon make up the deficit. This procedure combines malaria control with agricultural gain and could be widely practised in the taluk.

In some cases, villagers have been cut off from a main road by a canal and so have breached the canal to get their carts across. This has led to the formation of breeding places which have been eliminated by providing suitable culverts.

For control of breeding along canals and channels, experiments with Paris green have been successful, both when applied with an automatic distributor and when sprayed in a watery suspension. When Paris green floats on top of water *Anopheles* larvæ, which feed most of the time at the surface, will eat the poison and are killed within a very short time. In the automatic distributors, Paris green and charcoal powder are kept in hoppers from which the mixture is shaken out by the action of paddle wheels moved by the stream of the canal. Wind and water currents distribute the poison to the sides of the canal where the larvæ feed on it and are destroyed (Knipe and Russell). When sprayers were used, a man walked along the canal banks spraying Paris green suspended in a watery emulsion. Various types of spray pumps were used (Russell, Knipe and T. R. Rao, 1940).

We have had some success in one village with the naturalistic method of using *Wolfia* to exclude mosquito breeding from small tanks and pools. When this plant completely covers the water surface, no larvæ are found. It can be transplanted from pool to pool and grows fairly rapidly.

Malaria control by extending and intensifying cultivation

Hackett (1937) noted a saying in Italy that 'malaria flees before the plough'. He also quoted Aschenfeldt as having said in 1845, 'Nothing but the greatest wilderness or the most perfect cultivation protects an area from malaria fever'. But Hackett rightly points out that while this may have been the case in some areas it has certainly not been true in others. There are areas where severe malaria persists, apparently uninfluenced, in the face of intensive cultivation of the soil.

There has often been a tendency to consider malaria as a sociological problem to be attacked by such social measures as heightening agricultural or industrial activity, improving diets and

housing. But there is no sound evidence that famine and malnutrition, for example, are direct etiological factors in malaria, in fact such experiments as have been done indicate that a well-nourished individual is fully as susceptible to plasmodia as one who is malnourished. What Hackett (1937, p. 15) calls the American thesis, that malaria is a simple function of anopheline vector density, has never been upset and must be kept in mind. Any measure that tends to destroy the anopheline vector, to lower its density, or to keep it from man, may have prophylactic value. Otherwise, it cannot be classed as malaria control. 'Good housing', for example, has no malaria control value unless it includes screening and proper siting with reference to malaria vectors. It seems clear that as regards the immediate technique of malaria control one must not fail to make direct attacks on the insect vector. Attempts at control malaria by supplying routine social service or more opportunity for industrial and agricultural activity are apt to be futile.

Here, as in the case of the malaria of rice fields, the question is whether or not intensifying and extending cultivation will reduce the numbers of the mosquito vector. If it does, then 'malaria flees before the plough'. If the vector species is not disturbed or is perhaps increased in numbers then malaria has nothing to fear from the plough.

Reference has already been made to the observation that malarious Pattukkottai taluk was contiguous to the great rice-growing non-malarious Tanjore delta, and, of course, the reason for the absence of malaria in the latter area was a matter of great interest. Careful studies were made, comparing four villages near Tiruvadi in the delta and four similar villages in Pattukkottai taluk. These studies included an investigation of the manner of rice culture in each village. It was also necessary to examine minutely hundreds of *culicifacies* mosquitoes collected in each area. Their anatomical characters, their preferences for cow or human blood, their ability to carry malaria, and especially their relative abundance in each area, were observed and evaluated (Russell and T. R. Rao).

These studies proved that the *culicifacies* of the two areas were identical species, morphologically and biologically, with the same habits, and with equal susceptibility to experimental malaria. But the numbers present in the delta were markedly fewer than in the taluk. This was shown over a period of two years by measured collections in houses, cowsheds, and traps. There was no doubt that *culicifacies* mosquitoes were very much more abundant in Pattukkottai taluk than in the delta, and that this fact explained why the former area was malarious and the latter not. It is probable that if *culicifacies* were present in great numbers in the delta there would indeed be malaria there. But with a species like *culicifacies*, of

which only one in a thousand is found infected in the area under observation, very great numbers are required to propagate malaria.

So the next question was, 'Why are *culicifacies* mosquitoes less numerous in the delta, where so much rice is grown by wet cultivation'?

The answer seemed to be in the following points :—

1. The delta area near Tiruvadi was mainly a two-crop area, so that rice fields remained wet fallow only for short periods, prior to transplanting.

2. The delta area had practically no borrow-pits.

3. The delta area had practically no uncultivated low land on which waste irrigation water could stand.

4. The delta area had relatively few small field channels carrying fresh irrigation water.

By contrast,

1. Pattukkottai taluk was mainly a single crop area, so that most rice fields remained wet fallow for a long time, usually from mid-June to late August, at a time when the mosquito population increased rapidly.

2. The taluk had innumerable borrow-pits along the roads and canals.

3. There were many uncultivated low-lying lands in the taluk on which waste irrigation water remained from mid-June to the following February.

4. There were in the taluk enormous numbers of small field channels (called 'field *bodhis*') carrying fresh irrigation water.

Many observations made it clear that fallow fields, borrow-pits, field channels, and waste irrigation water were prolific source of *culicifacies*. It therefore became understandable why *culicifacies* was so much more abundant in the taluk than in the delta, and why, since *culicifacies* was the carrier, malaria was common in the taluk but not in the delta (Russell and T. R. Rao).

On the basis of these observations it appears that in Pattukkottai taluk, malaria would flee before a more efficient plough. The needlessly prolonged period of wet fallow fields, the single instead of double rice crop, the undue length of field channels, and their neglected condition, the wet waste lands, the untidy and defective irrigation, the unprotected irrigation wells—each of these factors contributes to the malaria of Pattukkottai taluk by adding to the numbers of the mosquito vector. All might be corrected by more intensive and more extensive as well as more intelligent agricultural practice.

As noted above, co-operation between various governmental agencies is of vital importance in preventing and controlling agricultural malaria. Not only is it necessary for public works and public health departments to work in unison against mosquitoes but far more co-operation by agricultural departments is required. For instance, when planning or developing an irrigation scheme in a potentially or actually

malarious area, efforts should be made by the agricultural advisers not only to curtail the mosquito output from wet fields but to replace malariogenic crops, such as rice, by less dangerous plantings such as millets or cotton wherever possible.

In order to demonstrate that it is not only a means of reducing the incidence of *A. culicifacies* but also a financially shrewd proposition to turn waste land into cultivation, an area of nine acres was dealt with near Alivalam, in Pattukkottai taluk in 1941-1942. This land had produced nothing but mosquitoes, including *A. culicifacies*, during each irrigation season, when it was either flooded or was the site of seepage water.

Nine rice fields were laid out at a cost of about Rs. 1,350, or Rs. 150 per acre. This land had a value before reclamation of only Rs. 15 per acre. After the rice fields had been laid out the value was, conservatively, Rs. 250 per acre, an immediate gain of Rs. 235, or a net gain of Rs. 85 per acre, over original cost and the expense of reclamation. This represented an immediate profit of Rs. 765 or a little over 50 per cent on the investment of Rs. 1,485. The net return in rice crops the first few years is estimated at Rs. 20 per acre, more thereafter as the land improves. Even at the low figure of Rs. 20 per acre the investment of Rs. 1,485 would yield an annual income of a little over 12 per cent.

Reduction in breeding of *A. culicifacies* was achieved because, instead of breeding unhampered throughout the irrigation season, this species only bred until the rice plants were about a foot high. As noted above, after this stage this species is not found in rice fields.

In other words, in Pattukkottai taluk, and no doubt in many other rural areas in India, it is no longer correct for revenue officials to say that their Government cannot afford to control malaria. The fact is exactly the reverse. A country like India, where the farmers are so poor, and where agriculture is the predominant industry, cannot afford to allow malaria to continue to ravage its countryside, financially as well as physically, when it is known that it costs less to control it than to permit it to remain.

Summary

This paper notes that India is predominantly an agricultural country and it points out how malaria impinges on agriculture by retarding agricultural development, by forcing the abandonment of fertile areas, by afflicting organized tea, coffee, rubber, and other plantations, by preventing maximum development and exploitation of forest resources, by complicating irrigation systems, by virtue of a great many man-made breeding places created by farmers, by exacting a yearly cash outlay from the already impoverished ryots for what they consider to be treatment, by the fact that in some areas there is an inverse correlation

between amount of malaria and the degree to which cultivation has been extended and intensified.

The relation between rice culture and malaria is discussed and it is pointed out that this relationship depends on the degree to which rice fields and their channels from breeding places for malaria mosquito vectors. Many rice-growing areas in India are non-malarious but in the Pattukkottai area described, rice fields and channels are definitely malariogenic, breeding *A. culicifacies* the vector. In the Nilgiris-Wynaad area, rice field supply and drainage channels are definite sources of the malaria vector, *A. fluviatilis*.

Casuarina-pit malaria, along a coastal strip north of Madras City, is also discussed. Here the shallow wells or pits, dug in the sandy soil to provide a source of water for the young trees, are prolific breeding places of *A. culicifacies*, the vector.

Reference is made to some of the ways in which irrigation, both construction and maintenance, is associated with malaria. There is also a consideration of what malaria costs the ryot in direct money losses. For instance, in one village the ryots were spending Rs. 2-8 *per capita* per year to treat malaria, losing in addition Re. 1-6 in wages *per capita* per year.

The control of agricultural malaria is considered and reference made to the fact that, whereas in 1936 it appeared that no method had been shown to be financially feasible for small rural communities in India, it is now possible to recommend spray-killing with pyrethrum extracts, at a cost of no more than a quarter of a rupee *per capita* per year, in many small villages. So, too, intermittent irrigation on a 5-wet, 2-dry day basis, seems feasible in some areas.

Control by antilarval measures is also cited and it is pointed out that, although this involves a certain initial outlay, maintenance can be provided for less than two annas *per capita* per year.

Finally, reference is made to the possibility of malaria control in the Pattukkottai area by intensifying and extending cultivation, and the reasons for believing this are explained.

The Treatment of Congenital Syphilis

By L. FINDLAY, M.D., F.R.C.P.

(Abstracted from the *Practitioner*, Vol. CXLVIII, May 1942, p. 280)

In any discussion of the treatment of congenital syphilis, special prominence must always be given to the statement that this is a disease which should seldom or never require treatment, for the simple reason that means are available to prevent its appearance. It cannot be too strongly emphasized therefore that prophylaxis is the correct method of approach to congenital syphilis. This means the timely and thorough cure of the acquired variety of the mischief in prospective parents, and especially of the mother during pregnancy. It is only in this way that 100 per cent of the children can be saved.

The uterus is a poor nidus for the spirochæte, so that the infection tends to remain latent. However, with the advent of conception and the development of the placental tissues, there is produced a favourable soil for the proliferation of the contagium vivum. This has been amply confirmed by the examination of the placenta of the syphilitic mother. Invariably spirochætes are detected in the placenta of the mother of syphilitic offspring, and always in greatest abundance in the decidual portion of the placenta. It is from this focus in the placenta that the foetus becomes infected and, although the migration of the spirochæte may take place at any stage during pregnancy, it would seem to occur generally during the latter half of gestation and perhaps most frequently during parturition.

ANTENATAL TREATMENT

It is generally admitted that if antisyphilitic treatment of the mother with salvarsan is begun before the fifth month of pregnancy, infection of the foetus is almost certainly avoided. However, good results may be obtained if the treatment is not instituted until even a later date, no doubt because, as already remarked, infection of the foetus is often delayed until during the process of parturition. In the author's experience, for instance, a healthy non-syphilitic child has always been born when treatment was begun before the beginning of the eighth month of pregnancy.

Antenatal treatment with salvarsan was found to be an advance on the older method of treatment with mercury and potassium iodide. By the administration of these latter drugs to the syphilitic mother during pregnancy, sometimes a healthy non-syphilitic child would be born, but if they were not again employed during the succeeding pregnancy, syphilitic pregnancy was almost certain to result. On the other hand, with treatment with salvarsan and mercury during pregnancy, not only was a healthy infant the rule, but without any further treatment the mother would continue to bear in her succeeding pregnancies healthy non-syphilitic children.

Technique.—The author's practice has been to treat the pregnant woman with neosalvarsan and mercurial inunction, beginning as early as possible, usually about the second month of gestation, and repeating the injection of 0.3 gm. of the arsenical compound at weekly or fortnightly intervals for at least eight times, or until the Wassermann reaction is negative. The women have been little upset by the treatment, apart from some headache and sickness during the twenty-four hours succeeding the injections. The mercurial inunction should be continued throughout the pregnancy.

TREATMENT OF THE CHILD

Should, however, the disease not have been prevented, either because antenatal treatment had not been instituted, or because it had been delayed unduly, there is no cause for despondency, for at no time has the cure of syphilis in the new born and young child been possible in such a large proportion of cases and, furthermore, with such little discomfort to the patient and his parents.

Salvarsan has the serious disadvantage that it has to be administered intravenously, always a difficult procedure in the child.

No. 594 of Ehrlich, which chemically is 3-acetyl-amino-4-hydroxyphenylarsonic acid, is generally known as acetarsone, and has been put on the market with the trade name of spirocid in Germany and of stovarsol in France. It contains 27.1 to 27.4 per cent of arsenic in comparison with 19 per cent in arsphenamine or salvarsan. It is a white, almost tasteless powder, slightly soluble in milk and water. The drug has been employed not only for the cure of the actively syphilitic child, but also for the potentially syphilitic child

as well, i.e., the new born of an untreated or insufficiently treated mother but not presenting any symptoms of the disease beyond a positive Wassermann reaction.

Practically all have found it superior in its effect to any other drug, and especially in the early manifestations of congenital syphilis.

Action of acetarsone.—Most authors speak of the rapidity with which the early manifestations of congenital syphilis improve during acetarsone therapy. The rash is found to disappear in from one to four weeks, snuffles in from four to six weeks, splenic enlargement in six weeks, and bone lesions radiologically appear completely healed within ten weeks. Naturally, less dramatic results are obtained in the case of the later manifestations of the disease as of course is true also of other methods of treatment. Not a few authors, however, record good results in the later visceral and osseous manifestations, and some, e.g., Bratusch-Marrain, have shown that acetarsone is also of value in cerebral syphilis. All authors remark on the improvement in the nutrition of the child which takes place during the course of treatment with acetarsone.

Toxic effects seldom occur and those that have been encountered have as a rule been mild and evanescent in nature. The most frequent toxic manifestations recorded have been slight looseness of the motions and moderate fever, but occasionally dermatitis, which in one or two isolated instances has proved fatal, has been observed. Withholding of the drug for a day or so is, as a rule, effective in causing toxic symptoms to disappear, when the treatment, starting again with diminished doses, may be safely resumed. Toxic effects have usually been observed in ill and wasted infants, so that special watchfulness is necessary in such patients.

Dosage.—In order to gauge the susceptibility of the individual child, all writers recommend that at first the drug should be administered in relatively small doses, which, however, are gradually increased until the optimum is being given. Although a few workers administer the drug daily without intermission during the whole course of a so-called 'cure', which extends to forty or fifty days, some advise a periodic intermission to give time for its complete elimination and a consequent diminution in liability to toxic effects. Thus it is given only on every alternate day or every fourth day, or again it is given for seven or ten consecutive days which are followed by a free interval of four days. In all schemes of treatment a free period of four to six weeks after the completion of one course, or so-called 'cure', is advised.

After the completion of one course of the treatment, or so-called 'cure', the result of the serological tests (Wassermann and Kahn or Meinicke) is noted. If the serological test is still positive, a second course is instituted after a rest period of four to six weeks, and if the test still remains positive, further courses are undertaken at four-weekly intervals until a negative reaction is obtained. If, however, after the first course, the serological test is negative, the child is kept under observation for a period of one year and the tests are repeated at three-monthly intervals in order to be sure that the cure has been complete.

SCHEME OF TREATMENT WITH ACETARSONE (AFTER MÜLLER)

The technique followed and found effective is that devised by Erich Müller but reinforced by daily mercurial inunction. This scheme has with one exception given good results, especially in children under one year of age. The single exception was an infant who had symptoms of congenital obliteration of the bile ducts. In all the other cases the cutaneous lesions rapidly disappeared and a negative Wassermann reaction was obtained at the conclusion of the first course of treatment. But to make certain that a cure had been established, a second course of treatment, with of course mercurial inunction, was always practised. In no case there were any toxic effects other than a temporary albuminuria.

The course of treatment extends over fourteen weeks divided into seven periods of two weeks each. For the first ten days of each period acetarsone is given daily and then intermitted for four days. After each period the urine should be examined for albumin to see if there has resulted any damage to the kidneys. If albumin is present, the next period should not begin until all albumin has disappeared.

Two scales, (a) and (b), of daily dosage are used. If the child is under 10 pounds in weight, or is very ill, the smaller dosage (a) is employed, and if the child is over 10 pounds in weight and vigorous, the larger scale of doses (b) is followed. The daily dose is divided into several portions, e.g., four, and given in a little water before or after the feeds.

Parents should be warned to stop the treatment on the appearance of any fever, vomiting, diarrhoea or rash, and not to resume its administration until the family practitioner has been consulted.

Acetarsone is prepared by Bayer Products, Ltd., under the trade name spirocid, and by Messrs. May and Baker under the name of stovarsol, and is supplied in 4 grains (0.25 gm.) tablets by both firms.

DETAILS OF DOSAGE

- Period 1. 1st and 2nd weeks.
10 days' acetarsone (spirocid or stovarsol),
(a) $\frac{1}{2}$ tablet (each tablet contains 4 grains or 0.25 gm.) and (b) 1 tablet daily.
4 days' interval.
- Period 2. 3rd and 4th weeks.
10 days' acetarsone, (a) 1 tablet and (b) $1\frac{1}{2}$ tablets daily.
4 days' interval.
- Period 3. 5th and 6th weeks.
10 days' acetarsone, (a) $1\frac{1}{2}$ tablets, and (b) 2 tablets daily.
4 days' interval.
- Period 4. 7th and 8th weeks.
10 days' acetarsone, (a) 2 tablets and (b) 3 tablets daily.
4 days' interval.
- Period 5. 9th and 10th weeks.
10 days' acetarsone, (a) 3 tablets and (b) 4 tablets daily.
4 days' interval.
- Period 6. 11th and 12th weeks.
10 days' acetarsone, (a) and (b) 4 tablets daily.
4 days' interval.
- Period 7. 13th and 14th weeks.
10 days' acetarsone, (a) and (b) 4 tablets daily.
4 days' interval.

Treatment of Fresh Compound Fractures and Wounds

By J. C. SCOTT

(Abstracted from the *British Medical Journal*, Vol. I, 14th February, 1942, p. 209)

In this paper are presented the personal views of the author who is in charge of the Accident Service at the Radcliffe Infirmary, Oxford.

Some recent publications have indicated that the extreme urgency of the treatment of compound fractures and wounds is still not universally recognized. In the author's opinion, any review of results of treatment which does not include the time interval between injury and treatment in each case is of little value. The only just cause for delay in treatment is the patient's general condition. Adequate resuscitation should be started immediately the patient arrives in hospital. This should include transfusion in every case of severe compound fracture.

The routine adopted in this Accident Service is to start with plasma by drip infusion on admission, with a change to whole blood if more than 2 pints (about

900 cm.²) are necessary. Early splintage is very important and emergency splintage should be carried out without any attempt at reduction. When the patient is ready for operation, the surrounding skin should first be carefully cleaned with soap and water. This cleaning is comparable to the washing of the surgeon's hands. The wound itself should then be washed with soap and water. No irrigation should be carried out. The excision of the wound should begin with the skin and continue in layers to the depth of the wound, all dead or grossly contaminated tissue being removed, where necessary extending the wound by incision. If the wound is more than six hours old, no attempt should be made to suture the skin. Skin sutures should never exert tension on skin edges. Wounds that are left open are dressed with fine mesh dry gauze, and an unpadded plaster is applied. No non-absorbent padding should ever be used in the neighbourhood of the wound, as this interferes with drainage. Counter-drainage should be established as required. Reduction of the fractures is carried out by the accepted method of manual or skeletal traction on the Zimmer machine. Sulphanilamide is sometimes used locally in wounds, although there is as yet no conclusive evidence of its value.

Anti-tetanic serum is administered as a routine. The prophylactic value of gas gangrene anti-toxin is not yet established but it should be used when available. The author's personal view is that in adequate doses it is of considerable value in the treatment of gas gangrene. Prophylactic oral administration of sulphonamides is not recommended, and it is suggested that these drugs have a place only when wound infection is present and the identity of the responsible organisms is known. There is no definite evidence that x-rays have a prophylactic value against gas gangrene.

Out of 31 patients with severe compound fractures of the extremities reported in this paper, the temperature rose above 99°F. (37.2°C.) in only 3. One of these had multiple injuries and bilateral compound fractures of the patellæ, excised and sutured elsewhere, and the right knee became infected. The second case, a severe compound fracture of the tibia and fibula, developed basal pneumonia subsequent to fractured ribs. The third case had a *Staphylococcus aureus* infection of the wound, which responded well to treatment. The average stay in hospital for all cases was seventeen days. There was a complaint of unpleasant odour from the plaster in only one case, a compound fractured femur with extensive skin loss. The bacterial flora in the wounds with and without local application of sulphanilamide is under investigation.

Intraperitoneal Sulphapyridine in Acute Abdominal Conditions

By R. H. GARDINER

(Abstracted from the *Lancet*, Vol. I, 14th February, 1942, p. 195)

It has recently been reported by workers at the Middlesex Hospital, London, that intraperitoneal administration of sulphanilamide in rabbits with the peritoneal cavity deliberately contaminated by the caecal contents, prevented the development of peritonitis and reduced the inflammatory process following resection of the gut.

The present author was led by this work to use intraperitoneal sulphapyridine in 15 cases of appendicitis. Several of the appendices were found to be gangrenous at operation, and all patients had purulent fluid present in the abdominal cavity, with varying grades of peritonitis, which in 2 cases was general. All cases in this series were considered by the author to require drainage of the abdominal cavity, and the abdominal wound would normally also have been drained if chemotherapy had not been employed.

In addition, 2 cases of resection of gangrenous small intestine (in one case due to adhesions and in the other to strangulated inguinal hernia) and 2 cases of

perforation of the sigmoid colon (in one due to diverticulitis and in the other to sigmoidoscopy) were treated with intraperitoneal sulphapyridine.

At the end of each operation, but before suturing, 10 g. of sulphapyridine was mixed with 4 ounces (about 120 cm.³) of saline solution to make a fine suspension. By means of a 10 cm.³ record syringe some of the suspension was injected into the peritoneal cavity around the operation area and a further quantity into the pelvis. Before the insertion of the last peritoneal stitches, another injection of the suspension was made into the peritoneal cavity, which was then closed. The remainder was injected down the drainage tube, which was then clipped. The powdery residue remaining was applied to the wound edges and the abdominal wall was closed.

The results of this treatment appeared to be promising, and in all the appendicitis cases except one (a woman of 75), the abdominal wounds were soundly united by the 10th day. Instead of the anticipated purulent discharge, a thin almost serous fluid was seen. In most cases the drainage tube was removed on or before the 5th day after operation. The average length of time spent in bed was 11 to 12 days, and patients were usually discharged on the 14th day. The 2 cases of perforation of the sigmoid colon and 1 of the cases of resection of the small intestine, recovered. The patient operated upon for strangulated inguinal hernia died of peritonitis.

The author suggests that further trials should be given to this method and that a combination of local and systemic chemotherapy might possibly have advantages. Such trials should include bacteriological examination of the abdominal fluid and determination of the blood concentrations of sulphonamide.

Treatment of Trichophyton Foot Infections in the Field

By FIRST-LIEUTENANT CLYDE J. RADEMACHER

(Abstracted from the *Military Surgeon*, Vol. 90, April 1942, p. 431)

THE care and treatment of the feet has always been a serious problem in armies. Many solutions, powders, and ointments have been used in the treatment of fungus infections of the feet with results none too satisfactory. In troops, trichophytosis, 'athletes foot', is a common cause of foot ailments, especially in the warmer climates.

In a battalion of 570, 75 cases of trichophytosis were found. These cases ranged in severity from macerated swollen feet with large fissures and crusting, which incapacitated the patient from all work, to a mere scaling with slight fissures between the toes. These were classified as to severity as follows:—

- | | |
|---|---------|
| I. Fissures between toes | 6 cases |
| II. Mild swelling; maceration between toes | 13 " |
| III. Moderately severe cases with swelling, maceration and fissures | 30 " |
| IV. Severe cases, incapacitated. Maceration and swelling of toes and feet | 26 " |

Treatment: At the start, half of the group were treated with pure sodium sulphathiazole crystals, dusted on the lesions, and half with 50 per cent sulphathiazole in talc dusted on once daily. The results were spectacular. Practically all the cases were markedly improved within forty-eight hours (with one daily treatment). There was no evidence of any difference in the two series except possibly a slight irritation from the pure crystals which are highly alkaline.

Therefore, from seventy-two hours on, one-half of the cases were treated with 50 per cent sulphathiazole in talc, and the other half of the cases with 25 per cent sulphathiazole in talc. The results in the two series were equally good. There is now a commercial product

of 5 per cent sulphathiazole in a bland ointment that has been reported satisfactory.

Care was taken to cover all infected areas with a film of the powder dusted on with an applicator. Observation of progress was made daily during treatment and at intervals of two weeks after treatment was stopped. Criteria of cure was healing of all lesions and the disappearance of adherent skin debris. All cases classified as cured were re-examined two weeks or longer after the last treatment for signs of recurrence.

Results of the six cases in class IV which were given the above treatment are as follows: Three became class I in an average of seven daily treatments. Three cases were apparently entirely cured at the end of one week; two, however, showed recurrence upon examination two weeks later. These undoubtedly were reinfections from shoes and socks. The spectacular part of these cases was that all the men were relieved of discomfort and able to wear their shoes within three or four days of starting treatment. The net result at the end of one month was one case cured and five cases carried on as class I.

Of thirteen cases in class III, nine appeared to be cured at the completion of treatment (7 to 10 days). Eight of these cases had recurred or were reinfected two weeks later. The remaining four cases were resistant and were reclassified as class I. Net result: one case entirely cured; twelve cases much improved and reclassified as class I.

Treatment of the 30 cases in class II treated for an average of 10 days produced the following results. Eleven cases remained cured; five cases recurred and were placed in class I; eleven cases showed improvement but were resistant; three cases were given incomplete treatment because of transfer or other causes beyond our control. Net result: 11 cases cured; 3 lost; and 16 much improved but needing further treatment.

Treatment of 26 in class I in which the longest period of treatment was 10 days resulted in the following: Nine cases were cured; eleven cases were resistant; six cases inadequately treated due to causes beyond control.

It became evident shortly that the 44 cases remaining under treatment were not responding further. Most of these cases were symptomless and therefore difficult to persuade to return for treatment. These 44 cases were all very much alike, characterized by thick scaling and small fissures between the toes. A few had small deep seated bullae on the feet. These cases were treated with powdered sulphathiazole 10 per cent in 2 per cent salicylic acid ointment. The length of treatment varied from two weeks to a month.

If the 14 cases that were lost are dropped from consideration, 55 or 90 per cent of the remaining 61 cases were cured. Ten per cent are still resistant; all of these are symptomless with the exception of a slight itching and are marked for duty with their companies.

The most spectacular feature of the whole series is the rapid improvement of the severe incapacitated cases which in the past have often needed hospitalization over long periods. A good deal of the disability in these severe cases is due to a secondary invader. This may account for the excellent results in these severe cases.

A simple manner of treatment could be the addition of ten per cent (10%) sulphathiazole to army foot powder used as a dusting powder. Another preparation might be ten per cent (10%) sulphathiazole in salicylic acid ointment, two per cent (2%). Insistence on care of feet and change of socks remains an important part of the treatment of feet.

Chemotherapy of Acute Bacillary Dysentery

By G. M. LYON, M.D.

(Abstracted from the *Southern Medical Journal*, Vol. XXXV, June 1942, p. 606)

THE guanidine analogue of sulphapyridine is known as sulphaguanidine or sulphanilylguanidine.

Attention was first directed to its possible value as a chemotherapeutic agent in intestinal infections by a paper published in September 1940, by Marshall and others.

Since 15th September, 1940, a group of us in a co-operative effort have subjected sulphaguanidine to a rather extensive test in the treatment of acute bacillary dysentery, popularly known in the mining sections as 'bloody flux'.

Our initial effort was to study sulphaguanidine in a small, well-controlled series of carefully selected patients who had the disease in a severe or moderately severe form and in whom treatment was instituted during the first week of fever or diarrhoea.

Our next step was to subject sulphaguanidine to the practical test of routine use in the treatment of the various forms and stages of 'bloody flux' as they were encountered in clinical practice in the offices, homes and hospitals of our mining sections where bacillary dysentery is endemic.

We have records of approximately 300 patients who had 'bloody diarrhoea' and who were treated with sulphaguanidine. Besides having a 'bloody diarrhoea' all of the patients included had such clinical evidences of acute bacillary dysentery as a characteristic history, fever, malaise, blood and pus, or pus and mucus in their stools. A great many had positive stool cultures or characteristic microscopic evidence when the particles of pus from the stools were examined microscopically.

Obviously not all were bacteriologically proven instances of bacillary dysentery. They were, however, all patients having 'bloody flux' and they were typical of the character and incidence of 'bloody flux' as it is observed in the mining and rural mountainous areas in which acute bacillary dysentery continues to be an important endemic disease, affecting particularly, but not by any means exclusively, infants and young children.

In general, the method of administration employed was that originally recommended by Marshall and employed in the clinical study already described. The initial dose was 0.1 gramme per kilogram of body-weight, while the maintenance dose was 0.05 gramme per kilogram of body-weight administered orally every 4 hours until the stools were less than 5 in 24 hours, and then 0.05 gramme per kilogram of body-weight every 8 hours for 48 to 72 hours. Approximately one-third of the patients received the drug every 4 hours for only 3 days, at which time it was discontinued unless the diarrhoea persisted. Special effort was made to insure an adequate urinary output. In general this was well observed. Particular attention was paid to the detection of any untoward effects which might result from the administration of the relatively new chemical.

From these experiences certain impressions are forthcoming. Besides these there are some definite conclusions which may be drawn, and further recommendations which can now be made in regard to the clinical use of the drug.

Sulphaguanidine has proven to be an effective therapeutic agent in the treatment of acute bacillary dysentery. In proper dosage, and when treatment was begun during the first 5 days of illness, recovery almost invariably occurred in 2 to 3 days. In only exceptional instances was it necessary to give the chemical for more than 5 days. When so used sulphaguanidine was almost entirely free from toxic effects. This almost complete freedom from dangers of toxicity is in striking contrast to that of the other sulphonamide compounds, one of which in particular, sulphathiazole, is effective in the treatment of acute bacillary dysentery and which indeed may be more effective than sulphaguanidine in the treatment of those diarrhoeas resulting from parenteral infections, or perhaps in the late or chronic forms of bacillary dysentery.

When chemotherapy was not employed until somewhat later in the disease, results were generally good, but failures on the other hand were encountered somewhat more often than when it was used early in

the disease. When treatment with the drug was instituted between the fifth and the eleventh day, results as a rule were better than after the eleventh day, but not so good as during the first 5 days. It is important to emphasize the desirability of early treatment.

It was found that when there was blood and pus in the stools and when fever was present, even though the treatments were not started early in the disease, the results were nearly always as satisfactory as in the patients treated earlier. Sulphaguanidine had its least beneficial effects when, however, the dysentery bacilli had disappeared, and when there was no blood or pus in the stools and at a time when presumably the activity of the dysentery bacilli had passed and the diarrhoea was that of the plain green watery type, characteristic of the frequently encountered 'post-infection' intestinal indigestion. This could be expected, however, in view of the underlying pathologic state.

One of the outstanding characteristics of bacillary dysentery although it is often overlooked, is that very frequently an impaired ability on the part of the intestinal tract to digest and assimilate food follows the stage of active bacterial infection. This is believed to be the result of the damage produced within the gastro-intestinal tract by the dysentery bacilli, or their toxins. In such cases sulphaguanidine cannot be expected to be a very effective agent, nor can it restore the damaged digestive system to its normal physiologic efficiency. Fortunately such cases were not commonly encountered. This form of 'post-infection' intestinal indigestion was formerly very common among infants and young children, and although to-day less common, its incidence tends to follow that of acute bacillary dysentery. Such a condition can be prevented by the early treatment of bacillary dysentery with sulphaguanidine. Although less common in adults, this sequelæ is not at all an infrequent one.

There is much to recommend the use of sulphathiazole, perhaps even sulphadiazine as well, in those cases where the persisting diarrhoea is the result of secondary bacterial invaders, with or without deep ulceration. Fortunately such conditions were rarely encountered during the period of our study except perhaps in those infections incurred in the neonatal period and in a few instances in which chemotherapy was instituted late in the infection. Occasional instances of apparently simple diarrhoea were encountered which appeared to have no significant bacterial infection, had no blood or pus in the stools, and which, in spite of adequate chemotherapy, more frequently than not presented no successful response to either sulphaguanidine or sulphathiazole. I believe it is quite likely that the diarrhoea in these patients may possibly have occurred because of (1) a previously unrecognized acute bacillary dysentery with the subsequent development of the 'post-infection' intestinal indigestion already described, or (2) a concomitant parenteral infection, or (3) as has been suggested by some, a diarrhoea due to a local or systemic virus infection. Although these patients were not included in the series as patients with bacillary dysentery, they are mentioned because of their interest in connection with our present discussion.

Very frequently what appeared in the beginning to be a simple diarrhoea turned out in 3 to 5 or more days to be a true bacteriologically proven bacillary dysentery. In several instances since the initial phase could not be distinguished from simple diarrhoea sulphaguanidine was not given until later in the disease. In these instances, results fortunately were, as a rule, good.

Sulphaguanidine, in general, was most effective when used in those patients treated soon after onset, who were most ill, and who had blood and pus in their diarrhoeal stools at the time chemotherapy was begun. It was least effective in those in whom treatment was not begun until after the acute bacterial invasion was over, and when the stools were simply green, watery

and without blood or pus and did not contain dysentery bacilli.

Sulphaguanidine has been observed to be effective against all strains of dysentery bacilli. Paradoxical as it is, the chemical has appeared to have the most remarkable effect in the treatment of the toxic Flexner and Shiga strains. Dr. L. C. Hall, of Paintsville, Kentucky, has described strikingly beneficial results in an epidemic caused by the Hiss-Y strain. While its successful use against the Shiga strain has been described by others, we have had only one proven Shiga infection under observation. This was a patient successfully treated by Dr. E. C. Richards at the Holzer Hospital, Gallipolis, Ohio. There is some limited evidence, particularly in the Baltimore experience, to suggest that sulphaguanidine was somewhat less effective against the clinically less toxic Sonne strain than against the Flexner. The former frequently gives rise to a mild afebrile diarrhoea without blood in the stools and often with little pus. Its distribution is more widespread than is generally recognized.

Practically all of the toxic effects which have been observed to occur with the use of the other sulphonamides have also been observed to follow the use of sulphaguanidine. We have, however, seen practically none of them. The toxic effects noted by others were due no doubt to the fact that the drug was given in doses larger than recommended by Marshall and larger than those employed by us, or there was, during the period of active chemotherapy, little attention paid to the importance of the frequency and the character of the stools in relation to the concentration of the drug in the intestinal tract when the stools were infrequent. If the drug is used as recommended originally by Marshall, and if there is meanwhile a proper urinary output, such toxic effects can be almost entirely avoided. An adequate urinary output is always a desideratum in the treatment of acute bacillary dysentery under any circumstances, and it is quite as necessary when employing a chemotherapeutic agent. If treatment with sulphaguanidine is terminated in 5 to 7 days toxic effects are rarely encountered. Toxic effects may be encountered somewhat more frequently in adults. In infants or young children they rarely occur.

Although sulphaguanidine was perhaps somewhat less effective after the first 5 to 10 days' illness, and after the blood and pus in the stools had given way to the plain watery stool which contained no dysentery bacilli, there is sufficient evidence at hand to indicate the desirability of employing sulphaguanidine in all suspected cases of bacillary dysentery, 'flux' or 'infectious diarrhoea' and in many of the apparently simple diarrhoeas which persist for more than 48 hours. It should be given in the amounts previously recommended every 4 hours for 3 to 5 days and thereafter if recovery has not occurred, it may be desirable, if the gravity of the illness warrants it, to give sulphathiazole, or perhaps sulphadiazine, for another 2 to 5 days. In the meantime, strict regard must be paid to the urinary output; for with all of the sulphonamide compounds there is a strict relationship between adequate urinary output and freedom from toxicity. This plus the fact that water tends to be diverted from the kidneys in all diarrhoeal states, must particularly be remembered in the use of sulphathiazole and sulphadiazine in such conditions.

It may be desirable to use sulphathiazole, or sulphadiazine in the place of sulphaguanidine at the onset when obvious or suspected infections appear outside the gastro-intestinal tract. While in such instances this practice may perhaps be more effective, in the few instances in which sulphathiazole was employed later in the disease, no strikingly favourable results were observed by us.

Sulphathiazole, as previously stated, has been shown to be effective in the acute stages of bacillary dysentery. It is also known to be more toxic than sulphaguanidine when used as both are usually employed. Because of this greater tendency of sulphathiazole to produce toxic effects, and because of the great care with which it should be given, it would seem clear that

it should be the drug of secondary choice in the treatment of acute bacillary dysentery in the early stages, while perhaps in the later stages or in the state of 'post-infection' intestinal indigestion, its use may be more strongly indicated. For use in the home, office, dispensary or in industrial practice, sulphathiazole is definitely not as safe as sulphaguanidine, and should not be employed therein as sulphaguanidine may be. Nor it is as safe as sulphaguanidine for use among armed forces in the field. One of the most satisfactory features of sulphaguanidine is the large margin of safety permitted in this respect without the sacrifice of therapeutic efficiency. Of practical importance is the fact that it is quite frequently necessary to treat patients with acute bacillary dysentery without benefit of hospitalization. For them sulphaguanidine is distinctly the drug of choice, for as we have seen when it is so used it is both effective and safe.

In our series of approximately 300 patients, if we exclude 7 deaths occurring within less than 24 hours of instituting chemotherapy, and if we exclude the 25 patients of the neonatal group still under study, only one death occurred among the patients treated with sulphaguanidine, provided treatment was begun during the first 5 days of illness (diarrhoea and fever) and provided they did not have some other important organic disease or infection (bacterial or viral) outside the intestinal tract. Even the one death included cannot rightfully be called a failure. This occurred in a patient of Dr. L. C. Hall, of Paintsville, Kentucky, the patient having hardly recovered from a severe nearly fatal diarrhoeal disease of unknown aetiology, the onset of which had been little more than one month before.

Parenteral infections, whether due to a virus of the influenza type, or to pyogenic bacteria, were observed to exert a detrimental influence on the clinical progress of the patient with bacillary dysentery, whether treated with sulphaguanidine or not, just as they do in other diarrhoeal states. It is not logical to expect parenteral infections to yield to sulphaguanidine therapy. On the other hand, it was observed with surprising frequency that under the influence of the drug the stools did become normal rather promptly and the intestinal tract appeared better able to carry out its work than it would have had the drug not been employed.

In several patients who in all probability had had bacillary dysentery for some days, or even weeks, before treatment was started, although the diarrhoea was checked early, the general clinical condition of the patient continued poor and the ability of the body to absorb and assimilate food continued to be greatly depressed.

In the late stages of acute bacillary dysentery or its sequelae it may be quite impossible to determine just what difficulties are due to a continuation of the primary bacterial invasion, what to active bacterial infection by secondary invaders of the intestinal tract, what to parenteral infection and what damage within the intestinal tract wrought by the primary bacterial invasion. It is generally the latter which results in serious impairment of the normal processes of digestion and assimilation. All of this complicates the problem of appraising the effectiveness of any chemotherapeutic agent in acute bacillary dysentery or other diarrhoeal states. The presence or absence of bacteria is not in itself sufficient evidence for classification, particularly when conclusions are to be drawn as to the effectiveness of a therapeutic agent. The underlying physiologic and pathologic states must be relatively the same if intelligent comparisons are to be permitted.

No persistent states of 'post-infection' intestinal indigestion or chronic intestinal indigestion developed in any of the patients in whom chemotherapy was begun within 5 days of the onset of fever or diarrhoea, although in the neonatal group there may yet develop some exceptions to this statement.

In those receiving the chemical early, there was surprisingly little disturbance of digestion either during the period of active therapy or following recovery. In spite of this, however, it has seemed advisable to employ during the period of active treatment a bland

diet which is likewise moderately restricted in amount. There is some reason, based upon careful observation, to believe that those patients who were on a diet which was high in protein (casein) and which was moderately restricted in amount, presented better and possibly somewhat more prompt recoveries. Cultured lactic acid milk, cottage cheese, Philadelphia cream cheese and custard, when given in moderate amounts, seemed to be the diet of choice. Vitamins in the form of powder were added to the cultured lactic acid milk of a great many of the patients, and may or may not have influenced the recoveries. Their use is logically indicated, although it is probably less important now that the clinical course can be regularly shortened by early chemotherapy. They are certainly strongly indicated in the illness lasting more than 2 or 3 days.

Sulphaguanidine was most effective during the time when the dysentery bacilli were more active. It was least effective when the activity of those bacteria was absent, and when their residue remained in the form of abnormal physiologic states within the intestinal tract. While the chemical effectively controlled the activity of the bacteria, it did not, by itself, correct damages already produced by the bacteria, or their toxins, once such damage was already established. By controlling the bacterial infection, sulphaguanidine may have enhanced the effectiveness of such measures as adequate fluid intake, glucose intravenously, calcium gluconate, transfusions of serum and whole blood, *et cetera*, enabling them to correct more effectively the attendant chemical disturbance. Sulphaguanidine itself did not, and it should be emphasized, will not overcome acidosis, dehydration, fluid imbalance or electrolyte disturbance. When altered physiologic states, or those characterized by unusual chemical pathology were already present before the institution of chemotherapy, it was necessary to employ measures directed toward these specific conditions. Particularly in the more protracted forms of the disease, admitted to study late in the clinical course, had these special measures been neglected, chemotherapy would undoubtedly have been much less effective.

Sulphaguanidine was not quite so effective in the recurrent attacks of bacillary dysentery and in the more chronic forms, as it was when used within 5 days of the onset of the original attack. If, however, the stools were bloody or contained pus, or if the culture demonstrated that they contained dysentery bacilli, the results were generally good. Even in those patients treated late, failures did not occur with absolute regularity. At times the beneficial effects of the drug were so striking, and so prompt even in the late stages, that one cannot escape the conviction that sulphaguanidine was so likely to yield a good result that, regardless of the stage of the disease, it should be administered in all cases of bacillary dysentery for at least 5 to 7 days in the manner recommended. With perhaps somewhat less evidence we were inclined to believe in the desirability of its use in practically all grave diarrhoeal states, the cause for which is not readily apparent, if they persist for more than 48 hours. If, at the end of that time, there is not a proper therapeutic response, the use of sulphathiazole or sulphadiazine for 5 to 7 days thereafter may be considered.

The impression just presented rests upon purely empirical observation. This much may be said, however, that much acute bacillary dysentery is unrecognized to-day, and it is generally in such a form that it is unrecognized. At times, most brilliant results occurred among patients of this group, patients who had an unrecognized dysentery bacillus infection.

Some of the most amazing results so far observed occurred in stubborn, serious cases of chronic bacillary dysentery. Generally we do not expect startling successes in these patients.

Relapse within the first 2 weeks after the use of sulphaguanidine in the treatment of acute bacillary dysentery were not common, occurring only 7 times in 267 patients. Certainly this was in striking contrast to the frequency with which they occurred in those not receiving chemotherapy.

Second infections, after 3 weeks or more of normal stools, occurred only 12 times in the same group. This is readily understandable when one considers the environmental situation to which the average one of these patients must return in his home, an environmental situation which provides unusual opportunity for repeated infections with the dysentery bacilli in a single individual.

There was no reason to believe, either from the bacteriological or from the epidemiological standpoint, that the use of sulphaguanidine tended to 'mask' infections of dysentery bacilli or to complicate the community health situation by increasing the 'carrier rate'. Our evidence along this line is admittedly incomplete.

In homes where outbreaks resembling the institution type of outbreak of bacillary dysentery have occurred, of which we had 5 clear cut, easily controlled ones, it was possible with sulphaguanidine to control promptly and effectively not only the individual cases, but the spread of the outbreak as well. The chemical has great value as a control agent in those crowded conditions of living which frequently are encountered in mining areas in the poorer districts and even in military camps or establishments. It would appear to be possible in an institution to check such an outbreak within a few days by giving everyone in the institution the chemical for a period of 5 to 7 days. It must be remembered in so doing that the maintenance dose should be employed, giving it only every 8 hours if the stools are less than 5 a day, as they are apt to be in those not already stricken with the malady.

Sulphaguanidine was of definite value in reducing the number of days of illness due to bacillary dysentery. Indeed this is one of the most striking influences which can be shown statistically. It is of unusual importance in industrial and military medicine. A wider use of the chemical will result not only in a continuously lower dysentery mortality rate, but in a greatly lessened economic loss from days of disabling sickness. Of the 259 patients treated with sulphaguanidine without regard to the time elapsing between the onset of illness and institution of chemotherapy, 219 patients had normal stools within 3 days, 21 in 4 days, 17 within 5 days, and only 2 had loose stools for more than 5 days. You will believe this with difficulty, I am certain.

Early recognition and early treatment are very important in the successful treatment of bacillary dysentery. This is more true in the actual clinical observations than the statistical evidence can reflect. The best results are definitely attained when chemotherapy is applied early in the disease. On the other hand, it may be effective, as we have seen repeatedly, when it is administered at a much later time.

Sulphaguanidine was as effective in the treatment of acute bacillary dysentery in adults as it was in infants and young children.

Chemotherapy has completely revolutionized the treatment of bacillary dysentery. Sulphaguanidine is quite as effective in the treatment of acute bacillary dysentery as sulphanilamide is in the treatment of some streptococcal infections or as the other sulphonamide compounds are in the pneumococcal infections. Besides its therapeutic effectiveness, the chemical is administered with ease, is well tolerated, and has such a wide margin of safety that it is the ideal agent for the treatment of bacillary dysentery.

Bed-Bug Infestation

(Abstracted from *Medical Research Council, Special Report Series No. 245*)

1. PROVIDED a source of blood is available, temperature is the most important factor in the bed-bug's environment. At the end of winter, the bug population in an unheated room will consist mainly of adults and large nymphs; there will be few small nymphs and a large proportion of the adult females will be unfertile. It is unlikely that many bugs will feed until the

temperature rises to 16°C., in the middle of May. They may be supposed to feed, on the average, once a fortnight in the early summer, once a week in August, and then once a fortnight in September and October; after that feeding ceases, owing to the low temperature.

2. From the temperature and the number of feeds the production of eggs by a given bed-bug population may be calculated. The first egg will be laid in the latter part of May, and the production rises to a peak in August. The first adults of the next generation are not mature until the second week in August; the number attaining maturity reaches a peak early in October, and thereafter rapidly declines owing to falling temperature.

3. In November, when feeding and egg-laying have ceased in an unheated room, there will be large numbers of nymphs and adults, of generations F_1 and F_2 together. Nearly all the small nymphs, however, will die of starvation during the winter, and calculations indicate that the natural winter mortality in the bug population may be as high as 80 per cent. This emphasizes the practical desirability of concentrating on the destruction of bugs at the end of winter and in early spring, when the numbers are lowest; at that time of year there are no live eggs (which are more resistant to some fumigants than are nymphs and adults).

4. The conditions described above are modified in centrally-heated flats or in warmed living rooms. While even here a considerable winter mortality among eggs is probable, fasting bugs could survive very well and some feeding might occur throughout the year. It follows that the bug population in warmed rooms tends to increase enormously from year to year.

5. Besides the egg there are five nymphal stages of the bed-bug, the fifth and last moulting into the adult. An individual in each stage must take one full meal of blood before it can pass into the next stage. The rate of development depends both upon environmental temperature and upon accessibility of host.

6. Environmental temperature has an important influence upon the activity of bugs—the higher the temperature of a summer night, the greater the numbers active. Slight fluctuations of temperature have a marked effect on activity. The threshold of activity may be as low as 7° to 10°C.

7. A temperature of 13–14°C. is most favourable to long life of the bugs without food; both above and below this level life is materially shorter at comparable humidities; for long life humidity must be high, so as to prevent loss of water by evaporation. Adult virgin females and mated males live the longest. The period of survival of fasting adults may exceed one year under climatic conditions close to the optimum.

At 13°C. eggs develop and hatch, the mean period being 49 days; they develop very slowly at temperatures even as low as 4°C., but they are unlikely to hatch so long as the temperature remains always below 13°C. Survival of eggs through the winter in inheated houses is very improbable.

8. A temperature of 45°C. (113°F.) kills the eggs in one hour and nymphs in 15 minutes; adult bugs are killed by a temperature of 44°C. (111.2°F.) for one hour.

9. The physiological differences between populations of bugs maintained by feeding on different hosts—man, mouse and fowl—are small; the bed-bug is thus a non-specific parasite.

10. Sulphur dioxide has proved a poor ovicide, and not very toxic to the nymphal stages of the bed-bug. Its bleaching and corrosive properties render it unsuitable as a general fumigant.

11. A study has been made of the insecticidal powers of heavy naphtha and its constituents. An important outcome of the work has been the light thrown on the mode of action of contact insecticides and heavy fumigants; in nearly all liquid insecticides the toxic principle forms only a small part, either by weight or by volume. The greater part consists of a carrier with, it may be, the addition of substances ('wettors and spreaders') to ensure adequate spread or

adhesion of the insecticide on the body of the insect or on the surface on which the insect rests.

12. The practical use of hydrogen cyanide as a fumigant has been thoroughly investigated, and a detailed technique for its safe application has been worked out.

13. An account is given of the circumstances leading to the abandonment of orthodichlorobenzene as a fumigant against the bed-bug.

14. Heavy naphtha is a useful contact insecticide, but its vapour action is much more effective. Details are given of the technique of using heavy naphtha vapour to disinfest houses, and of experiments on its practical application for this purpose. The Committee's official specification for disinfestation naphtha is set out (p. 31). The effects of climate and temperature upon heavy naphtha fumigation are discussed, and an account is given of van fumigation for infested furniture.

15. Suggestions for further research on disinfestation, and a note on contact insecticides containing organic thiocyanates, are appended.

16. The value of domestic hygiene and cleanliness in the control of bed-bug infestation is emphasized. It is shown that bugs can often be eradicated from houses and furniture by simple though vigorous cleansing.

17. The cleansing of infested furniture and the structures of dwellings requires direction and supervision by competent officers, who must be well acquainted with the life history and habits of the bed-bug.

18. Infestation of new houses for slum clearance can be largely prevented by supervision of the cleansing of the household belongings in the old house immediately before the tenants are removed to the new. Prevention of infestation can be further ensured by a well-organized 'follow-up' system operated by health visitors.

19. The tenants themselves profit by instructions from these officers; educational efforts such as exhibitions of house pests are useful for instructing the public in domestic hygiene.

20. Details are given of the experimental methods used to investigate different contact and fumigant insecticides for their probable toxicities to man.

21. Of the insecticides investigated, orthodichlorobenzene is shown to be dangerous and heavy naphtha relatively safe. It is considered that provided the precautions outlined in section III of this Report are carefully observed, there should be little reason to expect any danger to man from the use of heavy naphtha as a fumigant. As an additional safeguard, however, it is recommended that toxicity tests on a wide range of animals should be carried out with each new sample of heavy naphtha before it is issued as an insecticide.

22. A note is included on the toxic effects of the higher thiocyanate contact insecticides—'Lethane 384' and lauryl thiocyanate—and on the precautions to be taken in handling these substances.

23. This section concerns building design in relation to bed-bug infestation. It is pointed out that new buildings should be constructed so as to give minimum harbourage for the bug, and so that, in the event of infestation occurring, eradication of the pest may be easily and cheaply effected. Detailed constructional suggestions are made from these points of view.

24. A note is given of the Committee's recommendations regarding the prevention of bed-bug infestation in public air-raid shelters (see also Appendix B).

The Transmission of Kala-azar

(From the *Indian Journal of Medical Research*, Vol. XXX, 3rd July, 1942, p. 479)

THE recrudescence of kala-azar in severe epidemic form in Assam and certain adjoining areas, and also in Calcutta city, during the years from 1917 to 1929 afforded an opportunity for a fresh investigation on

the epidemiology of the disease. A phase of research was initiated in 1921 which has lasted up to the present time and during most of that period work has been especially directed towards the study of the sandfly as a possible vector of infection.

In 1921, an Inquiry on Kala-azar was started at the Calcutta School of Tropical Medicine by L. E. Napier with the active collaboration of R. Knowles. Certain epidemiological observations were made regarding kala-azar in Calcutta which led these workers to believe that a limited entomological survey of a certain part of Calcutta would be likely to indicate the insect responsible for transmission, and mainly for this purpose R. O. A. Smith joined this Inquiry in 1924. This Inquiry continued on a varying scale up to 1938 with L. E. Napier and later R. O. A. Smith in charge. *Phlebotomus argentipes* was found abundantly in this area and these workers selected this insect first for investigation for this reason and also because its general distribution in India coincided with that of kala-azar.

In 1924, a special Kala-azar Commission which absorbed the already existing Kala-azar Inquiry of the Indian Research Fund Association under H. E. Shortt was constituted to carry out field and laboratory investigations in Assam. S. R. Christophers was appointed Director, with H. E. Shortt as protozoologist and P. J. Barraud as entomologist. The Commission was financed on generous scale by the Indian Research Fund Association and was assisted by contributions from Local Governments concerned. In 1925, H. E. Shortt took over the Directorship and at varying periods A. C. Craighead, R. O. A. Smith, and K. V. Krishnan joined the Commission. C. S. Swaminath was a technical assistant during the period of investigation in Assam.

The first marked advance obtained was the finding of the development of typical herpetomonad forms in the fore-gut and mid-gut of the laboratory-bred *Phlebotomus argentipes* fed on parasite-containing blood of kala-azar patients, by the Inquiry in Calcutta. Later, this was confirmed by the workers in Assam.

A detailed account of the subsequent stages of the investigations on this species as a vector of kala-azar is embodied in the 1st and 2nd Reports of the Kala-azar Commission (*Indian Medical Research Memoirs*, Nos. 4 and 25) which cover the period up to 1931. Transmission to experimental animals by the bite of infected *Phlebotomus argentipes* had been obtained in a few instances but attempts to transmit in this way to human volunteers had not been successful. Many efforts had been made to obtain this final proof and the reasons for failure were obscure. The large-scale field work of the Commission was abandoned in 1931 and the matter was left in this disappointing position although much epidemiological and experimental evidence which had been obtained left little doubt that *Phlebotomus argentipes* was the vector.

On the closure of the Commission the Inquiry at the Calcutta School of Tropical Medicine was at first strengthened and later work was continued on a diminishing scale and was eventually reduced to a level which would only ensure such degree of continuity of experience as would provide a basis for renewed work in event of a fresh opportunity arising.

In 1939, kala-azar had assumed epidemic proportions in Bihar and R. O. A. Smith was placed in charge of a new inquiry in that province. The sandfly was again studied and new methods of breeding, maintaining and feeding *Phlebotomus argentipes* were developed, and with their use a much greater success than formerly was obtained in the transmission of kala-azar to experimental animals, all hamsters used being infected. Unfortunately, on account of war conditions, it was found necessary to close this Inquiry in 1941. Some of the technical staff was combined with those of a Protozoological Inquiry in the Madras Presidency which had also to be terminated and a combined team was formed which was posted to Assam to continue kala-azar work under direction. At this time kala-azar was recrudescing in that province and conditions existed in which it was possible to attempt again the transmission experiments to human volunteers under

suitable control. The new technique devised by Smith for obtaining sandflies in a highly infective state was employed. The successful result of this work has been recently reported by Swaminath, Shortt and Anderson.

Twenty years of patient investigation have gone to the forging of this final link in the evidence that *Phlebotomus argentipes* is the insect vector of human kala-azar in India, and the many workers who have taken part in the investigations at different stages and have contributed to the final solution of the problem are to be congratulated on this outcome of their work.

Relative Nutritive Value of Different Forms of Milk

By S. K. KON

(Abstracted from the *Nature*, Vol. CXLVIII, 22nd November, 1941, p. 607)

THE present relative shortage of fresh liquid milk in Great Britain has made it important to assess the nutritional properties of other forms of milk. The author points out that the milk proteins and certain of the vitamins are most likely to be affected by various treatments. In raw milk the protein deficiency in building body protein may be as high as 90 per cent. The vitamin-A content reaches 150-200 international units per 100 ml. from May to December and drops to half that quantity for the rest of the year. The vitamin-D content is low, varying with the season and depending on the action of direct sunlight on the cow. The riboflavin content varies with the feed, rising from 100 microgrammes per 100 ml. in the stall feeding period to 150-200 microgrammes when the cows are of pasture. Vitamins-B₁ and C contents are independent of feed and vary little throughout the year, the vitamin-B₁ content being 10-15 international units per 100 ml., the vitamin-C content 2-2.5 mg. per 100 ml. The C content, however, falls off very rapidly on exposure to light. In the usual commercial preparations of milk, pasteurized, sterilized, spray or roller dried, and condensed sweetened or unsweetened, there is no loss of vitamin A or D, though in skim milk, fresh or dried, there is of course practically no A or D left. The only effect of pasteurization is to cause a 20 per cent loss of vitamin C and a 10 per cent decrease in vitamin-B₁ value. Sterilized milk shows a decrease of 6 per cent in the biological value of the proteins, a 50 per cent loss of C and a 30 per cent loss of B₁. It has the advantage of keeping for a longer time than other liquid milks. Spray drying causes a loss of only 5 per cent in the biological value of milk proteins, a loss of 20 per cent of the vitamin-C content and 10 per cent of the B₁ content. Roller drying produces only a slightly inferior milk to spray drying. The proteins have deteriorated somewhat more, the loss of vitamin C is about 30 per cent and of B₁ up to 33 per cent. Sweetened condensed milk of good quality shows only a 5 per cent loss of C and a 5-10 per cent loss of B₁. Unsweetened evaporated milk must be heated to a higher temperature to keep it. There is a slight decrease in protein value, a 60 per cent loss of C and a 30-50 per cent of B₁. Skim milk except for the loss of A and D is nutritionally valuable because of its high protein, Ca and riboflavin content. The survey shows that all these various preparations of milk possess very valuable nutritional properties and can be used by the adult population as satisfactory substitutes of liquid milk.

British children, pregnant women and nursing mothers receive an extra allowance of fresh liquid milk.

Interpretation of Chemotherapy Through Nutritional Studies

By H. McILWAIN

(Abstracted from the *Lancet*, Vol. I, 4th April, 1942, p. 412)

THE normal nutritional needs of bacteria can be found by chemical fractionation of their growth media,

and in many cases have been expressed in terms of pure substances. Nutritional analyses show that bacteria, in the presence of antibacterial agents (mercuric salts, acriflavine, sulphanilamide and other sulphonic acid derivatives), require more substances than are normally needed for their growth. The inhibitors (antibacterial agents) therefore increase the nutritional requirements of bacteria.

Some substances found necessary for normal bacterial growth (aneurin, cozymase) take part in enzyme reactions and these reactions account for the organism's need of such substances. The additional substances for which need is induced by inhibitors are probably required in order to take part in reactions which have been affected by the inhibitor.

Enzyme systems can in many cases be considered to correspond to the 'receptors' of Ehrlich. The structural specificity required for drug-action is comparable to that required in growth-essentials. Some grouping in a drug may be toxophoric by virtue of its similarity to a group in a growth essential; the SO₂NH₂ of sulphanilamide simulates the -COOH of p-aminobenzoic acid to a degree sufficient for it to react with and block enzymes which are essential and normally react with p-aminobenzoic acid.

According to this view, chemotherapeutic interference is due to the functional replacement by the interfering agent of substances whose metabolism is affected by the inhibitor; acriflavine and some arsenicals interfere with (among other processes) hydrogen transport, which interfering agents, e.g., methylene-blue, are capable of performing.

Different organisms need different preformed substances for growth; enzyme processes involved in their growth are different and consequently a given inhibitor can affect various organisms differently. Such nutritional differences have been demonstrated between susceptible and non-susceptible species and strains of micro-organisms and may in part explain the difference in susceptibilities between host and parasite. Drug-fast strains are considered to have been 'trained' so that they differ in their nutritional needs or synthesizing abilities with respect to the essential metabolites with which the drug in question interferes. Amino-carboxylic acids are normally needed for growth of *Staph. aureus* and *Bact. typhosum* but organisms can be trained to synthesize them. Such trained strains are not susceptible to inhibition by alpha-amino-sulphonic acids, which inhibit normal strains by interference with their utilization of alpha-amino-carboxylic acids.

Post-operative Administration of Fluids to Children

By G. M. ARNOTT

and

W. F. YOUNG

(Abstracted from the *Lancet*, Vol. I, 2nd May, 1942, p. 523)

DURING recent years much knowledge has been gained of the fluid requirements of adults in the post-operative period, and the present paper records an attempt to apply this knowledge to children.

Before a normal fluid balance can be maintained, the dehydration of an ill child must be relieved. Dehydration, varying from mild to moderate and severe, is relieved by volumes of fluid equivalent to 3 per cent to 6 per cent of the body-weight. Because metabolism, blood-volume and renal function are related to the surface area rather than to the body-weight, the normal daily fluid requirement of children was calculated by this formula:—

Child's requirement =

$$\text{Adult's requirement} + \frac{\text{surface area of adult}}{\text{surface area of child}}$$

The adult's requirement was taken to be 3,000 cm³.

The authors have tabulated the requirements of children between the ages of 6 months and 14 years according to this calculation.

Easily remembered volumes are:—

750 cm. ³ at 1 year	1,500 cm. ³ at 8 years
1,000 cm. ³ at 3 years	2,500 cm. ³ at 12 years

The indications for administering the fluid by the oral, rectal and intravenous routes are discussed. Ten per cent Dextri-maltose flavoured with fruit juice and a continuous drip of tea-water or 1/5 normal saline are recommended for use by the oral and rectal routes respectively. Normal saline (0.9 per cent) and 4.1 per cent glucose in 1/5 normal saline are used for intravenous therapy (this fluid is isotonic).

At the outset of treatment the normal daily requirement is supplemented by the extra volume necessary for the relief of dehydration. When using the intravenous route in a severely dehydrated child, this extra volume should be spread over the first 48 hours to avoid undue strain on an already embarrassed circulation. The use of normal saline is confined to the replacement, by approximate equal volumes, of fluid lost by vomiting, suction drainage or atherostomy. The administration of this solution in patients suffering from intestinal obstruction should be controlled by repeated readings of the blood chemistry. In all other circumstances 4.1 per cent glucose in 1/5 normal saline is used. Intravenous sodium sulphate and cane-sugar solutions are employed if a diuresis indicates.

The progress of the patient under this treatment is adequately controlled by frequent urinary examinations: a return towards a normal output, a fall in the specific gravity, the presence of chlorides and the absence of ketones being favourable signs. Serial analyses of the blood chemistry are invaluable in the more complicated cases. The authors agree with Jones and Morgan that a moderate acidemia is of no special significance in the absence of dehydration and is not in itself an indication for administering larger amounts of sodium chloride.

A fluid therapy which substitutes a water-retention and oedema for dehydration does not help the patient's recovery after operation. The aim of the present author's treatment, however, has been to restore a normal fluid intake and output. The application of the treatment is illustrated in six cases, showing the volumes administered and changes in the urine and blood chemistry. The renal improvement as the dehydration was relieved and the renal function returned to normal was most noticeable, and the recovery of a 7 months baby after a right hemicolectomy for gangrenous intussusception was particularly gratifying.

The Pathogenesis of the Sprue-Syndrome

By HURST

(Abstracted from the *General Hospital Report*, Vol. XCI, 19. 1)

HURST believes that all sprue, non-tropical sprue (or 'idiopathic steatorrhea') and coeliac disease (or 'Herter-Gec disease') varieties of the same disorder—the 'sprue syndrome'—which differ only in the part of the world in which they originate and in the age of the patient are three characteristic and constant features of the sprue syndrome:

- (1) the stools contain excess of split fat in the form of fatty acid crystals, but no excess of neutral fat, mucus or starch, and no inflammatory material
- (2) radiography detects the disappearance of the normal finger-herring-bone pattern of the duodenal jejunal mucous membrane produced by the villi
- (3) no pathological changes are found in the intestines after post-mortem changes are prevented.

With adequate treatment the normal absorption of fat is restored together with the normal radiographic appearance of the duodenum and jejunum.

The author suggests the characteristic features of the sprue syndrome are the result of paralysis of

the muscularis mucosae. This would lead to loss of the pumping action of the villi, by means of which fat is conveyed from the lacteal radicles of the villi into the larger lacteals, and to flattening of the villi into conniventes, the constantly changing pattern of which depends upon the activity of the muscularis mucosae, without any accompanying pathological changes in the mucous membrane. Paralysis of the muscularis mucosae may be secondary to loss of the normal stimulants of Meissner's plexus, from which it derives its nerve supply, or to the effect of vitamin deficiency or some toxæmia on the plexus.

An exception must be made for those cases of the sprue syndrome associated with disease of the mesenteric glands in which the hindrance to fat absorption occurs at the level of the glands instead of in the villi.

A New Method of Controlling the Head Louse

By J. R. BUSVINE

and

P. A. BUXTON

(Abstracted from the *British Medical Journal*, Vol. I, 11th April, 1942, p. 464)

THE usual methods of treating for head lice are laborious and unpleasant. Also they give no protection from the rapid reinfestation which usually follows from relations or associates. The present authors, working from the Department of Entomology of the London School of Hygiene and Tropical Medicine, made tests on hundreds of infested young women and children, as a result of which they recommend the following insecticides as alternatives:—

(1) Twenty-five per cent technical lauryl thiocyanate (marketed in Great Britain and the U.S.A. as 'lorol rhodanate') in a white oil.

(2) Fifty per cent 'Lethane 384 Special' (12.5 per cent N-butyl carbitol thiocyanate; 37.5 per cent beta-thiocyanatoethyl laurate; 50 per cent refined paraffin) in a similar oil.

(3) Derris emulsified to form a cream.

The advantages are:—

(a) That very little (2–8 cm.² according to the amount of hair) need be applied. This is rubbed about the scalp like an ordinary brilliantine or hair cream. It is not noticeable and therefore is not disliked by the patient.

(b) A single application will cure 90 per cent cases liable to reinfestation without combing out nits or any other measure.

(c) Hair clipped from a treated head up to a week after treatment is lethal to lice. This protects the patient from reinfestation during that time.

(d) The cost is low, being less than a half-penny per application.

Two disadvantages are:

(a) All three preparations have a slight disagreeable odour, but this can be easily masked by adding about 2 per cent citronella, etc.

(b) Frequent application of derris or thiocyanates to large areas of skin may cause dermatitis. But applied to the head as directed, most liquid is taken up by the hair. The authors found no symptoms at all in over 200 cases with each preparation.

Sulphathiazole in the Treatment of War Wounds

By J. T. HEYL

(Abstracted from the *Proceedings of the Royal Society of Medicine*, Vol. XXXIV, October 1941, p. 782)

SULPHATHIAZOLE was used in 83 cases of injury, mostly associated with compound fracture; all but 8 of the wounds were over 24 hours old. The dose was 4 to 9 g. daily for 7 to 10 days; no increase of toxicity

occurred with the higher doses. The blood concentration was generally between 2 to 6 mg. per 100 cm.³; most often it was between 2 and 4 mg. Of the 83 cases, vomiting occurred in 7, skin rashes in 7 and fever in 7 (8.5 per cent), different cases being involved by the different affections. Four of the skin rashes resembled erythema nodosum; they appeared between the sixth and tenth days, the blood concentration being within the usual limits, and they disappeared within two days of stopping the drug. Similarly the drug-fevers were associated with average blood concentrations. No macroscopic hæmaturia due to sulphathiazole occurred; this freedom from urinary complications is attributed to the maintenance of a large fluid intake, over 100 ounces (about 2,800 cm.³), daily. The urine should also be kept alkaline. In some cases the concentration of drug in the urine rose as high as 450 mg. per 100 c.c., which is considerably above the saturation limit.

Thirty patients admitted for knee operations were given 10 gm. of sulphathiazole during the 18 hours before the operation. The blood levels ranged from 2.8 to 12 mg. per 100 cm.³, averaging 6.1 mg. The concentrations in the fluid of the knee joint were about the same, 80 to 86 per cent of the drug being present in the free form. In two cases in which the

joint fluids were septic the same result was obtained as in uninfected joints. This shows that sulphathiazole passes readily from the blood into joint cavities.

In some patients the compound was given prophylactically, to prevent infection developing. For this purpose a blood level of 2 mg. per 100 cm.³ is desirable at the time of operation. The author's cases were not sufficient to assess the value of this procedure; but he notes that it did not prevent suppuration around pins in a significant percentage of cases.

In other patients the compound was given therapeutically, but the results are difficult to evaluate. The author gained the impression that sulphathiazole benefits wounds containing sensitive hæmolytic streptococci, but bacteriological proof could not be obtained.

When the compound is applied locally, according to the author's technique (not described), it persisted as lumpy masses; in vasine packs it often persisted for 2 to 3 weeks, and in bony recesses it has been observed after 6 weeks. In 6 patients, 1 to 4 gm. of the powder were spread round the wound in a thin layer; traces appeared in the blood after four hours and persisted for 14 days; the blood level never rose above 1.5 mg. per 100 cm.³. There was no constant effect, either deleterious or beneficial, upon epithelialization and the formation of granulation tissue.

Reviews

STITT'S DIAGNOSIS, PREVENTION AND TREATMENT OF TROPICAL DISEASES.—By Richard P. Strong, M.D., Sc.D., D.S.M., C.B. Sixth Edition. Volumes I and II. 1942. H. K. Lewis and Company, Limited, London. Pp. xv plus 871 plus xi in volume I. Illustrated. And Pp. vii plus from 872 to 1747 plus xi in volume II. Illustrated. Price, £5-5-0 for two volumes combined

THE appearance of these two volumes on tropical medicine is an event of very great importance to all medical men in the tropics. Stitt's book on tropical diseases has enjoyed a world-wide reputation, probably second only to that of Manson's book, which was well deserved. It presents tropical medicine from the American point of view, which is not necessarily very different from that of the African and Asiatic points of view, but it is natural that there are here and there different emphases.

The present edition of Stitt's book is edited and largely re-written by Dr. R. P. Strong, Emeritus Professor of Tropical Medicine at the Harvard University. Dr. Strong has added as much as any living man to our knowledge of tropical medicine and it is very appropriate that he should assume the responsibility for this important book.

One cannot discuss the two volumes page by page though the reviewer would very much like to do so as he has spent some weeks perusing nearly every section most minutely. One can say that on the whole the information on every subject is both extensive and accurate. It is also presented in a very palatable form that will appeal to the student and research worker.

In nearly every subject, however, there is always some opportunity for difference of opinion and it is only natural that a writer will lay more emphasis on his own point of view. The malaria section is a very complete exposition of the subject and is entirely up-to-date; for example, he discusses in some detail the invasion of Brazil by *Anopheles gambiae*, imported from Africa. In the matter of treatment, Dr. Strong takes the older view regarding the value of large doses of quinine. This is not in concert with general world opinion on the subject, and it is a gospel that one would hesitate to preach at the present day, even if one's opinion did coincide with Dr. Strong's, in view of the very great quinine shortage.

The subject of blackwater fever is dealt with exhaustively and the modern point of view is well presented.

The section on trypanomiasis is good, particularly that of the South American trypanosomiasis. One feels perhaps that a little emphasis might be given to the question of goitre, and the inclusion of figure 52 showing a group of goitrous children conveys the idea that this infection actually causes goitre, whereas recent work suggests that the association of *Trypanosoma cruzi* infection and goitre is an accidental one.

The section on leishmaniasis is equally good and perhaps the writer has done almost more than justice to the work that has been done on this subject in India and particularly at the School of Tropical Medicine, Calcutta.

A few diseases like typhemia and undulant fever have been given much more space than are usually given to them in textbooks of this kind. This is not said in any critical spirit; on the contrary we feel that when a writer has paid special attention to any one subject he should give the reader the advantage of his special knowledge. This is particularly true in the case of undulant fever; probably nowhere else can such a comprehensive account of undulant fever be found as in this textbook.

Another similar example is Bartonellosis. The reviewer has acquired a much clearer mental picture of this unique disease from Dr. Strong's account than he ever had before, from other sources.

Cholera and the dysenteries are given very adequate treatment. To the epidemiology of cholera considerable space has been devoted and here as elsewhere good use is made of the epidemiological data collected by the Health Commission of the League of Nations. These chapters on cholera and dysenteries here is nearly a page devoted

The chapter on the rickettsias is an excellent one. It is interesting that typhus fever is not included in this chapter but is given a separate one. It seems doubtful to the reviewer that this disease deserves a separate chapter in a textbook of tropical medicine. It does not occur anywhere at the present day—and we are in the fourth year of a war—and it never was a tropical disease. When it could be fitted into the chapter on rickettsias there was some excuse for its

inclusion, but Dr. Strong won't give it place here, a decision which may or may not be a sound one.

The first real criticism applies to the section on leprosy. In this chapter there are certain points which are not usually presented in textbooks and which are very useful, but on the whole we feel that the chapter has been written from one point of view and is based on the experience of American workers, most of whom happen to have worked mainly in countries where leprosy is seen mainly or solely in its severest forms and where compulsory isolation is practised, so that the reader in India will find himself saying 'this picture may represent leprosy in some parts of the world but it does not describe leprosy as we see it here'. There are many mis-statements regarding leprosy in certain parts of the world and particularly in India; for example, the number of lepers in India is given as 100,000 which was an estimate made in 1893, and there are no references whatsoever to more recent estimates which often mention figures ten times this figure. There are many other examples where emphasis is given to old observations and to theories which have been superseded and abandoned. In the section on the pathology of this disease, there is no clear distinction made between the nodular and neural types which show very different histologies. Under clinical manifestations, the same criticism is applicable; no mention is made of the high incidence of very mild non-progressing cases of leprosy seen in some countries. Under nerve leprosy it is stated that wrist drop is not uncommon and that foot drop is rare, whereas actually the opposite is the truth. Under symptoms, it is stated that in the majority of cases of leprosy beyond the primary stage some rise of temperature is constantly observed. Experience of leprosy workers in general is that apart from the lepra reaction and a secondary infection, there is usually no rise of temperature whatsoever.

The account of the treatment of the disease is, on the whole, good but contains some inaccurate and misleading statements. It includes the remark that 'Engel Bey recommends . . .'. Engel Bey wrote 40 years ago and on the whole much too much emphasis is laid on older forms of treatment that have been superseded.

References are always a problem in a book of this kind. It is a problem to which there is no real solution and one sympathizes with the writers of certain standard textbooks who have solved it by giving no references at all. Dr. Strong's attempt at a solution is not very satisfactory. He has referred to innumerable workers in the text, but has only included a fraction of these amongst his references, and he has not been very careful to verify these. Perhaps the reviewer was unlucky, but the first six references he looked up were wrong in some important point.

To avoid closing this review on a querulous note, the reviewer will summarize his criticism by saying that the present edition has surpassed its predecessors in every way, in the amount of information, in the accuracy of its presentation, and in the general soundness of the views expressed, and that it has securely established the place of this book in the front rank of books on tropical medicine. As a book of reference on the whole subject of tropical medicine, it will be considered the best there is by the majority of workers in this field.

L. E. N.

TEXTBOOK OF PATHOLOGY.—By Sir Robert Muir, M.A., M.D., Sc.D., LL.D., F.R.S. Fifth Edition. 1941. Edward Arnold and Company. Pp. vii plus 991. Illustrated. Price, 35s.

Muir's book needs no introduction. It is one of the most reliable textbooks on the subject. Although first and foremost a Scottish student's book, it has been popular with medical students far and wide.

The present edition incorporates the chief advances which have been made in the various branches of pathology during the five years since the previous edition was published. A certain amount of re-modelling

has been made and some portions have been re-written, while a few descriptions have been condensed; this has afforded space for the new matter without increase in the length of the book.

The volume is divided into sections of general and special pathology, seven chapters (284 pages) being devoted to the former and thirteen (686 pages) to the latter. The sections on tumours, hæmopoietic system and endocrine glands are particularly good. The account of nephritis is full and up to date. In the treatment of less important diseases and some of the tropical conditions, the author seems to have exercised considerable restraint; this will not however affect an average student. The important additions to this edition include regional ileitis, vitamin K and its relation to coagulation, and to hæmorrhage in obstructive jaundice, Albers-Schönberg disease, the genetics of hæmophilia, etc.

Illustrations are numerous, well chosen and clearly reproduced. There are a number of references in footnotes to important monographs and special publications.

It is a remarkable achievement on the part of publishers to have been able to bring out such a well-printed volume with good paper in war time and give it to us at the pre-war price.

R. C.

DISEASES OF THE RESPIRATORY TRACT.—By Jacob Segal, M.D., F.A.C.P., F.A.C.C.P. 1941. Oxford University Press, London. Pp. ix plus 172. Price, 10s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

This synopsis or outline of diseases of the respiratory tract has little to commend it to the student for whom it appears to be intended.

It has the appearance of having been dictated from lecture notes to a non-medical secretary and of not having been revised as to spelling. Nor have the proofs been carefully read. There are, for instance, four spelling errors in the first fourteen pages—viz, 'Sica', 'particular', 'atack' and 'diagnoiss'.

Items for criticism occur upon thirty-one of its pages.

Although the symptoms and signs of lobar pneumonia are listed under ten headings no mention is made of the most important sign, bronchial breathing, or of other auscultation phenomena.

Pyrexia and tachycardia are not mentioned in massive collapse of the lung, though they occur early and characteristically.

The sulphonamides are mentioned but no dosage is given.

Fever, chills (1), vomiting and pain in the extremities are amongst the list of symptoms of acute follicular tonsillitis.

C. M. S.

OBSTETRICS.—By Harvey Clock Williamson, M.D., and George Schaefer, M.D. 1941. Oxford University Press, London. Pp. viii plus 113. Price, 10s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

This book is a synopsis of obstetrics and is not claimed by the authors to be a textbook on that subject. It is more essentially a synopsis than most books that bear that title, but every other page has been left blank, leaving ample space for more notes or sketches by the student. No unnecessary words are used and only important facts are included, but the subject-matter is well classified and should be of great help to the student in systematizing knowledge acquired by wider reading. The text includes recent advances in obstetrics such as the chemotherapeutic treatment and roentgenographical classifications of pelvic types by Caldwell and Maloy. This book should be of particular value to the student working for his qualifying examinations, and, though it will not teach him the art of obstetrics, it should be of considerable help in the final days of preparation for his examinations.

HISTOLOGY AND EMBRYOLOGY.—By Jos. F. Nonidez, Sc.D. 1941. Oxford University Press, London. Pp. ix plus 199. Price, 10s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

'The outline is not intended as a laboratory guide but merely as a supplement to a textbook.' This extract from the preface states fairly the nature of the book. A histology book without an illustration is no source of knowledge, but the average student may find it helpful in pre-examination revision. Perhaps brief comments on the relation between function and histological appearance might have been added without unduly increasing the size of the outlines.

The industrious student who will use the space provided for his own illustrations and additional notes, will find the histology section good. The embryology has suffered from excessive compression, so that in the absence of diagrams it can be understood only by the advanced student to whom the omission of many details will be irritating.

J. A. R.

SURGERY OF HEAD AND NECK.—By Arthur S. McQuillan, A.B., M.D., F.A.C.S. 1941. Oxford University Press, London. Pp. vi plus 138. Price, 10s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

In 129 pages, the author has attempted an outline of surgery of head and neck which 'is meant to be an outline of general surgery'. This claim appears to rest solely on the inclusion of diseases such as rabies, glanders, and gas gangrene (but not tetanus). In the space available, he has been able to give little more than a catalogue of diseases and salient points rather disorderly in places and showing lack of balance, e.g. one-quarter of the book is devoted to the thyroid, and more space is allotted to malignant tumours of the thyroid than to head injuries.

This book might assist an unfortunate student faced with an examiner who demands a rapid numerical but superficial list of signs, complications, etc.

J. A. R.

AIDS TO OSTEOLOGY.—By Nils L. Eckhoff, M.S. (Lond.), F.R.C.S. Fourth Edition. 1942. Baillière, Tindall and Cox, London. Pp. vii plus 260 with 42 figures in the text. Price, 6s.

This little book, of pocket size, follows the orthodox treatment of its subject-matter. There is no undue compression; the whole is reliable and readable; and the information appears adequate for the ordinary student. Diagrams are introduced in this edition, and, while adequate for explanation, should not tempt the student from his real teacher—the bones. This can be recommended confidently to any student who is dismayed by the size of the ordinary textbook of anatomy.

J. A. R.

FIRST AID IN EMERGENCIES.—By Eldridge L. Eliason, A.B., M.D., Sc.D., F.A.C.S. Eleventh Edition. 1941. (With a Supplement on Civilian Defence and Poison Gases.) J. B. Lippincott Company, Philadelphia and London. Pp. xii plus 260 plus 16, with 126 illustrations. Price, 9s.

This book, first published in 1915, has now reached its eleventh edition. It is interesting to compare this American book with similar British publications, which tend to present their matter in a stereotyped manner often with the unnecessary use of medical and surgical terms or of special first-aid terms, and to devote too much space to unnecessary detail and to procedures which are of doubtful utility.

Why in first aid must we always call bleeding 'hæmorrhage', breathing 'respiration', a bruise 'contusion', the blood cells 'corpuscles'? Why cannot we call a fracture a break, and even the abdomen the belly? Why should we need use such terms as

'supine position', 'digital pressure', 'thermal disinfection', 'compound' and 'comminuted' fracture (surely 'open break' and 'smashed' or 'splintered break' are better terms), and 'upper' and 'lower extremities' (why not arm and leg)? Many persons taking first-aid training have never heard these terms and the whole subject tends to become unreal. Are these and other common faults avoided in American books on first aid? It appears that in this American publication to some extent they are, but not by any means entirely.

This book has a wider scope than most British publications and in many respects comes half way between the ordinary first-aid manual and the 'Home Doctor'. Because of the great distances in America, and the fact that medical aid to travellers, hunters, etc., may be delayed for days or weeks, the book describes some procedures usually left entirely to doctors.

The material and the presentation in the body of the book are good and the illustrations are numerous and excellent, but the unnecessary use of technical terms is not entirely avoided, and some of the bandaging and strapping procedures described and illustrated are perhaps unnecessarily complicated. It is, however, good to see a book on first aid in which general principles are usually stressed more than complicated detail. For example, in the treatment of 'fractured thigh (femur)' the principles are outlined and the need for traction is emphasized but there is not the usual detailed account of the precise number of bandages to be used and the site and the order of their application.

In addition to dealing with injuries, etc., the book has chapters on plant poisons (26 pages with many illustrations), medicines, emergencies, infectious and transmissible diseases, and abdominal pain.

The American background of the book is interestingly shown here and there. There is a note under gun-shot wounds which states that 'in civil life the bullet is usually soft lead'; there is a reference to tularæmia (which is wrongly stated to be 'a highly fatal condition') and also a mention of the 'kissing-bug'.

The Civilian Defence Supplement is far less satisfactory. It consists of sixteen pages, three and half of which are devoted to general behaviour in an air raid, one to bombs, particularly incendiary, and the remaining eleven and half pages to poison gases. There is no discussion whatever of the types of injuries commonly encountered in air raids and of their first-aid management and treatment. This supplement was obviously added hurriedly. It is of very little use to the first-aid worker.

The price of the book is rather high for a popular first-aid manual.

J. L.

THE ADOLESCENT CRIMINAL—A MEDICO-SOCIOLOGICAL STUDY OF 4,000 MALE ADOLESCENTS.—By W. Norwood East, M.D. (Lond.), F.R.C.P. (Lond.). 1942. Messrs. J. and A. Churchill, Limited, London. Pp. xi plus 327, with 112 tables. Price, 45s.

The author is a well-known authority on the psychology of crime, so that this book adds more lustre to his reputation. In this country where little, if any, attention is paid to the psychological aspects of crime and the mental make-up of offenders against the law, a book of this sort should not only be very welcome, but set an example to Indian psychiatrists to make a report along more or less the same lines as regards crime and criminals in India. The author states that the objects of his enquiry were four: Three were immediate in purpose: it was desired, first, to obtain the fullest information which would enable ample consideration to be given to each case before recommending the lad to the Court of Trial as a suitable subject, on general grounds, for detention in a Borstal institution; second, to ascertain the presence of any mental defectiveness or other mental abnormality which should be reported to the court; third, to utilize the medical data and other factors in the life

histories of the lads to assist in the classification of the various types of offenders and to ensure their transfer to the appropriate Borstal institutions. At the same time, this reduced the risk of contamination to a minimum and facilitated the application of different methods of training to the different types of offenders. At one end of the scale is a Borstal institution which receives the lads who have most experience in criminality, at the other end is an institution which receives lads in the initial stages of crime. In one institution the older lads are collected, in another those who require special attention on account of some physical disability or personality abnormality. The importance of detailed information in connection with the above will be seen from the fact that during the years 1930 to 1937, when the 4,000 lads were collected, some 21,512 lads received into Wormwood Scrubs prison were examined as to their fitness for Borstal detention. The fourth object of the investigation, with which we are here concerned, was as already stated, to apply modern scientific methods to the elucidation of some of the causal factors which contribute to adolescent criminality.

Each chapter begins with a discussion of the matter dealt with in the chapter and ends with a summary of the points recorded and discussed. Every feature—physical, psychological, sociological, environmental, et cetera—is dealt with in detail and illustrated with tables giving figures and percentages. It will be a surprise to many to learn that these observations show quite conclusively that the most 'criminal' age in a British boy's life is when he is 13 years old. The number of boys who are mentally, temperamentally, or normally abnormal at the age of 13 is nearly double the number aged 19. This fact disproves the assertion that crime is a 'disease'. Dr. East considers that juvenile crime is generally due to social immaturity rather than mental abnormality and that males commit crime more frequently than women, because their responsibilities are usually greater and their instinctive tendencies more despotic. Most people will agree with Dr. East that habits are more easily acquired than corrected, a matter noticeably the when an effort is made to rase habit-disorders, such as nail-biting, bed-wetting, constipation, stammering and some forms of habitual criminality. A habit, Dr. East maintains, is not broken by the passive acceptance of the admonition of someone in authority. Because of feeble motivation, bad habits are not overcome and for this reason many petty offenders become recidivists. One point that seems to have escaped the attention it deserves from Dr. East is the part played in the temperament of a child by his (or her) dread of losing the 'love' of others. Most students of child psychology seem agreed that loss of 'love' or a fear of its loss is an important factor in behaviourism and a potent cause of certain misemeanours, especially petty larceny.

It is satisfactory to have the assurance of so eminent an expert as Dr. East that public opinion in Great Britain is now opposed to methods of punishment which are essentially retributive, and favourable to those which are deterrent, preventive and reformatory. It is to be hoped that education and the inculcation of a keener sense of 'pity' will bring about a similar change in public opinion in this country.

O. B.-H.

NEW MEASURES FOR OBTAINING BETTER CONTROL AND PREVENTION OF VENEREAL DISEASES.—By M. F. Lister, O.B.E., M.B., Ch.B. (Glasgow). E. and S. Livingstone, Edinburgh. Pp. 36. Price, 3d., postage 2½d.

AFTER seventeen years as a venereal disease specialist, the author's views of the subject have undergone radical changes, and in this booklet he pleads for the removal of the stigma of venereal from the two diseases, viz, syphilis and gonorrhoea, which, according to him, is not caused by sexual immorality only. He holds that mental unrest, strain and physical hardships contribute to the onset of these diseases, just as they

do in the case of tuberculous disease. He is not much in favour of the modern methods of control—indeed he considers them harmful, for they instil fear into the hearts of the people and fear is the fundamental cause of disease.

Dr. Lister believes that the initial lesion in syphilis arises from an infection within the body, not by coming in contact with *Spirochaeta pallida*, but by the spirochaetes and bacteria growing within the body and being carried by blood or lymphatics to the congested genital area or elsewhere. The fact that some sexual offenders escape infection is explained by their cleaner and healthier skin and mucous surfaces and better control of their emotions and actions. As regards gonorrhoea, it is really the *Micrococcus calarrhalis* that by passage through the body and growth in the genital area develops into gonococcus just as it develops into meningococcus, if it gains admission to the cerebrospinal fluid.

The booklet is written in a rambling fashion based on the author's sentiments and surmises and has, in our opinion, no scientific value. His 'new measures' for prevention consists in the cultivation of the love of a Divine Being, removal of poverty and causes of excessive anxiety and fear, etc.—on which, however, we have no dispute with him.

R. C.

(We would draw the paper controller's attention to this book.)

HEALTH BULLETIN NO. 30. 'FOOD AND DIET.' WRITTEN FOR CHILDREN. Published by The Manager of Publications, Delhi. 1942. Pp. 20. Illustrated. Price, Annas 3 or 4d.

THIS bulletin is meant to impart elementary knowledge about nutrition to children, as it is desirable that they should know that the kind of food they eat has a great influence on their health and that much ill-health and disease is due to eating the wrong sort of diet. It gives a concise account of the proximate principles of food; value of important articles of diet, cooking and regular meals, and some of the results of wrong feeding. Importance of milk as the best food for children has been stressed; India needs more milk and purer milk. There are a few illustrations—on sources of vitamins, milk consumption in different provinces, etc. The one on 'milking' of rice is obviously a misprint. It is strongly recommended that all schools should possess copies of this bulletin; and indeed it should prove valuable not only to children but also to many adults.

R. N. C.

Abstracts from Reports

ANNUAL REPORT OF THE SUDAN MEDICAL SERVICE FOR THE YEAR 1940

THE state of public health in the Sudan remained satisfactory during the year, with the exception of an extensive outbreak of yellow fever in the Nuba Mountains. Smallpox spread into Darfur and Kassala provinces from neighbouring countries, but it was possible to prevent an epidemic. Relapsing fever occurred as usual along the line of the pilgrim route across the Central Sudan. Cerebro-spinal meningitis occurred in the Southern Sudan. The low Nile flood and well spaced rains again resulted in a low incidence of malaria.

The hospital work in many parts of the country was disorganized temporarily owing to the Sudan becoming a theatre of war. Medical work as a whole had to be maintained on a care and maintenance basis, owing to the number of British and Sudanese medical staff of all cadres who were in the army. It says much for the remaining staff, who were often carrying on in the face of great difficulties, that the medical work as a whole was not more seriously

affected. It has been possible to maintain progress in preventive medicine, as this branch is so important in war that it must be maintained at a high standard of efficiency at all costs. The training of subordinate sanitary staff continued without interruption. The school medical and dental services were well maintained. Extensive research was carried out on kala-azar in the Eastern Sudan, and on yellow fever in the Nuba Mountains.

An extensive epidemic of yellow fever occurred in the Nuba Mountains. The disease broke out in July, and by the end of the year had practically died out. There were 15,633 cases, with 1,627 deaths. This disease had not previously been reported in the Sudan. Cases of smallpox were reported in Darfur and Kassala provinces, introduced into the Sudan from French Equatorial Africa and Arabia Saudia respectively. Relapsing fever occurred in the Central Sudan during the winter months and was particularly prevalent in the irrigated area of Gezira province. Cerebro-spinal meningitis was prevalent in the western part of Equatoria province.

Bilharziasis has ceased to be of any public health importance in the Northern Sudan, although stringent measures are necessary to maintain this state of affairs. The number of cases of kala-azar reported was higher than normal, probably due to the special attention given to the disease by the research staff of the Stack Laboratories and the increased popularity of hospital treatment as the result of the employment of new and more efficient drugs. The incidence of leprosy is probably slowly declining. Malaria was far less prevalent than usual in the Northern Sudan, owing to the exceptionally favourable climatic conditions. Cases of sleeping sickness continued to occur in the Zande district of Equatoria province, but no cases were reported from the Kajo Kaji district, where the disease occurred last year.

Three thousand two hundred and four pilgrims left the Sudan for Jedda, and were vaccinated and inoculated before departure with calf lymph and cholera vaccine made in the Stack Laboratories. Fourteen cases of smallpox occurred among the returning pilgrims who included many unvaccinated pilgrims who had left *via* Massawa. While the last boatload of pilgrims were in quarantine, the huts were bombed and machine-gunned by an Italian aircraft and four pilgrims were injured.

Fifteen medical students were under training at the Kitchener School of Medicine during the year, and training courses were held for public health officers, dispensers, sanitary overseers, female nurses, midwives, laboratory assistants, medical assistants, and hospital orderlies. Seven medical students passed the final examination of the Kitchener School of Medicine, and one public health student obtained the diploma of the Royal Sanitary Institute. Four medical officers completed a six months' post-graduate course in Khartoum in April.

In the Stack Medical Research Laboratories, twenty-five thousand six hundred and eighty-six routine examinations were carried out, compared with 24,540 in 1939, and 22,633 in 1938. The outbreak of war with Italy was followed by a temporary drop in the number of specimens received from civil hospitals, but there has been a considerable increase in the amount of work carried out for the army. One hundred and eighty-seven routine bacteriological examinations of water were carried out, and large quantities of vaccine made in the laboratories were issued during the year.

Investigations were carried out on kala-azar, typhoid fever, vaccine lymph and yellow fever.

The medical entomologists continued to carry out malarial research in the Gezira province. He also carried out entomological research in the Eastern Sudan on the sandfly distribution and habits as regards kala-azar, and in the Nuba Mountains on those of the *Aedes aegypti* and other possible vectors of yellow fever. The Wellcome Chemical Laboratories carried out analyses for departments and private firms, and 2,115 analyses were carried out during the year.

ANNUAL REPORT OF THE NATIONAL ASSOCIATION FOR SUPPLYING MEDICAL AID BY WOMEN TO THE WOMEN OF INDIA (COUNTESS OF DUFFERIN'S FUND INCLUDING THE WOMEN'S MEDICAL SERVICE) FOR 1941

The work has continued steadily throughout the year in spite of war time conditions, and definite expansion in certain directions had taken place.

The Office of President of the National Association and its connected activities continued to be held by Her Excellency the Marchioness of Linlithgow, C.I., from whose extended stay in India we greatly benefit through Her Excellency's continued interest and advice. Sir Cameron Baderoch remained as chairman of the council and of the executive committee, and Lieutenant-General Sir Gordon Jolly, as vice-chairman. The only change in the executive committee was the replacement of the Hon'ble Sir Mohammed Yakub, Kt., by Sir Muhammad Yamin Khan, as one of the members nominated by Her Excellency the President, on the former's appointment to Hyderabad after five years of valuable service on the committee.

There have been eight meetings of the executive committee during the year and two meetings of the selection committee. The council meeting was held at the end of March at the Viceroy's House with Her Excellency the President in the chair, and this was followed by the annual general meeting.

At the end of 1940, the executive committee decided to suspend the post of medical adviser in the United Kingdom for the duration of hostilities, as all the members of the Women's Medical Service and Training Reserve had returned to India and it was unlikely that recruitment from overseas could continue for the present.

The greatest difficulty the hospitals have had to face this year has been the shortage of sisters and staff nurses owing to the demands of the army. When we consider that there are as yet only 5,000 registered, fully trained nurses in the whole of India, compared with 105,000 in Great Britain, and that many of these have been trained at small, poorly equipped hospitals and possess little in the way of educational qualifications, then we can only be thankful that our hospitals have been able to err on with their limited staffs, and accomplish so much in the way of training pupil nurses and midwives as well as of caring for the patients, who continue to attend in increasing numbers in spite of the gradual breaking down of purdah customs.

Among the developments that have taken place during the year, the opening of two new hospitals and the building of a third are to be recorded. The fine Alice Horsman Memorial and Dufferin Hospital was opened at Cawmore by Lady Hallett, accompanied by His Excellency the Governor, on 26th March, 1941. This was erected at a cost of over three lacs of rupees through the princely generosity of Sir Henry Horsman and his brother, who were responsible not only for the building but also for the very up-to-date equipment. The hospital will have over 100 beds, including a considerable number in private rooms—an increase of 100 per cent on the previous accommodation.

At Quetta, the new Lady Sandeman Dufferin Hospital was able to function from early in the year, and it was not formally opened by Lady Metcalfe, the President, until 28th October. Conditions were very unsettled owing to the war and a recrudescence of earthquake shocks, and full use could not be made of the facilities provided; but it is expected that the volume of medical work will increase steadily as time goes on, and not only the women of the locality but also the children will benefit from this very comfortable little hospital.

At Jubbulpore plans for a two storied hospital of 80 beds were approved and the building was taken in hand at once, the foundation stone being laid by

Lady Twynam on 1st . . . It is hoped th it will be completed by March 12 and then the wn will have good medical facilities for its women and children at last. The Countess of Dufferin's F . . . Council has contributed a sum of Rs. 17,000 . . . the building and equipment.

At Calcutta, the building or the Nurses' . . . of the Dufferin Hospital has commenced.

At Agra, a satisfactory exchange of buildings between the Medical College and the Lady Lyall Dufferin Hospital was agreed on.

This year the recurring income of the Countess of Dufferin's Fund was spent as usual on grants to provincial Dufferin branches and hospitals as well as on scholarships to students in Medical Colleges.

The work in the various hospitals officered by members of the Women's Medical Service has continued to progress in spite of a serious shortage of nursing staff, and difficulties caused by financial stringency and by lack of understanding of modern medical need by some of the municipal and other members of the hospital managing committees.

Members of the service have taken an active part in A. R. P. work when necessary, and others have volunteered to lecture in First Aid in their free time.

At the end of 1941 the strength of the service was 48; of these only 34 were confirmed and the rest were temporary members. Among these officers, seventeen were of European or colonial domicile, twenty-five were Indians, and the rest were members of the domiciled community of naturalized Armenians.

The main source of income of Countess of Dufferin's Fund is the interest it earns on investments which amounted to Rs. 774 (cost price) on 1st January, 1941. In addition, the Fund receives a fixed annual contribution of Rs. 40 from Their Excellencies the Viceroy and Vicereine and realizes rent of Rs. 2,250 from Irwin Lodge, Sida, which was purchased in 1923.

ANNUAL REPORT FOR 1941 OF THE RESEARCH DEPARTMENTS OF THE COLLEGE OF THE PHARMACEUTICAL SOCIETY, LONDON

The college has now been temporarily accommodated in Cardiff. The work of the various research departments has continued. Further evidence has been obtained that the ordinary process of boiling vegetables does not decrease their vitamin A content. Two synthetic compounds have been obtained possessing physiological activity similar to that of corticosterone. Results of recent experiments indicate that the blood histamine increases after removal of adrenals. Injections of cortical extract given immediately after the operation apparently reduced the blood histamine within one hour, the effect lasting from 3 to 24 hours. The question of the immediate administration of cortical extract is briefly discussed, and an investigation to elucidate their problems is proceeding.

Service Notes

APPOINTMENTS AND TRANSFERS

COLONEL J. B. HANCE, C.I.E., O.B.E., V.H.S., Officer on Special Duty in the Office of the Director-General, Indian Medical Service, is appointed to officiate as Deputy Director-General, Indian Medical Service, with effect from the 1st September, 1942, vice Lieutenant-Colonel (Ty. Colonel) R. Haj, C.I.E., granted leave.

Colonel R. Hy, C.I.E., assumed charge of the office of Inspector-General of Civil Hospitals, Punjab, with effect from the forenoon of the 1st October, 1942.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to The Editor, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.
